# IV Hazards of Transfusion

## 44

## Overview of Hemovigilance

Dorothy Stainsby,<sup>1</sup> Jean-Claude Faber,<sup>2</sup> & Jan Jørgensen<sup>3</sup><sup>1</sup>National Medical Co-ordinator (Retired), Serious Hazards of Transfusion, Manchester Blood Centre, Manchester, United Kingdom<sup>2</sup>Director Blood Transfusion Service (Retired), Luxembourg Red Cross, Luxembourg, Luxembourg<sup>3</sup>Director Blood Transfusion Centre (Retired), Aarhus University Hospital, Aarhus, Denmark

The term “hemovigilance” has become widely used over the past decade to describe the systematic surveillance of adverse transfusion reactions and events, encompassing the whole transfusion chain and aimed at improving the safety of the transfusion process, from donor to recipient, “vein to vein.”<sup>1</sup> The term was coined in France in the early 1990s, has been developed and adopted internationally, and is now an integral part of transfusion practice.

Hemovigilance in its broader sense encompasses other important aspects of transfusion safety; surveillance of donors to ascertain the residual risks of transfusion-transmitted infections, traceability of transfused blood components, monitoring of blood utilization, epidemiology of transfused patients, and monitoring of the hazards of blood conservation. Compilation of this information, together with clinical assessment of transfused patients, has the potential to provide much-needed evidence of the outcomes, risks and benefits of blood transfusion, and transfusion alternatives.

Plasma derivatives may be included in hemovigilance or may be monitored according to pharmacovigilance. More recently, the concept of “biovigilance”<sup>2</sup> emphasizes the need for similar systems for donated tissues and stem cells.

This chapter focuses on surveillance systems, their design, what has been learned from them, how this information has been used to improve practice, and how information from other sources can contribute to the interpretation of these data.

### Requirements for an Effective Hemovigilance Scheme

A World Health Organization guideline on adverse event reporting and learning systems<sup>3</sup> emphasized that the effectiveness of an adverse event reporting system is measured not only by

accurate collection and analysis of data, but also by its use to make recommendations that improve patient safety. The guideline outlined the following core concepts:

- The fundamental role of patient safety reporting systems is to enhance patient safety by learning from failures of the health-care system.
- Reporting must be safe. Individuals who report incidents must not be punished or suffer other ill effects from reporting.
- Reporting is of value only if it leads to a constructive response. At a minimum, this entails feedback of findings from data analysis. Ideally, it also includes recommendations for changes in health-care procedures and systems.
- Meaningful analysis, learning, and dissemination of lessons learned require expertise and other human and financial resources. The agency that receives reports must be capable of disseminating information, making recommendations for changes, and informing the development of solutions.

These concepts are directly relevant to hemovigilance systems and are applicable both locally and nationally. At the hospital level, there is a need for a point of contact for clinical staff to report reactions and adverse events. This may be a transfusion practitioner or safety officer, hematologist, transfusion medicine specialist, or blood bank manager. There must be a “reporting and learning culture” within which events are used as learning opportunities, but also within a framework of professional competence and accountability; hemovigilance reporting should be an integral part of the risk management or clinical governance framework of the institution.

Hemovigilance reporting may be mandatory, as developed in France, or voluntary, as exemplified by the Serious Hazards of Transfusion (SHOT) scheme in the United Kingdom (UK). In both models, active participation is encouraged by educational feedback, and by confidence that centrally submitted data will be used effectively to build an evidence base for recommendations aimed at improvement. Confidentiality of patients, donors, and reporters must be ensured and the scheme must comply with legislative requirements for data protection.

At regional or national level, the hemovigilance scheme must be seen as impartial, independent, supportive, and professionally

credible. Data should be validated, analyzed, and reported within a predictable timeframe, and published in a format that can be used to support education and training. Active involvement and “ownership” by professional bodies will help to ensure that recommendations are incorporated into clinical practice.

Collection of complete data on adverse reactions and events requires local awareness and vigilance, and a robust reporting system that is easily understood and user friendly. The scope of the system must be clear to reporters, definitions must be unambiguous, and the system must be sufficiently flexible to respond to developments and changes in transfusion practice.

## The Scope of Hemovigilance

In discussing the scope of hemovigilance, the terms agreed upon by the Hemovigilance Working Group of the International Society of Blood Transfusion (ISBT) (P Robillard, personal communication) are used here.

An **adverse event** is an undesirable and unintended occurrence before, during, or after transfusion of blood or blood components that may be related to the administration of the blood or component. It may be the result of an error or an incident and it may or may not result in an adverse reaction in the recipient.

An **incident** is when the patient receives a blood component that did not meet all the requirements for a suitable transfusion for that patient, or was intended for another patient. It thus includes transfusion errors and deviations from standard operating procedures or hospital policies. It may or may not result in an adverse reaction.

A **near miss** is an error or deviation from standard procedure or policy that is discovered before the start of the transfusion.

An **adverse reaction** is an undesirable response or effect in a patient temporally associated with the administration of blood or blood components. It may be the result of an incident or an interaction between the recipient and blood, a biologically active material.

It is then necessary to determine the severity of the reaction, and the imputability, ie, the degree to which, on completion of investigation, the transfusion is considered to be the cause of the reaction. The ISBT Working party scales of severity and imputability may be found in Appendix 44-1 at the end of this chapter.

Adverse reactions occurring during or within 24 hours after transfusion are likely to be recognized as being transfusion related, but the longer the interval between the transfusion and the reaction, the less likely the reaction is to be identified and the causation determined. Continuing education of clinicians responsible for transfused patients is needed to improve awareness of transfusion reactions and ensure that they are investigated and reported appropriately.

## What Should Be Reported?

### Adverse Reactions

As will be described in the following section, national hemovigilance systems vary in their scope and in the type and severity of adverse

reactions they wish to have reported to them. There is some commonality; all established systems would expect to receive reports of severe allergic or anaphylactic reactions, acute and delayed hemolytic reactions, transfusion-transmitted infections (TTIs), transfusion-related acute lung injury (TRALI), transfusion-associated graft-vs-host disease (TA-GVHD), and posttransfusion purpura (PTP). These severe reactions are uncommon, and a hemovigilance scheme such as SHOT that restricts its scope to serious reactions receives approximately 10 such reports per 100,000 blood components issued by the blood services.<sup>4</sup> Most schemes invite reports of transfusion-associated circulatory overload (TACO), the frequency and importance of which are increasingly widely recognized.<sup>5</sup>

Many hemovigilance systems also encompass less severe reactions, eg, febrile nonhemolytic transfusion reactions (FNHTRs), and mild allergic reactions presenting with only mucocutaneous symptoms and signs. Some systems also receive reports of alloimmunization, ie, the finding of a new clinically significant red cell antibody in a previously transfused patient but without clinical or laboratory signs of hemolysis. Minor reactions are common and, although they may be distressing for the patient, they require minimal clinical intervention. However, they produce a large workload if they are required to be reported to the hemovigilance system.<sup>6</sup> It may be argued that such comprehensive reporting is excessively time-consuming and cannot be clinically justified; however, because the observed rate of FNHTRs is known to be 0.5% to 1% of red cell transfusions overall,<sup>7</sup> the number of these reports from an individual institution can provide a useful indicator of active participation in hemovigilance, and enable benchmarking between hospitals (P Robillard, personal communication).

Although clear definitions of adverse reactions are necessary to ensure consistent reporting and enable comparisons, it must also be possible to report previously unrecognized complications that may not fit into one of the recognized definitions.

### Adverse Incidents

These events, sometimes referred to as “incorrect blood component transfused” (IBCT), result from avoidable system failures throughout the transfusion chain. Experience from the SHOT scheme over a period of 8 years has indicated that the observed rate of such events is 7:100,000 blood components issued, with a fatal outcome in 0.7:100,000.<sup>4</sup> Other studies, using different methods, have calculated an error rate of 1:19,000<sup>8</sup> and a risk of death caused by an ABO-incompatible transfusion of 1:1,800,000 allogeneic red cell transfusions.<sup>9</sup>

Detailed analysis of these incidents reveals that in approximately 50% of events there are multiple errors in the transfusion process, that approximately 70% of errors occur in clinical areas (the most frequent error being failure to ensure at the bedside that the right blood is being given to the right patient), and that 30% happen in hospital laboratories.<sup>10</sup>

### Near Misses

Near misses include those occasions an error was detected, either by chance or as a result of quality checks, and an incident

prevented. As in other fields (eg, aviation), the study of near misses in health care can highlight high-risk areas and may also identify effective recovery systems. Near misses are approximately 10 times more frequent than incidents, and again, the work required for comprehensive reporting must be balanced against the potential benefit. These events may enable identification of previously under-recognized errors. For instance, “wrong blood in tube” (ie, pretransfusion blood sample taken from the wrong patient or labeled with the wrong patient’s details) is an infrequent cause of IBCT. However, sampling errors are, in fact, common, accounting for 56% of near-miss reports.<sup>4</sup>

A structured system for medical event reporting in transfusion medicine (MERS-TM) can identify high-risk areas and processes requiring system change.<sup>11</sup> A 3-year pilot project of near-miss reporting in Ireland using this approach demonstrates the value of such an approach.<sup>12</sup>

### Blood Management

With the impending threat of blood supply shortages and increasing awareness of the known and unknown risks of transfusion, much emphasis has been placed on alternatives to allogeneic transfusion and conservative transfusion policies. If hemovigilance is to provide a true picture of the risks and benefits of transfusion, then the hazards of blood conservation should also be included. Few systems currently record the risks of blood recovery and reinfusion or adverse reactions to pharmacologic agents.

Transfusion safety encompasses the appropriate use of blood components, but requires assessment by clinical audit.<sup>13</sup> It is not within the scope of hemovigilance.

### Biovigilance

A number of commonalities can be recognized between blood transfusion and transplantation of tissues and hemopoietic stem cells. Infectious complications, system failures, and other adverse events may occur in both situations. Although the clinical situations and stakeholder groups may differ, the basic principles are the same, and experience in hemovigilance is of value when designing adverse event reporting and learning systems for tissues and cells. In Europe, legislation for tissues mirrors that for blood, and the development in the United States of new and comprehensive systems for “biovigilance” is awaited with great interest.<sup>2</sup>

### Passive Reporting vs Active Surveillance

Passive reporting systems, such as those described here, capture adverse events occurring within a short time following transfusion, provided clinical suspicion is high and an effective reporting mechanism is in place. Active surveillance of transfusion recipients may reveal a different picture, as illustrated by the difference in the incidence of TRALI reported by SHOT as 0.6 per 100,000 blood components issued<sup>4</sup> but reported by a single hospital with high clinical awareness as 1 in 8000 blood components issued.<sup>14</sup> Similarly, a prospective study of bedside errors found

major errors (including misidentification) in 15 of 3485 units transfused.<sup>15</sup>

Recognition of delayed complications may also require a different approach. Evidence for transfusion transmission of variant Creutzfeld-Jakob disease (vCJD) has been obtained only by rigorous implementation of active surveillance, involving the tracing of recipients of blood components from donors who were subsequently identified as developing vCJD, and retrospective tracing of blood donors who provided components to patients who developed vCJD.<sup>16</sup>

### Traceability

Two-way traceability, from donor to recipient and reverse, is essential for good manufacturing practice and for hemovigilance, and is a requirement of the European Union (EU) Blood Directive<sup>17</sup> and the United States Food and Drug Administration (FDA) regulations.<sup>18</sup>

The ISBT 128 identification system for blood components provides a global standard for identification of human blood, tissue, and organ products to individual donors across international borders and disparate health-care systems, and has been designed and perfected over a 12-year period.<sup>19</sup> Blood collectors must be able to trace blood from the donor, through component processing and testing, to the point of issue to the hospital blood bank; thereafter, the hospital blood bank or transfusion service is responsible for documenting that a specific blood component was transfused to an individual recipient, or its final fate if not transfused.

Forward immediate traceability is essential if a donor becomes ill with a TTI within the shelf-life of the donation, when prompt treatment of the recipient may preempt the development of clinical illness. In the case of a blood pack fault or test kit failure, a robust traceability system will facilitate rapid recall of components and minimize risk to patients. In the longer term, full two-way traceability is essential for look-back, eg, when a new screening test is introduced<sup>20</sup> or a new transfusion-transmissible agent recognized.<sup>21</sup>

---

## Models of Hemovigilance in Different Countries

### History

Pharmacovigilance was the first surveillance system in the arena of health care, covering medicinal products of all kinds. Hemovigilance, as a separate surveillance system, was first implemented in France in 1994, as required by the updated French regulation on blood in a response to a “blood scandal.” In the UK, anticipation of forthcoming European legislation, together with concerns regarding transfusion safety, led to the establishment of SHOT in 1996.

By the end of the 1990s, the concept of hemovigilance was developing across Europe but there was a lack of commonality of definitions, terminology, structure, and scope of reporting. In many countries, development was hindered by organizational

difficulties, lack of funding, unclear mandates, undefined responsibilities, inadequate training, and inability to make changes in response to reported findings.

At the turn of the millennium, hemovigilance was established and functioning in several countries across Europe, although not all were national systems. In some countries hemovigilance was required by law, in some it was officially established but not functioning, and in still others it was established as a voluntary system. Table 44-1 shows the situation in the 15 “old” member states of the EU in 2004.

The two national systems in France and the UK represented polarities in European hemovigilance. In France, the hemovigilance system was from the start centralized and nationwide, with a legal requirement for written notification of each and every side effect in relation to a blood transfusion (grades 1 to 4). Between 7000 and 7500 reports are generated annually, with an estimated 2.5 million blood components transfused every year in France.<sup>6</sup>

In the UK, where hemovigilance was designed as a national, voluntary, professionally led scheme covering transfusion reactions of grades 2 to 4, and IBCT regardless of outcome, the number of notifications is much lower than in France, with 2630 reports received in 8 years, 70% of which were IBCT.<sup>4</sup>

Subsequently, hemovigilance systems were established in nearly all of the 15 “old” member states of the EU.

The Republic of Ireland contributed to SHOT until 1998, when the Irish National Haemovigilance Office was established, again in response to “blood scandals” relating to hepatitis C virus. The Irish program is largely modeled on SHOT, and has included a pilot study of near misses.<sup>12</sup>

In Germany, blood components are considered by law to be medicinal products. As such they fall under German Drug Law, and pharmacovigilance applies to component production.

For the clinical aspects of transfusion (the users of blood components), hemovigilance applies and there is a major challenge in linking these surveillance activities together.

In Austria, the situation is comparable to Germany, although surveillance of collection, preparation, and transfusion of blood components are part of hemovigilance.

In the Benelux countries (Belgium, the Netherlands, and Luxembourg), small surveillance systems were established; initially these were fragmented and lacking in coordination. The Transfusion Reactions in Patients (TRIP) scheme in the Netherlands is now well established and produced its first annual report in 2003.<sup>22</sup> A major contribution of the Benelux countries lies in their leading role in creating and developing the European Haemovigilance Network (EHN).

In Denmark, hemovigilance was initially established on a local basis, until the creation of the Danish Registration of Transfusion Risks (DART).<sup>23</sup> The Danish system was the first to introduce structured donor hemovigilance, and the importance of donor adverse reactions was emphasized from the outset. The Danish model has largely influenced donor hemovigilance in other European countries, as now required by the EU Blood Directives.

In Greece, there is a long tradition of hemovigilance and, despite the complex structure of the Greek transfusion system because of geographic and political factors, these surveillance activities have generated interesting data.<sup>24</sup>

In Spain, impressive progress has been made recently, showing that, even in a complicated political environment, professionals from the field who have a strong will to bring hemovigilance forward can achieve significant results in a short period.

For the 12 “new” member states (joining the EU in May 2004), little is known about national hemovigilance activities, but this will change quite rapidly as these countries work toward compliance with the EU Blood Directive.

**Table 44-1.** Hemovigilance in Europe in 2004 before Implementation of the European Union Blood Directive

| Member State   | Status of Hemovigilance | Mandatory or Voluntary | Responsible Organization                                     |
|----------------|-------------------------|------------------------|--------------------------------------------------------------|
| Austria        | Started in 2003         | M                      | Österreichisches Bundes-Institut für Gesundheit              |

## The EU Blood Directives and the Future of European Community Hemovigilance

### Blood Directives

The key role of hemovigilance in blood transfusion safety is reflected in the EU Blood Directive 2002/98/EC.<sup>17</sup> This Directive of the European Parliament and of the Council of Europe sets standards of quality and safety for the collection, testing, processing, storage, and distribution of human blood and blood components and amends Directive 2001/83/EC. An entire chapter is dedicated to hemovigilance, and encompasses traceability and notification of serious adverse events and reactions.

According to the Directives on blood, hemovigilance is defined as “a set of organized surveillance procedures relating to serious adverse or unexpected events or reactions in donors or recipients, and the epidemiologic follow-up of donors.” It is stated that “it is important to introduce a set of organized surveillance procedures to collect and evaluate information on the adverse or unexpected events or reactions resulting from the collection of blood or blood components in order to prevent similar or equivalent events or reactions from occurring thereby improving the security of transfusion by adequate measures. To this end a common system of notification of serious adverse events and reactions ... should be established in member states.”

The legal framework on blood at the European Community level comprises four Directives:

- 2002/98/EC (Directive on principles and organization)
- 2004/33/EC (Directive on donations, donors, and blood components)
- 2005/61/EC (Directive on traceability and notification—hemovigilance)
- 2005/62/EC (Directive on a quality management system).

The Directives lay down standards of quality and safety of human blood and of blood components, in order to ensure a high level of human health protection. These are minimum standards, and do not require harmonization of activities related to blood transfusion in the member states of the EU.

In the context of blood matters, including hemovigilance, it is important to understand that the European Treaty (treaty of Amsterdam, establishing the European Community) sets limits in Article 152 that restrict the Directives on blood to collection and testing of human blood and blood components, whatever their intended purpose, and their processing, storage, and distribution when intended for transfusion. However, the Directives do not apply to clinical activities.

Hence, although hemovigilance (including rapid alert) should encompass the whole blood chain from donor to recipient and vice versa, including production and clinical use, current legislation can cover only the producers (the blood establishments) and to some extent the hospital blood banks. It cannot include users and their clinical activities, which are the exclusive responsibility of the individual member states. This obviously creates a complex situation in Europe with regard to hemovigilance systems.

In Chapter V of Directive 2005/61/EC, on hemovigilance, there are legally binding requirements for traceability (Article 14) and for the notification of serious adverse events and

reactions (Article 15). In the definition of “hemovigilance” it is stated that the organized surveillance procedures should relate to serious adverse or unexpected events or reactions in donors or recipients, and to the epidemiologic follow-up of donors.

The Directive requires reporting of only serious adverse or unexpected events or reactions.

A “*serious adverse event*” is defined in the Directive as any untoward occurrence associated with the collection, testing, processing, storage and distribution of blood and blood components that might lead to death or life-threatening, disabling, or incapacitating conditions for patients or that results in, or prolongs, hospitalization or morbidity.

A “*serious adverse reaction*” is defined in the Directive as an unintended response in a donor or patient associated with the collection or transfusion of blood or blood components that is fatal, life-threatening, disabling, incapacitating, or that results in, or prolongs, hospitalization or morbidity.

In the definition of “hemovigilance” it is required that organized surveillance cover both donors and recipients. The principle of subsidiarity allows other issues to be determined by individual EU member states, which may adopt regulations in addition to the provisions in the Blood Directives. However, the Directives must be transposed into national legislation by the member states.

### European Hemovigilance

Some years ago the need for EU-wide cooperation was anticipated when several countries decided to create a network for hemovigilance. The EHN was founded in 1998 by representatives from Belgium, France, Luxembourg, the Netherlands, and Portugal; these countries were later joined by Austria, Denmark, Finland, Greece, Ireland, Malta, Slovenia, Spain, and United Kingdom. The boundaries were more recently extended to include Canada, Croatia, Iceland, New Zealand, Norway, Singapore, and Switzerland. Further expansion is likely in future.

The EHN is conceptually a bottom-up organization of professionals from the field and includes different specialties: transfusion medicine, hematology, internal medicine, and civil servants.

The aim of the EHN is to develop and maintain in Europe a common structure with regard to safety of blood and blood components and hemovigilance in blood transfusion and transfusion medicine. To this end, the EHN pursues the following objectives:

- Favor exchange of valid information between members.
- Increase rapid alert and early warning between members.
- Encourage joint activities between members.
- Undertake educational activities relating to hemovigilance.

To fulfill these objectives, the EHN has:

- Developed and maintained a website ([www.ehn-org.net](http://www.ehn-org.net)).
- Established an on-line system for rapid alert and early warning.
- Worked toward standard definitions relevant to hemovigilance, in collaboration with ISBT.
- Initiated standardization of processes and forms.
- Started to compile, analyze, and compare data generated by the national hemovigilance systems.
- Organized annual European Haemovigilance Seminars.

The Rapid Alert system (RAS) was established and has been maintained by the EHN as a high priority from the outset, providing a framework for the international transmission of information on unexpected adverse reactions or equipment defects. It is especially useful for those countries where no previous system existed. A designated official contact person (OCP) in each country is responsible for the transmission and receipt of information, and coordinates with the blood services regarding appropriate corrective or preventive action to maintain or improve safety.

The EHN-RAS is a network of OCPs who are nominated or nationally agreed-upon individuals, responsible for entering, retrieving, and filtering information, and onward transmission if appropriate. The EHN-RAS has been used to disseminate information on newly recognized transfusion reactions (eg, red-eye syndrome), adverse reactions in donors (eg, allergic or anaphylactic reactions associated with apheresis devices), defects in disposables, problems with equipment or information technology, and deficiencies in reagents.

In the first 5 years more than 30 alerts were launched and disseminated to participating countries and organizations, and the RAS has developed with increasing cooperation of manufacturers. There remains scope for further development.

In Europe it was recognized quite early that hemovigilance has an important role. With the impact of the Directives on blood, national hemovigilance systems in Europe will converge to some degree, but will remain autonomous. The development of EHN has demonstrated that international cooperation at a professional expert level is possible, and can be effective in improving the safety and quality of blood transfusion. It is encouraging that newly established hemovigilance schemes worldwide are seeking to maintain and further develop established professional links, and EHN works closely with the Haemovigilance Working Group of the ISBT.

## Development of Hemovigilance Worldwide

An international forum in 2006 indicated the extent to which hemovigilance is becoming an integral and important part of transfusion practice worldwide.<sup>25</sup> Twenty-four countries responded to a survey; all but a few had a full hemovigilance system in place. The Japanese Red Cross has had a comprehensive hemovigilance system since 1993, and data are now coming from New Zealand, Russia, the Czech Republic, Slovakia, Poland, South Africa, and Brazil, as well as established systems in Europe, Scandinavia, and Canada. Work is in progress to develop hemovigilance in the US, Australia, and North Africa.

Comparisons of observed incidence of adverse reactions between countries with different practices can assist risk/benefit analysis and policy decision making. For example, in Norway, where there is 100% use of solvent/detergent-treated plasma (Octaplas, Octapharma, Lachen, Switzerland), the frequency of adverse events observed with plasma is low in comparison with that of other countries using Fresh Frozen Plasma (FFP).<sup>25</sup>

If comparative data are to be useful, like must be compared with like or, at the very least, differences in methodology must be recognized and understood. To this end the Haemovigilance Working Group of the ISBT is developing consensus definitions of adverse incidents in recipients and donors.

Denominator data are needed for interpretation of hemovigilance findings in the context of transfusion practice. The number of reported incidents is meaningful only when expressed against a denominator of blood components transfused. However, in many countries, including the UK, the only accurate figure available is the number of components issued by the blood collectors, with little or no reliable data on the number of components actually transfused, the number of transfusion episodes, or transfused patients. The question also arises as to whether the denominator should include blood components issued to hospitals that do not report incidents, as is done by SHOT in the UK, or should be restricted to components issued to actively participating hospitals, as in Canada (P Robillard, personal communication).

Epidemiologic studies are beginning to cast light on the clinical situations in which blood is used and the demographic profile and survival of transfused patients.<sup>26-28</sup> This will enable the future development of more sophisticated denominator data, identification of high-risk patients and situations, and estimation of the risks of transfusion in an individual patient.

---

## Hemovigilance Related to Blood Donors and Blood Donation

Systematic surveillance of the first part of the transfusion chain—the collection of blood from the donor—is an essential element of hemovigilance, and aims to secure and improve the safety of both the donor and the recipient. It should include registration of unexpected adverse events in whole blood and component donors and the action taken as a result. These events may be adverse reactions or complications resulting from donation, or adverse events related to the selection and management of donors, which may directly harm the donor or influence the quality of the product, thereby harming the recipient.

Provision of information about the risks of donation based on evidence from surveillance, together with good clinical management of any complications, indicates a high professional standard of the blood collection facility and its care of the well-being of the donors. This, in turn, will improve donor confidence and satisfaction, making it more likely that the donor will return, thus benefitting the national supply of blood.<sup>29,30</sup> In 2004, awareness of the importance of donor complications was raised by presentations of preliminary data from a pilot study.<sup>31,32</sup> A joint working group from the ISBT and EHN was established, and has proposed a classification and a set of definitions of complications related to blood donation (Appendix 44-2), to form the basis for a registry. It is hoped that the use of this registry will enable development of an evidence base to support improvements in donor care and selection.

### Complications Related to Regular Whole Blood Donation

Data on the occurrence of these complications are sparse, because most hemovigilance systems have not hitherto included donor adverse events. Large studies have been reported from single blood centers in the United States and in Greece<sup>33-38</sup>; comprehensive national data have been reported from Denmark<sup>39</sup>; and data collected with the use of the definitions agreed-upon have been presented at several meetings (Table 44-2).

The rate of reported donor complications has varied according to the severity and range of reactions included. Preliminary data registered according to the ISBT classification suggest that the overall rate of complications may be as high as approximately 1 per 100 donations. The most common complications related directly to the bleeding process are vasovagal reactions (2/3) and injuries of soft tissues, vessels (1/3), nerves, or tendons caused by the inserted needle.

#### Vasovagal Reactions

Vasovagal reaction is the most common donor complication (488 per 100,000 donations). The predominant symptoms are general discomfort, weakness, anxiety, dizziness, nausea, sweating, vomiting, pallor, and hyperventilation, associated with hypotension and bradycardia. The two last symptoms are essential for the diagnosis.

Most vasovagal reactions are mild and transient, but some donors may lose consciousness (vasovagal syncope). In the more severe cases this may result in an accident, if the donor faints and falls, or may be associated with convulsions and incontinence. It is important to reassure the donor that these reactions do not indicate a predisposition to true epilepsy.

Vasovagal reactions are generated by the autonomic nervous system stimulated by psychologic factors, and by the volume of blood removed relative to the donor's total blood volume. Therefore, donor age, weight, and donation status have been found to be significant variables.<sup>40</sup> The risk can be reduced by fluid replacement,<sup>41</sup> and by careful management of the donors during their stay in the blood facility.

Some vasovagal reactions (~10%)<sup>39</sup> occur after the donor has left the donation area, so-called delayed reactions. These reactions are potentially dangerous, as the donor may be at risk of a serious accident, and occasional deaths have been reported anecdotally.

In order to lower the risk of delayed reactions, and of serious outcome of these, it is essential to ensure that the donor feels completely well before leaving the donation area. Many facilities permanently defer donors following a severe delayed vasovagal reaction. Donors with hazardous occupations where they or others could be put at risk (eg, pilots) should not return to work within 24 hours of donation.

#### Hematomas

Hematoma is the second most common complication related to blood donation (275 per 100,000 donations). The symptoms are bruising, swelling, and pain at the venipuncture site.

A hematoma may occur if the needle punctures small arterial vessels, or if blood leaks from the vein during or after venipuncture. Blood in the soft tissues behind the biceps tendon will initially spread behind the tendon and may not produce any

visible swelling or pain. As the hematoma increases in size, it tracks along the blood vessels, nerves, and tendons to the forearm, and may cause paresthesiae in the fingers because of compression or irritation of the median nerve.

Accidental puncture of a large artery in the antecubital fossa carries a high risk of a hematoma and of delayed bleeding, and other rare but serious complications (Appendix 44-2). Donor care staff should be trained to recognize and correctly manage arterial puncture, so as to avoid extremely rare, but very severe, complications such as compartment syndrome of the forearm.

Injury to the median nerve in the antecubital fossa accounts for only 8% of all immediate adverse reactions, but gives rise to nearly all serious long-term complications.<sup>39</sup>

In approximately one-third of these cases the median nerve is directly damaged by the venipuncture needle.<sup>39</sup> The donor may experience immediate severe shooting pain, radiating down the forearm, sometimes associated with paresthesiae in the median nerve distribution of the hand. Indirect nerve injury may be caused by pressure from an increasing hematoma, with symptoms of pain and paresthesiae developing later.

Anatomical studies have shown marked individual variation in the arrangement of nerves and blood vessels in the antecubital fossa, and injuries may occur despite good venipuncture technique.<sup>42</sup> It is essential however that venipuncturists are familiar with normal anatomy of the region and are trained in correct techniques of needle insertion, together with prompt recognition and correct management of complications. To reduce the risk of direct nerve injury, the needle should be inserted only once and, if unsuccessful, no further attempts should be made.

Hematoma should be managed by stopping the donation immediately if the donor complains of symptoms, applying pressure to the venipuncture site, and recommending that the donor rest the arm and avoid manual work for 24 hours. The donor should return to the blood center or seek medical treatment if there is persistent bleeding from the venipuncture site or if the swelling increases.

### Long-Term Effects of Regular Whole Blood Donation and Apheresis

The surveillance of donors should also include the long-term effects of regular whole blood donation and repeated apheresis. Those of most concern are depletion of iron, calcium, and plasma proteins. The surveillance of repeat donors of whole blood should include at least the measurement of the hemoglobin concentration on each occasion. Programs of intensive plasmapheresis should include monitoring of plasma albumin concentrations.<sup>43</sup>

### Learning from Hemovigilance

Effective hemovigilance requires not only accurate and complete collection of data, but also interpretation of the data in the context of what is known of transfusion epidemiology and practice, and use of the data to improve patient safety, both locally and nationally.

**Table 44-2.** Occurrence of Complications Related to Donation of Whole Blood

| Occurrence Shown as Number of Cases/100,000 Donations |                                                      | Donor Complications (all grades) |          |              |       | Donor Complications (serious) <sup>†</sup> |          |              |       |

\*Data collected in accordance with *Standard for Collecting and Presentation of Data on Complications Related to Blood Donation* (Version 2007).<sup>†</sup>Complications with symptoms that lasted for more than a year or that needed medical treatment were graded as serious.<sup>‡</sup>Personal communications.

Early SHOT data focused attention on avoidable system failures in the transfusion chain, with the potential for serious patient harm. Acute intravascular hemolysis caused by major ABO incompatibility is the most feared outcome, but transfusion errors can cause patient harm in other ways, such as failure to provide blood of the correct specification for the patient, eg, irradiated cellular components for immunosuppressed patients at risk of TA-GVHD, or D sensitization of D-negative females of childbearing potential. Volume overload or unnecessary exposure to blood components can result from 1) incorrect decision making; 2) prescribing errors such as volume miscalculation; or 3) transfusing based on a misleading hemoglobin level from a sample diluted by intravenous infusion, from the wrong patient, or from a laboratory result that is incorrect or wrongly documented.

Over a 10-year period, during which time 30 million blood components were issued from the UK blood services, SHOT received 3770 reports, of which 2717 (72%) were of IBCT (see Table 44-3 and Fig 44-1). Ninety-five percent of these patients survived with no serious effects, but 24 deaths were attributed wholly or in part to avoidable transfusion errors, and 100 patients suffered major morbidity.<sup>44</sup>

Detailed analysis of these incidents is necessary if lessons are to be learned from them. For example, the SHOT questionnaire

on IBCT elicits the stage(s) of the transfusion chain where the error(s) occurred, and has thus been able to identify that 70% of errors occur in clinical areas, the most frequent error being failure to correctly perform the pretransfusion patient identification check at the bedside.<sup>10</sup> Approximately 30% of errors occur in hospital transfusion laboratories<sup>10</sup> and detailed knowledge of the circumstances can help to support improvements in standards of practice.

Errors in blood sampling for pretransfusion testing are usually detected in the laboratory if the patient is previously known. Data on near misses from SHOT and from the National Haemovigilance Office in Ireland<sup>12</sup> have revealed the true frequency of such errors and highlighted the importance of correct patient identification at the point of blood sampling.

Information on the time and place of transfusion, and the level of staff involved, is useful—not to apportion blame, but to target education and training and to direct efforts toward improving standards of practice. Such detail will be forthcoming only if reporters are assured that information will be used positively and constructively, and in total confidence.

Reports to SHOT, when interpreted in the context of epidemiologic data, suggest that night-time transfusion carries an increased risk<sup>45</sup> compared to those administered during the day

\*The HTR category was formerly DTR (delayed transfusion reactions); from 2006, all hemolytic reactions are included in HTR.

†Major morbidity is classified as the presence of one or more of the following:

- Requirement for intensive care and/or mechanical ventilation.
- Dialysis or renal impairment.
- Minor hemorrhage from transfusion-induced coagulopathy.
- Intravascular hemolysis.
- Potential D sensitization in a female of childbearing potential.

‡Excludes seven unclassified cases from 1998/1999.

SHOT = serious hazards of transfusion; IBCT = incorrect blood component transfused; ATR = acute transfusion reaction (included acute hemolytic reactions until 2006); HTR = hemolytic transfusion reaction (pre-2006 this included only delayed hemolytic transfusion reactions); PTP = posttransfusion purpura; TA-GVHD = transfusion-associated graft-vs-host disease; TTI = transfusion-transmitted infection.

**Figure 44-1.** Analysis of reports to SHOT over the 10-year period 1996.

SHOT=Serious hazards of transfusion; IBCT=Incorrect blood component transfused; ATR=Acute transfusion reaction (included acute hemolytic reactions until 2006); HTR=Hemolytic transfusion reaction (pre-2006 this included only delayed hemolytic transfusion reactions); PTP=Post transfusion purpura; TA-GVHD=Transfusion-associated graft-vs-host disease; TTI=Transfusion-transmitted infection.

and that transfusion to pediatric patients is more likely to result in an adverse outcome than adult transfusion.<sup>46</sup>

Successive SHOT reports have led to a number of national safety initiatives including professional guidelines on blood administration,<sup>47</sup> a nursing guideline,<sup>48</sup> a Safer Practice Notice from the National Patient Safety Agency relating to bedside pre-transfusion checks,<sup>49</sup> and a Quality Standard on transfusion.<sup>50</sup>

Hemovigilance data can be enormously valuable for monitoring changes in practice, such as the implementation of universal leukocyte reduction, which in France was noted to result in a reduction in the incidence of FNHTRs,<sup>9</sup> and in the UK was found to reduce, but not eliminate, TA-GVHD and alter the pattern of PTP.<sup>51</sup> Hemovigilance data have also been used to monitor measures to reduce the risk of bacterial contamination of platelets, and strategies to reduce the incidence of TRALI.

Cumulative SHOT data on transfusion-related mortality and morbidity<sup>4</sup> revealed the importance of TRALI as the leading cause of such outcomes. These findings are consistent with those from other countries, although hemovigilance data almost certainly underestimate the risk of this controversial and complex complication of transfusion. In institutions with a high index of suspicion of TRALI, its incidence has been estimated as 1:2000 to 1:8000 plasma-containing components.<sup>14,52</sup> Reports of TRALI to SHOT remained level at an average of 14 (range 11-19) per year for the first 5 years, but rose to 26 in 2001/2002, and to 36 in 2003, with increasing awareness of the condition. This led, in 2003, to a policy implemented by the UK blood services to obtain plasma, as far as possible, from male donors, to minimize the risk of TRALI caused by passive transfer of HLA or granulocyte antibodies arising in female donors as a result of pregnancy. The success of this policy has been measured by ongoing hemovigilance reporting; the number of cases of TRALI with high imputability reported to SHOT fell from 22 in 2003 to 13 in 2004, to six in 2005, and to three in 2006.<sup>44</sup>

Careful collection and analysis of hemovigilance data in the context of accurate denominator data has enabled risk estimation of transfusion in the developed world, as exemplified by Canada.<sup>53</sup> Such data must be made available, in comprehensible format, to doctors prescribing blood and patients receiving it, so that informed decisions can be made regarding risks and benefits, in the short and long term. Hemovigilance systems must be flexible, forward looking, responsive to developments in transfusion practice, and, above all, in touch with clinicians prescribing blood, and the requirements of patients.

### Appendix 44-1. ISBT Criteria for Severity and Imputability of Transfusion Reactions

| Grade/Score          | Definition                                                                                                                                                                                                                                                                                                                                            |
|----------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Severity</b>      |                                                                                                                                                                                                                                                                                                                                                       |
| 1 (non-severe)       | The recipient may have required medical intervention (eg, symptomatic treatment) but lack of such would not result in permanent damage or impairment of a body function.                                                                                                                                                                              |
| 2 (severe)           | The recipient required in-patient hospitalization or prolongation of hospitalization directly attributable to the event. OR<br>The adverse event resulted in persistent or significant disability or incapacity. OR<br>The adverse event necessitated medical or surgical intervention to preclude permanent damage or impairment of a body function. |
| 3 (life-threatening) | The recipient required major intervention following the transfusion (vasopressors, intubation, transfer to intensive care) to prevent death.                                                                                                                                                                                                          |
| 4 (death)            | The recipient died following an adverse transfusion reaction.*                                                                                                                                                                                                                                                                                        |
| <b>Imputability†</b> |                                                                                                                                                                                                                                                                                                                                                       |
| Definite (certain)   | When there is conclusive evidence beyond reasonable doubt that the adverse event can be attributed to the transfusion.                                                                                                                                                                                                                                |
| Probable (likely)    | When the evidence is clearly in favor of attributing the adverse event to the transfusion.                                                                                                                                                                                                                                                            |
| Possible             | When the evidence is indeterminate for attributing the adverse event to the transfusion or an alternate cause.                                                                                                                                                                                                                                        |
| Unlikely (doubtful)  | When the evidence is clearly in favor of attributing the adverse event to causes other than the transfusion.                                                                                                                                                                                                                                          |
| Excluded             | When there is conclusive evidence beyond reasonable doubt that the adverse event can be attributed to causes other than the transfusion.                                                                                                                                                                                                              |

\*Grade 4 should be used only if death is possibly, probably, or definitely related to transfusion. If the patient died of another cause, the severity of the reaction should be graded as 1, 2, or 3.

†Once the investigation of the adverse transfusion event has been completed, this is the assessment of the strength of relation to the transfusion of the event.

### Appendix 44-2. Standard for Collecting and Presenting of Data on Complications Related to Blood Donation

In order to facilitate international benchmarking, it is recommended that this standard be used when data on complications related to blood donation are presented. The Standard consists of

- Descriptions. A list with the categories grouped according to a code system.
- Data collection, Part 1. A list with description of the categories and definition of the grades of severity.
- Data collection, Part 2. An addendum with a form suitable for collecting data according to the standard.

The categories are divided in two main groups according to etiology and localization in the body. Some rare, but important, complications have been included in order to secure reports on occurrence. For the sake of simplicity they are grouped together under 300—Rare, important complications. The description of the categories includes definition, symptoms, complications, and grades of severity. Medical terms are defined as indicated in common medical dictionaries. The severity is graded according to duration of symptoms and of requirements for medical treatment.

The level of imputability is not included except for some of the complications in group 300—Rare, important complications.

If some of the symptoms essential for the definition of a category are missing, the complication can be registered in a more common or broad category. For example, if a donor complains of pain in the arm, the complication belongs to one of the following categories depending on when the symptoms occurred:

When needle was inserted Direct needle injury of a nerve (121).

After needle was inserted Indirect needle injury of a nerve by a haematoma (122).

However, if this information has not been registered the complication can be categorized as a nerve injury without specification (120).

## Complications Related to Blood Donation

### List of categories, numeric code, description, and grading (Version Madrid 2007)

| 100 Local Reactions Related to Needle Insertion |                                                          |                                                                                  |                                                                                                                                                                               |                                                                                                                                                                                 |

# Immunomodulatory and Proinflammatory Effects of Allogeneic Blood Transfusion

**Eleftherios C. Vamvakas,<sup>1</sup> José O. Bordin,<sup>2</sup> & Morris A. Blajchman<sup>3</sup>**

<sup>1</sup>Vice-Chair and Director of Clinical Pathology, Department of Pathology and Laboratory Medicine, Cedars-Sinai Medical Center, Los Angeles, California, USA

<sup>2</sup>Associate Professor, Division of Hematology and Transfusion Medicine, Universidade Federal de São Paulo, São Paulo, Brazil

<sup>3</sup>Professor Emeritus, Departments of Pathology and Medicine, McMaster University; Medical Director, Canadian Blood Services, Hamilton, Ontario, Canada

As knowledge about the mechanisms of immune responsiveness and tolerance evolves, and as new tools to measure alterations in immunity become available, additional immunologic consequences of allogeneic blood transfusion (ABT) are detected. The lingering question has been whether these observations represent no more than laboratory curiosities, or whether they reflect some clinically relevant alteration in the recipient's immune function—the so-called “immunomodulatory” effect of ABT.<sup>1</sup> The constellation of all such ABT-associated laboratory and clinical findings is known as transfusion-related immunomodulation (TRIM). Initially, TRIM encompassed effects attributable to ABT by means of immunologic mechanisms only; however, more recently, the term has been used more broadly, to encompass additional effects that could be related to ABT by means of both immunomodulatory and proinflammatory rather than only immunomodulatory mechanisms.<sup>2</sup>

ABT may either cause alloimmunization or induce tolerance. ABT introduces a multitude of foreign antigens into the recipient, including HLA-DR antigens found on the donor's dendritic antigen-presenting cells (APCs). The presence or absence of autologous HLA-DR antigens on the donor's white blood cells (WBCs) plays a decisive role in whether alloimmunization or immune suppression will ensue following ABT.<sup>3</sup> Transfusions sharing at least one HLA-DR antigen with the recipient will induce tolerance, while fully HLA-DR-mismatched transfusions lead to alloimmunization.<sup>4</sup> In addition to the degree of HLA-DR compatibility between donor and recipient, the immunogenicity of cellular or soluble HLA antigens found in transfused blood components depends on the viability of the donor dendritic APCs and the presence of the required costimulatory signals for the presentation of the donor antigens to the recipient's T cells. Nonviable APCs and/or absence of the requisite costimulatory signals result in T-cell unresponsiveness.<sup>5–7</sup> Thus, when a multitude of antigens

is introduced into the host by ABT, the host response to some of these antigens is often decreased, and immune tolerance (or TRIM) ensues.<sup>8</sup> Several immune-function alterations have been documented in association with ABT (Table 45-1).<sup>9,10</sup>

All these ABT-related laboratory immune alterations could potentially be associated with clinical effects. Evidence from a variety of sources indicates that ABT enhances the survival of renal allografts<sup>11</sup>; may increase the recurrence rate of resected malignancies and the incidence of postoperative bacterial infections; may reduce the recurrence rate of Crohn's disease<sup>12</sup> and the risk of fetal loss in women with recurrent spontaneous abortions (RSAs); may activate infections with cytomegalovirus (CMV) or human immunodeficiency virus (HIV); and/or may increase short-term (up to 3 months after transfusion) mortality from all causes.<sup>13,14</sup>

Different biologic mechanisms may be involved in each of these purported clinical manifestations of TRIM, and the clinical evidence supporting each of the aforementioned hypotheses should be examined on its own merits.<sup>13,15</sup> The specific constituent(s) of allogeneic blood that mediate(s) the TRIM effect(s) also remain(s) unknown, and published literature has

**Table 45-1.** Documented Immune Function Alterations in Association with Allogeneic Blood Transfusion

- Decreased T-helper (CD4) cell count
- Decreased helper/suppressor (CD4/CD8) T-lymphocyte ratio
- Decreased lymphocyte response to mitogens
- Reduction in delayed-type hypersensitivity
- Decreased natural killer (NK) cell function
- B-cell activation
- T-cell activation
- Hypergammaglobulinemia
- Decreased cytokine (interleukin-2, interferon- $\gamma$ ) production
- Suppression of lymphocyte blastogenesis
- Decreased monocyte/macrophage phagocytic function
- Increased production of anti-idiotypic antibodies
- Increased production of anti-clonotypic antibodies

**Figure 45-1.** TRIM effects, postulated mediators of TRIM, and preventive strategies that could be effective if the TRIM effects were mediated by each corresponding mediator. The purported deleterious TRIM effects are mediated by an unknown constituent(s) of allogeneic blood that may (or may not) include one (or more) of the mediators shown. Stored autologous blood obtained by preoperative autologous blood donation is replete with white blood cell (WBC)-derived soluble mediators, because both autologous and allogeneic WBCs deteriorate equally during storage, releasing such mediators. Fresh autologous blood, transfused within hours of collection and processing, is free of WBC-derived soluble mediators and can be procured by acute normovolemic hemodilution (ANH), intraoperative blood recovery (IBR), or postoperative blood recovery (PBR). WBC-reduction filters do not retain WBC-derived soluble mediators, accounting for the difference between prestorage and poststorage WBC reduction in abrogating the TRIM effects mediated by such mediators. Modified with permission from Vamvakas.<sup>16</sup> CMV = cytomegalovirus; HIV = human immunodeficiency virus.

suggested that TRIM effects may be mediated by: 1) soluble HLA Class I peptides that circulate in allogeneic plasma; 2) soluble biologic response modifiers released in a time-dependent manner from WBC granules or membranes into the supernatant fluid of Red Blood Cell (RBC) or platelet concentrates during storage; and/or 3) allogeneic mononuclear cells (Fig 45-1).<sup>15</sup>

## Beneficial Clinical TRIM Effects

### Enhanced Survival of Renal Allografts

The only clearly established TRIM effect is beneficial—not deleterious: it is the enhanced survival of renal allografts in patients who have received pretransplant ABT.<sup>11,17</sup> Patients who receive allogeneic blood have been shown to have a significantly better renal allograft survival than untransfused patients, regardless of the number of HLA-A, HLA-B, and HLA-DR locus mismatches between recipient and donor.<sup>11,18</sup> This is true even when there is a common HLA haplotype, or shared HLA-B and HLA-DR antigens between donor and recipient.<sup>19</sup> The TRIM effect has also been reported with allografts between HLA-identical siblings.<sup>20</sup>

The ABT-related enhancement of renal allograft survival has been confirmed by animal data and clinical experience worldwide. In fact, it used to be standard policy in many renal transplant units to deliberately expose patients on transplant waiting lists to one or more allogeneic RBC transfusions. Subsequently, the beneficial effect of pretransplant ABT was thought to be less important—after cyclosporine and other potent immunosuppressive drugs were introduced. As a consequence, many centers discontinued its use. However, a multicenter observational study, reporting on 58,036 renal allografts from cadaveric donors after

the advent of cyclosporine, indicated that patients who received ABT were still more likely to have a successful renal allograft than those who did not.<sup>21</sup>

This study reported that the 1-year renal allograft survival of patients receiving pretransplant ABT was 3% to 5% better than that of those who did not receive ABT. Similar results were also reported for patients who received renal allografts from living-related donors.<sup>22</sup> The beneficial effect of pretransplant ABT in the outcome of cadaveric renal allografts was confirmed by a randomized controlled trial (RCT) conducted at 14 transplant centers.<sup>23</sup> Patients were randomly assigned to receive either three pretransplant, non-WBC-reduced RBC transfusions or no ABT. The renal allograft survival was significantly higher in the 205 transfused patients than in the 218 untransfused subjects (90% vs 82% at 1 year,  $p = 0.02$ ; 79% vs 70% at 5 years,  $p = 0.025$ ). The beneficial effect of ABT was found to be independent of age, gender, underlying disease, prophylaxis with lymphocyte antibodies, or the presence of preformed lymphocytotoxins.<sup>23</sup>

Two RCTs<sup>24,25</sup> have compared types of pretransplant ABTs given to prolong graft survival. Both studies were small, enrolling 52 and 144 patients, respectively. The first RCT<sup>24</sup> compared non-WBC-reduced and WBC-reduced RBCs and found no difference in graft survival. The other RCT<sup>25</sup> compared recipients of one HLA-DR-mismatched ABT, one HLA-DR-matched ABT, and no ABT. There was no difference in graft survival at 1 year or at 5 years.

Recipients of non-WBC-reduced whole blood or RBCs have better 1-year cadaveric allograft survival than patients given WBC-reduced blood components such as frozen-thawed-deglycerolized RBCs. These data indicate that allogeneic WBCs are involved in eliciting this beneficial TRIM effect.<sup>26</sup> However, the mechanism(s) involved in the ABT-related enhancement of renal allograft

survival remain(s) to be elucidated, and many questions about the optimal use of ABT in such patients remain to be answered. The latter include: the optimal number of ABTs, the volume of RBCs with each ABT, and the timing of the ABTs to produce the optimal clinical effect; and whether the TRIM effect of pretransplant ABTs poses any hazard(s) in addition to conferring benefit.

ABT administered during the actual operation for renal transplantation has not been shown to affect subsequent allograft survival.<sup>17</sup> Patients who receive more than 10 RBC units have a better 1-year allograft survival than patients who receive only 1 or 2 RBC units. However, patients who receive more than 10 RBC units appear to have a poorer overall allograft survival than those who receive fewer than 10 RBC units.<sup>27</sup> Such data suggest that multitransfused patients often develop cytotoxic antibodies and thus are at greater risk for earlier and more severe allograft rejection episodes.<sup>22</sup> Along these lines, Solheim<sup>28</sup> has reported another potential benefit from pretransplant ABTs, which is especially relevant in settings where there is a shortage of organs for transplantation. When several prospective recipients on a renal transplant list produce crossmatch-negative results with an available organ, pretransplant ABTs could help identify high-responder patients (ie, patients most likely to form cytotoxic antibodies in response to pretransplant ABTs, and also most likely to reject a transplanted kidney because of formation of cytotoxic antibodies after a negative crossmatch). Transplant surgeons could thus channel the scarce organ away from such patients and give it to a patient in whom it is most likely to survive.<sup>28</sup>

An experimental animal model has suggested that the beneficial effect of donor-specific ABT might be related to the type of transplanted organ. Whereas ABT appears to lead to permanent acceptance of all renal allografts, this benefit was not observed with pancreas, skin, or heart allografts.<sup>29</sup> Although additional data are required to understand how ABT induces its beneficial effect in renal transplantation, the authors believe that the use of pretransplant, non-WBC-reduced ABT remains a potentially useful intervention in the management of selected patients scheduled for renal transplantation even today; however, this benefit may not apply to settings where universal WBC reduction has been implemented.

### **Reduced Risk of Recurrent Spontaneous Abortions**

Transfusion of allogeneic WBCs has been proposed as a form of immunotherapy for the prevention of RSAs.<sup>30,31</sup> In this setting, the fetus represents a semi-allogeneic graft to its mother, and maintenance of a pregnancy depends on immunologic equilibrium between the implanted fetus and the maternal immune response to the fetus. When the genetic parents share HLA antigens, this balance may be altered and maternal blocking antibodies may not be formed, predisposing the pregnant woman to RSAs. Different transfusion protocols of allogeneic WBCs have been used at various centers to reduce the risk of RSAs, employing WBCs obtained from either sexual partners or third-party donors. Such WBCs have been administered intravenously, intracutaneously, or as an intradermal injection of mononuclear cells obtained by gradient separation. WBC-containing blood

components have included pooled buffy coats, single-donor buffy coats, or RBC suspensions containing WBCs.

The American Society for Reproductive Immunology (ASRI) conducted a worldwide collaborative individual-patient-data (IPD) meta-analysis to examine the efficacy of immunotherapy with allogeneic WBCs in patients with a history of RSAs<sup>32</sup> and concluded that such treatment was effective. The effect was small, with only 8% to 10% of affected women benefiting from the treatment. In contrast to the ASRI data, a recent multicenter RCT<sup>33</sup> that enrolled 183 women with a history of three or more spontaneous abortions reported a nonsignificant decrease in live-birth rate in patients randomly assigned to immunotherapy as compared with controls (36% vs 48%). However, the size of this RCT was likely inadequate to establish a clinically relevant treatment effect. Thus, the efficacy of transfusions of allogeneic WBCs for the treatment of patients with RSAs remains to be established.

### **Reduced Risk of Recurrence of Crohn's Disease**

Several observational studies have examined whether postoperative recurrence in patients with Crohn's disease—an immune-mediated disease—can be reduced by the perioperative administration of ABT. Pooled data from the available studies suggest that the recurrence rate in transfused and untransfused patients is similar: 37.5% vs 40.5%.<sup>12,34-37</sup> However, such integration of the reported data may be inappropriate, because the available studies are observational and medically heterogeneous (ie, using different follow-up periods and surgical interventions). Nonetheless, an IPD meta-analysis of 622 patients with Crohn's disease found no effect of perioperative ABT on subsequent need for surgical intervention, independent of age, gender, disease location, or extent of the resection.<sup>38</sup> Because many factors affect the risk of recurrence in patients with Crohn's disease, a large RCT is needed to clarify the role of ABT, if any, in modulating disease activity in patients with this disorder.

---

## **Deleterious Clinical TRIM Effects**

### **Increased Recurrence of Resected Malignancies**

If ABT has a beneficial effect in renal transplantation, where immunosuppression is beneficial because it may prevent allograft rejection, ABT could also have deleterious effects in situations where impairment of the recipient's immune function can be detrimental. In 1981, 8 years after the first report of the beneficial effect of pretransplant ABT on renal allograft survival,<sup>11</sup> Gantt<sup>39</sup> voiced his concern that perioperative ABT for curative resection of a malignancy might provoke recurrence of cancer. Thus, if the host's immune response to a tumor contributes to controlling the tumor's growth, one would expect that impairment of the host's immunity, caused by ABT, would impair this defense mechanism and facilitate tumor growth.

More than 100 observational studies of ABT and cancer recurrence have been reported,<sup>40</sup> and their unadjusted results (ie, their findings before adjustment for the effects of confounding factors)

were subjected to three meta-analyses.<sup>40-42</sup> When the available results were integrated for seven cancer sites, there was agreement between the three overviews on the magnitude and statistical significance of the risk of cancer recurrence, death from cancer recurrence, or overall mortality in transfused compared with untransfused patients. A statistically significant adverse clinical outcome was found among transfused (compared with untransfused) patients for all cancer sites evaluated except for cervix.<sup>40</sup> A statistically significant ABT effect in the observational studies that had presented multivariate analyses adjusting for the effects of confounding factors was found in 24 studies, including 11 studies of colorectal cancer, four studies of head and neck cancer, one study of breast cancer, two studies of gastric cancer, four studies of lung cancer, and two studies of prostate cancer.<sup>40</sup> This ABT effect has not been confirmed by the available RCTs of perioperative ABT and cancer recurrence that are discussed later in this chapter (see TRIM effects mediated by allogeneic mononuclear cells).

### Increased Risk of Postoperative Bacterial Infection

None of the purported adverse TRIM effects of ABT has been established by RCTs, and the debate over the existence of clinical deleterious TRIM effects has been long and sometimes acrimonious.<sup>43-48</sup> Initially, the debate focused on differing interpretations of the findings of approximately 40 observational studies that had compared the risk of postoperative bacterial infection between transfused and untransfused patients undergoing gastrointestinal surgery, orthopedic operations, cardiac surgery, or various other surgical procedures. These studies tended to indicate that patients receiving perioperative ABT (compared with those not receiving ABT) almost always had a higher risk of developing postoperative bacterial infection.<sup>43</sup> The studies also indicated that patients receiving transfusion generally differed from those not receiving transfusion in several prognostic factors that predisposed to adverse clinical outcomes.<sup>44</sup> Based on these two sets of observations, some authors concluded that ABT has a direct deleterious effect on the recipient, causing an increased risk of postoperative bacterial infection.<sup>43</sup> Other investigators concluded that clinical need for ABT can be a surrogate marker for a variety of adverse prognostic factors and that the other variables that generated the need for ABT in the published studies also determined the subsequent clinical outcome.<sup>44</sup>

Today, the controversy over TRIM is focused on differing interpretations<sup>45-48</sup> of the findings of the available RCTs of perioperative ABT and postoperative infection. There have been 22 RCTs<sup>49-70</sup> that compared the risk of postoperative infection and/or mortality between patients randomly assigned to receive non-WBC-reduced allogeneic vs autologous or WBC-reduced allogeneic RBCs. Three of these RCTs<sup>50,52,71</sup> also compared the risk of cancer recurrence between the two randomization study arms. Nineteen RCTs were conducted in the perioperative setting; three more RCTs enrolled HIV-seropositive patients,<sup>62</sup> all hospitalized patients,<sup>65</sup> or trauma patients.<sup>70</sup>

Based on an integration of the results of all nine RCTs published or reported through 2002<sup>49,52,54,58-60,63,66,67</sup> and comparing the risk of postoperative infection between patients randomly

assigned to receive non-WBC-reduced vs WBC-reduced ABT in the event that they needed perioperative transfusion, two meta-analyses<sup>45,46</sup> concluded that non-WBC-reduced ABT is associated with postoperative infection. In contrast, a third meta-analysis<sup>47</sup> that integrated the findings of all 12 RCTs published or reported through 2005<sup>49,52,54,58-60,63,66-70</sup> found no association between non-WBC-reduced ABT and postoperative infection. Similarly, no association between ABT and postoperative infection was detected when the findings of RCTs<sup>50,51,55,56,64</sup> comparing recipients of allogeneic and autologous RBCs were integrated.<sup>72</sup>

The reasons for the disagreements between the three meta-analyses<sup>45-47</sup> that compared recipients of non-WBC-reduced vs WBC-reduced ABT have been discussed.<sup>48</sup> There were two main reasons for the disagreements: 1) the inclusion in the analysis of all 12 RCTs available today vs the nine initially published RCTs; and 2) the integration (or not) of the results of all 12 (or all nine) RCTs despite extreme medical heterogeneity. Medical heterogeneity refers to differences in study design with respect to such factors as the RBC product transfused to the non-WBC-reduced arm (ie, non-buffy-coat-reduced vs buffy-coat-reduced allogeneic RBCs or whole blood), the RBC product transfused to the WBC-reduced arm (ie, WBC-reduced RBCs or whole blood filtered before or after storage), the transfusion dose, the surgical setting (gastrointestinal, cardiac, or other), the types of postoperative infections evaluated, the criteria for diagnosing postoperative infection, and the frequency of postoperative infection recorded in each study.<sup>48</sup>

One would expect more of a TRIM effect in association with the transfusion of non-buffy-coat-reduced (compared with buffy-coat-reduced) allogeneic RBCs because the buffy-coat-reduced RBCs used in Europe contain only about one-third of the donor WBCs found in the non-buffy-coat-reduced RBCs used in North America. Second, one would expect a greater reduction of a TRIM effect(s) attributable to the transfusion of prestorage (compared with poststorage) filtered WBC-reduced allogeneic RBCs, because of the removal of WBC-derived soluble mediators through prestorage (but not poststorage) filtration (Fig 45-1). Third, one would expect more of a TRIM effect in cardiac (compared with other) surgical settings, because in cardiac surgery allogeneic mononuclear cells and/or WBC-derived soluble mediators might serve as a second inflammatory insult that compounds the diffuse inflammatory response to the extracorporeal circuit.<sup>73</sup>

Therefore, one would not expect all 12 RCTs available today (or all nine initially published RCTs) to have targeted the same TRIM effect. In contrast, depending on their design, these 12 (or nine) RCTs probably targeted TRIM effects that varied in magnitude and/or nature, making the integration of all 12 (or all nine) RCTs by a meta-analysis inappropriate. For example, RCTs administering RBCs filtered before storage to the WBC-reduced arm<sup>52,58,60,63,66-70</sup> investigated TRIM effects mediated by both WBC-derived soluble mediators and allogeneic mononuclear cells (Fig 45-1). However, RCTs transfusing RBCs filtered after storage to the WBC-reduced arm<sup>49,54,58,59</sup> investigated only those TRIM effects mediated by allogeneic mononuclear cells. Meta-analyses should integrate results only from subsets

of RCTs that are medically sufficiently homogeneous to justify the assumption that all combined studies have targeted a TRIM effect that is *biologically* similar.<sup>48</sup> Results from meta-analyses of such homogeneous subsets of RCTs are presented later in this chapter where TRIM effects mediated by WBC-derived soluble mediators or allogeneic mononuclear cells are discussed.

Blumberg et al<sup>46</sup> had earlier attributed the disagreements between the three meta-analyses<sup>45-47</sup> to the reliance on the intention-to-treat principle in the meta-analysis that did not detect an adverse TRIM effect of ABT<sup>47</sup> vs the use of results from “as-treated” analyses in the two meta-analyses that did detect a deleterious TRIM effect.<sup>45,46</sup> Intention-to-treat analyses often have reduced statistical power to detect a treatment effect compared with “as-treated” analyses.<sup>46</sup> However, both intention-to-treat and “as-treated” analyses demonstrated a deleterious TRIM effect when the analysis integrated the findings of *all* nine initially published RCTs. Neither the intention-to-treat nor the “as-treated” analysis showed an association between non-WBC-reduced ABT and postoperative infection when the analysis integrated the results of *all* 12 RCTs available today (Table 45-2).<sup>48</sup>

### Increased Risk of Short-Term Mortality

An association between non-WBC-reduced ABT and short-term (up to 3 months after transfusion) mortality from all causes was described in the RCT of van de Watering et al.<sup>58</sup> This RCT had been designed to investigate an association between non-WBC-reduced ABT and postoperative infection and, instead of that association, it observed an association between non-WBC-reduced ABT and mortality. The association between ABT and mortality was reported as a data-derived hypothesis,<sup>58</sup> and the authors postulated

that non-WBC-reduced ABT may predispose to multiple-organ failure (MOF), which might—in turn—predispose to mortality. These investigators undertook another RCT that confirmed the association between ABT and mortality but did not find an association between non-WBC-reduced ABT and increased MOF.<sup>63</sup>

Several preclinical<sup>74-78</sup> and clinical<sup>73,79-89</sup> observations have supported the hypothesis that ABT in general, and non-WBC-reduced ABT in particular, may be associated with MOF. The mechanisms underlying the development of MOF are unclear, but most evidence suggests that tissue injury is mediated by reactive oxygen species and proteolytic enzymes released from activated neutrophils.<sup>90-92</sup> Silliman et al<sup>74</sup> proposed that ABT may exercise a neutrophil-priming effect mediated by bioactive lipids that accumulate during storage. They postulated that rapidly deteriorating WBCs in stored RBC units release cytotoxic enzymes that may act on fragmented red cell membranes to produce mediators that are responsible for neutrophil priming and endothelial-cell activation (Fig 45-2).

These investigators<sup>74-76</sup> demonstrated that plasma obtained from stored RBC units primes neutrophils for superoxide production and enhanced cytotoxicity, and also activates pulmonary endothelial cells in a dose- and age-dependent fashion. The length of RBC storage was important in these studies, because no evidence of neutrophil priming was obtained when plasma stored for short periods was used. Silliman et al<sup>77</sup> also showed that lipids from the plasma supernatant of RBCs stored for 42 days cause acute lung injury in isolated pulmonary models. Similarly, Chin-Yee et al<sup>78</sup> reported that plasma supernatant from stored RBCs activates neutrophils. In that study, WBC reduction of the RBC units abrogated the effect.<sup>78</sup>

**Table 45-2.** Meta-Analyses of RCTs of Non-WBC-Reduced Allogeneic Blood Transfusion and Postoperative Infection: Impact of the Method of Analysis and the Number of RCTs Included in the Analysis<sup>48</sup>

| Number of RCTs included in the Analysis <sup>†</sup>                                          | Method of Analysis          |                    |                         |                                          |                    |                         |
|-----------------------------------------------------------------------------------------------|-----------------------------|--------------------|-------------------------|------------------------------------------|--------------------|-------------------------|
|                                                                                               | Intention-to-Treat*         |                    |                         | “As-Treated”*                            |                    |                         |
|                                                                                               | Number of Patients Analyzed | Summary Odds Ratio | 95% Confidence Interval | Number of Patients Analyzed <sup>‡</sup> | Summary Odds Ratio | 95% Confidence Interval |
| 9 RCTs <sup>49,52,54,58-60,63,66-67</sup> published or reported through 2002 <sup>45,46</sup> | 5017                        | 1.38               | 1.03-1.85 <sup>§</sup>  | 3265 (65.1%)                             | 1.56               | 1.06-2.31 <sup>§</sup>  |
| 12 RCTs <sup>49,52,54,58-60,63,66-70</sup> published or reported through 2005 <sup>47</sup>   | 6290                        | 1.24               | 0.98-1.56               | 4460 (70.1%)                             | 1.31               | 0.98-1.75               |

\*The intention-to-treat analyses included all patients randomly assigned preoperatively to receive non-WBC-reduced or WBC-reduced allogeneic blood in the event that they needed perioperative transfusion. The “as-treated” analyses retained only those patients from each randomization arm who ended up receiving transfusion during or after surgery.

<sup>†</sup>Integration of all nine (or all 12) RCTs, as shown in this table, is inappropriate because of the extreme medical heterogeneity of the studies (see text). Therefore, readers should resist the temptation to assign a medical or biological meaning to the figures presented in the table. Instead, readers are referred to Figs 45-4 and 45-5, which depict the results obtained when medically homogeneous subsets of these RCTs<sup>49,52,54,58-60,63,66-70</sup> were integrated.

<sup>‡</sup>The percentage of all randomized patients that was included in the “as-treated” analyses is given within parentheses.

<sup>§</sup>Statistically significant adverse ABT-related immunomodulatory effect ( $p < 0.05$ ).

**Figure 45-2.** Proposed mechanism leading from the accumulation of bioactive lipids in the supernatant fluid of stored non-WBC-reduced Red Blood Cells (RBCs) to the development of multiple-organ failure in the recipient.<sup>74-78</sup>

Based on this observation that ascribes a neutrophil-priming effect to ABT (Fig 45-2), it is possible that the recently reported<sup>58,63</sup> association between ABT and short-term mortality could, in fact, reflect a “proinflammatory” rather than an “immunomodulatory” effect of ABT. However, for the time being and until these effects can be clearly defined, the authors believe that the association between ABT and MOF or mortality should be covered under the general overarching concept of adverse “TRIM” effects.<sup>2</sup>

In the study of Johnston et al,<sup>80</sup> patients receiving allogeneic RBCs had a significantly higher risk of MOF than recipients of polymerized hemoglobin. Neutrophils obtained from recipients of RBCs demonstrated priming, as evidenced by increased beta-2 integrin expression, superoxide production, and elastase release. Neutrophils obtained from recipients of polymerized hemoglobin showed no evidence of priming. Studies investigating the benefits obtained from placing a WBC reduction filter in the arterial line of the cardiopulmonary bypass circuit<sup>81-83</sup> suggested that non-WBC-reduced ABT may provoke cardiac and/or pulmonary failure. Furthermore, associations between ABT and prolonged mechanical ventilation<sup>84,85</sup> or MOF<sup>79,86-89</sup> were reported by some, but not all,<sup>93,94</sup> observational studies.

Recently, on the basis of an observational study of 248 patients, Netzer et al<sup>95</sup> reported that ABT in patients with acute lung injury was associated with increased in-hospital mortality. Following adjustment for confounding factors, ABT given after the onset of acute lung injury was associated with a 13% increase in mortality per unit of transfused RBCs ( $p < 0.0001$ ), but ABT given before the onset of acute lung injury was not associated with any higher risk. Both non-WBC-reduced and WBC-reduced ABT were associated with a significant ( $p < 0.001$ ) increase in mortality, although the magnitude of the increase in risk was greater when non-WBC-reduced (rather than WBC-reduced) RBCs had been used. Along the same lines, Murphy et al<sup>96</sup> linked the United Kingdom population register with the clinical, intensive-care-unit (ICU), hematology, and blood bank databases of 8516 patients who had undergone cardiac surgery over 8 years (1996-2003). When transfused and

untransfused patients were compared after adjustment for confounding factors, ABT was found to be associated with a higher risk of postoperative infection, ischemic postoperative morbidity, and early (0 to 30 days) as well as late (31 days to a year) mortality.

An association between non-WBC-reduced ABT and prolonged mechanical ventilation or MOF has not yet been reported by any RCT. Eleven RCTs, comparing recipients of non-WBC-reduced vs WBC-reduced allogeneic RBCs, and reporting on cancer recurrence, postoperative infection, or mortality as the primary outcome have presented information on short-term (up to 3 months after transfusion) mortality from all causes.<sup>54,57,58,60,63,65-70</sup> Because WBC reduction filters do not retain soluble mediators, if ABT exercised the described WBC-dependent neutrophil-priming effect mediated by bioactive lipids that accumulate during storage (Fig 45-2), allogeneic RBCs WBC-reduced before storage should abrogate this effect; but allogeneic RBCs WBC-reduced after storage should confer no benefit. Despite this theoretical prediction, no increase in mortality in association with non-WBC-reduced ABT was detected either across the subset of RCTs transfusing RBCs filtered before storage to the WBC-reduced arm, or across the subset of RCTs transfusing RBCs filtered after storage to the WBC-reduced arm.<sup>47</sup>

However, across five RCTs conducted in cardiac surgery<sup>58,63,66,68,69</sup> that had transfused RBCs filtered before storage to the non-WBC-reduced arm, non-WBC-reduced ABT was associated with a 72% increase in postoperative mortality [summary odds ratio, 1.72; 95% confidence interval (CI), 1.05–2.81;  $p < 0.05$ —Fig 45-3]. As already discussed, the TRIM effect seen across these studies may be associated with factors prevalent in the setting of patients undergoing cardiac surgery. For example, one can speculate that bioactive lipids accumulating during the storage of non-WBC-reduced RBCs and/or allogeneic mononuclear cells *may* represent a second inflammatory insult. That insult *may* compound the diffuse inflammatory response associated with the cardiopulmonary bypass circuit that *may* predispose recipients to MOF that *may*—in turn—predispose to mortality.<sup>73</sup>

**Figure 45-3.** Postoperative mortality in cardiac-surgery patients. Randomized controlled trials (RCTs) investigating the association of non-WBC-reduced allogeneic blood transfusion (ABT) with short-term (up to 3 months after transfusion) mortality from all causes and conducted in the setting of cardiac surgery.<sup>58,63,66,68,69</sup> For each RCT, the figure shows the odds ratio (OR) of short-term mortality in recipients of non-WBC-reduced vs WBC-reduced allogeneic Red Blood Cells, as calculated from an intention-to-treat analysis; and the summary OR across the depicted RCTs, as calculated from a meta-analysis.<sup>47</sup> A deleterious ABT effect (and thus a benefit from WBC reduction) is demonstrated by an OR >1, provided that the effect is statistically significant ( $p < 0.05$ ; ie, provided that the associated 95% CI does not include the null value of 1).

### Effect of the Length of RBC Storage

If bioactive lipids or other soluble mediators accumulating in a time-dependent manner during storage were associated with adverse outcomes, observational studies should be reporting an association between prolonged storage of transfused non-WBC-reduced allogeneic RBCs and increased risk of occurrence of these adverse outcomes (because the longer the non-WBC-reduced allogeneic RBCs are stored, the higher the level of such soluble mediators they will contain). Also, the red cell storage lesion (Chapter 4) occurs in both the non-WBC-reduced and the WBC-reduced units, generating considerable numbers of nonfunctioning red cells. Such nonfunctioning red cells are removed from the recipient's circulation within 24 hours of the transfusion. Removal of large numbers of nonfunctioning red cells places a considerable burden on the reticuloendothelial system of a multitransfused recipient—a burden that could interfere with the host's response to bacteria and other challenges.

Nine observational studies have reported on the association between prolonged storage of transfused allogeneic RBCs and increased risk of morbidity or mortality. Four studies<sup>97-100</sup> reported on the association of prolonged storage of transfused RBCs with postoperative infection; one study<sup>79</sup> on the association between prolonged storage of transfused RBCs and MOF; and three studies<sup>101-103</sup> on the association between prolonged storage of transfused RBCs and increased mortality. The earlier studies<sup>79,97-102</sup> found prolonged storage of transfused non-WBC-reduced allogeneic RBCs to be associated with an increased risk of these adverse outcomes but van de Watering et al<sup>103</sup> found no association between prolonged storage time of transfused RBCs and increased mortality or longer stay in the ICU. Recently, in the setting of cardiac surgery, Gorman Koch et al<sup>104</sup> compared 2872 patients given RBCs stored for 14 days or less with 3130 patients given RBCs stored for more than 14 days. Prolonged storage was associated with an increase in the risk-adjusted rate of a composite of complications ( $p = 0.03$ ), while at 1 year mortality was significantly increased in patients given blood stored for more than 14 days (11.0% mortality) compared with patients given blood stored for 14 days or less (7.4% mortality). The effect of the length of storage on non-WBC-reduced RBCs on clinical outcomes has not yet been evaluated in RCTs.

### "Before-and-After" Studies

In the late 1990s, Canada and many western European countries implemented universal WBC reduction of cellular blood components by means of prestorage filtration. Once universal WBC reduction is implemented, the opportunity to conduct RCTs to establish adverse TRIM effects attributable to allogeneic WBCs is removed. It is, however, possible to compare the risk of infection or mortality in recipients of non-WBC-reduced RBCs before implementation of WBC reduction with the risk of infection or mortality in recipients of WBC-reduced RBCs after implementation of WBC reduction. Such "before-and-after" studies are observational, and—as such—they cannot establish causal relationships. Five before-and-after studies have reported data on the risk of infection,<sup>105-109</sup> and five such studies have reported data on the risk of short-term mortality.<sup>105,106,108-110</sup>

In Canada, Hébert et al<sup>108</sup> conducted a large study including 9525 patients undergoing cardiac surgery, 1731 patients undergoing orthopedic surgery, and 3530 patients admitted to the ICU. These investigators observed a statistically significant ( $p = 0.04$ ) decrease in short-term mortality (from 7.0% to 6.2%) after WBC reduction was introduced, without a concomitant reduction in the risk of postoperative infection. They offered the hypothesis that the observed decrease in the number of deaths might not have been mediated through suppression of the recipient's immune function, but through a proinflammatory microvascular effect of transfused WBCs that affects several organ systems. This hypothesis was buttressed by the findings of a companion before-and-after study in premature infants.<sup>109</sup> In that setting, the implementation of universal WBC reduction coincided with a reduction in several secondary morbidity outcomes from

several organ systems (ie, bronchopulmonary dysplasia, retinopathy of prematurity, necrotizing enterocolitis)—an observation consistent with a diffuse proinflammatory microvascular effect of allogeneic WBCs.

However, when all before-and-after studies were considered together in a meta-analysis,<sup>111</sup> and the findings of the unadjusted analyses from five studies<sup>105-109</sup> were integrated, there was an unadjusted association of WBC reduction with a decreased risk of postoperative infection. This association did not persist when findings from the multivariate analyses of the observational studies that had adjusted for the effects of confounding factors<sup>106,108,109</sup> were integrated. There was neither an unadjusted<sup>105,106,108-110</sup> nor an adjusted<sup>106,108,109</sup> association of WBC reduction with decreased short-term mortality.<sup>111</sup>

## TRIM Effects Mediated by Soluble Molecules Circulating in Allogeneic Plasma

### Soluble HLA Molecules

Soluble HLA proteins and immunoreactive HLA peptides remain important candidates as mediators of the TRIM effect(s). It has been suggested that nonpolymorphic peptides derived from HLA Class I molecules induce antigen-nonspecific immunosuppression, while polymorphic HLA Class I peptides have antigen-specific immunomodulatory effects.<sup>112-114</sup> It also seems possible that allogeneic plasma containing soluble HLA antigens may enter the recipient's thymic circulation, producing clonal deletion of the recipient's T cells that are directed against the allogeneic donor antigens.<sup>115,116</sup>

### Factor VIII Concentrates

In-vitro studies have indicated that low-molecular-weight components found in Factor VIII concentrates may inhibit the proliferative responses of peripheral blood mononuclear cells to phytohemagglutinin.<sup>117</sup> In these studies, high-purity Factor VIII concentrates have been shown to reduce the induction of T-cell-activation molecules such as the interleukin (IL)-2 receptor (CD25), the transferrin receptor (CD71), CD38, the CD11a/CD18 ratio, and HLA-DR antigen expression.<sup>117</sup> Moreover, evidence has been provided that this inhibitory action of Factor VIII concentrates was at least partly as a result of their contamination by transforming growth factor (TGF)- $\beta$ .<sup>118</sup>

### Autoantibodies

For some unknown reason, some people spontaneously produce large amounts of neutralizing autoantibodies to a number of growth factors (eg, granulocyte-macrophage colony-stimulating factor) or cytokines (eg, IL-1, IL-6, interferon- $\alpha$ ).<sup>119</sup> The autoantibodies in question are detectable in immunoglobulin preparations and correspondingly in plasma for transfusion. Therefore, if such donors donate blood, large amounts of neutralizing autoantibodies to growth factors or cytokines may be transferred to recipients by transfusion. In the plasma of transfusion recipients who had received plasma from donors with high titers of high-affinity neutralizing autoantibodies to IL-6 (0.1% of

normal donors), Hansen et al<sup>119</sup> demonstrated a 500-fold or greater increase in the concentration of complexed IL-6/autoantibody to IL-6, as compared with free IL-6 detectable in the patients' plasma before the transfusion.

When these autoantibodies reach a certain level, they may render a donor (or the recipient of plasma from such a donor) cytokine-deficient, but overt clinical sequelae of such a cytokine deficiency have not been reported. Hansen et al<sup>119</sup> christened this phenomenon transfusion-related inhibition of cytokines (TRICK). Depending on the cytokine or growth factor involved, TRICK could conceivably increase the transfusion recipient's susceptibility to infection or delay hematopoietic recovery after stem cell transplantation.

### Evidence from RCTs

The authors know of only one RCT<sup>66</sup> whose design permitted the investigators to examine the hypothesis that soluble plasma molecules circulating in allogeneic plasma may mediate TRIM effects. Wallis et al<sup>66</sup> randomly assigned 597 patients undergoing cardiac surgery to receive plasma-reduced, buffy-coat-reduced, or WBC-reduced allogeneic RBCs. In terms of their WBC content, plasma-reduced RBCs are equivalent to the buffy-coat-rich RBCs used in North America. The highest risk of postoperative infection was observed in the plasma-reduced study arm, in which the incidence of postoperative infection was 17.1%, as compared with 10.8% in the buffy-coat-reduced arm and 11.3% in the WBC-reduced arm ( $p = 0.20$ ). Although the difference between the three study arms was not significant, it appeared as though plasma removal did not confer a benefit with regard to the prevention of TRIM, or—by extension—that allogeneic plasma did not mediate TRIM.

## TRIM Effects Mediated by WBC-Derived Soluble Mediators

### Mediators Originating in WBC Granules

Biologic response modifiers accumulating in blood components during storage have been implicated in the pathogenesis of TRIM.<sup>120</sup> These mediators are contained in intracellular WBC granules, and are released in a time-dependent manner as the cells deteriorate.<sup>121</sup> Nielsen et al<sup>121</sup> reported that the concentration of histamine, eosinophil cationic protein, eosinophil protein X, myeloperoxidase, and plasminogen activator inhibitor-1 increase 3- to 25-fold in the supernatant fluid of RBC components between Days 0 and 35 of storage. Histamine, eosinophil cationic protein, and eosinophil protein X have been shown to inhibit neutrophil function, thereby contributing to the development of immunosuppression and tissue damage.<sup>122,123</sup>

### Soluble HLA Molecules and Fas Ligand

Soluble HLA molecules are present in the serum or plasma of healthy individuals. The liver is the main source of soluble HLA molecules found in the circulation. High levels of these molecules have been found in the serum or plasma of transplant recipients and patients with a variety of conditions, including

inflammatory, autoimmune, and infectious diseases. Soluble HLA molecules are also found in the supernatant fluid of stored RBCs and platelets, in direct proportion to the length of storage and the number of cells present. The biologic significance of these molecules has not been fully established, although it has been reported that they may be involved in the downregulation of the immune response and/or induction of tolerance.

Ghio et al<sup>124</sup> and Puppo et al<sup>125</sup> found soluble Fas-ligand (sFasL) and soluble HLA Class I molecules in the supernatant plasma of RBC and whole-blood-derived platelet units. The sFasL content of either 30-day stored RBCs or 5-day stored platelets was approximately 20 ng/mL. The infusion of sFasL in transfused blood components may bind the Fas molecule expressed on the natural killer (NK) and cytotoxic T cells of the recipient, thus preventing the binding of the Fas molecule on these immune cells to the Fas-ligand on virus-infected cells. Therefore, the infusion of sFasL in transfused blood components may impair the function of NK and cytotoxic T cells in the recipient, thus preventing apoptosis of virus-infected cells.<sup>126,127</sup> Ghio et al<sup>124</sup> and Puppo et al<sup>125</sup> demonstrated the functional capacity of sFasL molecules in stored blood components by culturing Jurkat cells in the presence of plasma supernatant from stored RBCs. Jurkat cells express Fas, and are thus susceptible to the effects of sFasL present in transfused blood components. In this in-vitro experiment, sFasL from the plasma supernatant of stored RBCs triggered apoptosis of the Jurkat cells, which was measured by flow cytometry.

These authors<sup>124,125</sup> also documented the accumulation of soluble HLA Class I molecules in stored RBCs and platelets, although the concentrations achieved were only 4 ng/mL in 30-day stored RBCs and 5-day stored platelets. Furthermore, stored supernatant plasma was shown to exercise an immunosuppressive effect in functional experiments, in that it inhibited the cytotoxic activity of lymphocytes known to be cytotoxic for cells infected with Epstein-Barr virus (EBV). This was not a nonspecific effect, because the cytotoxic activity of lymphocytes was restored after the stored supernatant plasma was depleted of soluble HLA Class I molecules. However, only supernatant plasma from stored non-WBC-reduced (as opposed to WBC-reduced) cellular blood components inhibited the cytotoxic activity of lymphocytes directed against EBV-infected cells. Similarly, prestorage WBC reduction prevented the accumulation of sFasL in stored RBCs.

### Apoptotic WBCs

Innerhofer et al<sup>128,129</sup> reported that impaired proliferative T-cell responses, decreased CD3+ counts, and a state of inappropriate immune activation, along with a diminished cytolytic response, occur even after transfusion of WBC-reduced RBCs containing a median residual WBC count of  $0.03 \times 10^6$  WBCs/unit (ie, a count far below the  $5 \times 10^6$  limit that qualifies a cellular blood component as “WBC-reduced”). If that were the case, it would appear that not only transfused intact, immunologically competent WBCs, but also transfused apoptotic or necrotic WBCs, could be important in provoking TRIM responses. Furthermore, activation of complement components<sup>130</sup> and formation of

anaphylatoxins<sup>131</sup> have also been reported during storage, but their significance in the context of TRIM is uncertain.

### Evidence from Animal Models

If soluble biologic response modifiers and remnants of apoptotic or necrotic WBCs accumulating in blood components during storage were shown to be responsible for some of the adverse TRIM effects of ABT, WBC reduction procedures intended to prevent such TRIM effects should be performed before storage, before WBC deterioration, and before the release of soluble biologic response modifiers from cell membranes or granules (Fig 45-1). The available WBC reduction filters do not retain soluble biologic response modifiers and are also ineffective in removing cell fragments. Therefore, both biologic response modifiers and the remnants of apoptotic or necrotic cells can be expected to persist in a blood component subjected to WBC filtration after storage. The importance of the timing of WBC reduction as regards the TRIM effect has been demonstrated in experimental animals.<sup>132</sup>

Bordin et al<sup>132</sup> showed that ABT promotes growth of established animal tumors and that the tumor-growth promoting effect of ABT can be ameliorated by prestorage (but not by poststorage) WBC reduction. These authors<sup>132</sup> used outbred New Zealand White (NZW) rabbits with established tumors as blood recipients, and outbred California Black rabbits as allogeneic blood donors. “Syngeneic” donor blood was collected from NZW rabbits who were littermates, or siblings, of the transfusion recipients. Non-WBC-reduced allogeneic, poststorage WBC-reduced allogeneic, prestorage WBC-reduced allogeneic, or syngeneic RBCs were transfused on Days 4 and 9 after the infusion of syngeneic epithelial tumor cells. All rabbits were killed 28 days after the infusion of the tumor cells, and the number of pulmonary tumor nodules was counted. Rabbits that received non-WBC-reduced allogeneic, poststorage WBC-reduced allogeneic, prestorage WBC-reduced allogeneic, or syngeneic RBCs had a median of 50.0, 39.0, 20.0, and 17.5 pulmonary nodules, respectively. The difference between non-WBC-reduced allogeneic and prestorage WBC-reduced allogeneic or syngeneic transfusion was highly significant ( $p < 0.0001$ ), but the difference between non-WBC-reduced allogeneic and poststorage WBC-reduced allogeneic transfusion was only marginally significant ( $p = 0.06$ ).

### Evidence from RCTs

With respect to infection, a recent theory<sup>133,134</sup> attributes the purported susceptibility of transfused patients to infection to a sustained inhibition of neutrophil chemotaxis caused by TGF- $\beta$ . TGF- $\beta$  renders neutrophils insensitive to chemotactic stimulation. Inhibition of chemotaxis is caused by both exogenous TGF- $\beta$ , contained in the supernatant of transfused blood components,<sup>133</sup> and endogenous TGF- $\beta$  produced by the recipient's neutrophils in response to sFasL and soluble HLA molecules found in the transfused supernatant.<sup>134</sup>

However, the results of meta-analyses of medically homogeneous subsets of RCTs that reported on postoperative infection

**Figure 45-4.** Risk of postoperative infection after transfusion of prestorage-filtered WBC-reduced RBCs. Randomized controlled trials (RCTs) of ABT and postoperative infection administering prestorage-filtered allogeneic RBCs to the WBC-reduced study arm.<sup>52,58,60,63,66-70</sup> The figure shows the odds ratio (OR) of postoperative infection in recipients of non-WBC-reduced vs WBC-reduced allogeneic RBCs, as calculated from an intention-to-treat analysis of each study; and the summary OR across the depicted RCTs, as calculated from a meta-analysis.<sup>47</sup> A deleterious ABT effect (and thus a benefit from WBC reduction) is demonstrated by an OR >1, provided that the effect is statistically significant ( $p < 0.05$ ; ie, provided that the associated 95% CI does not include the null value of 1).

contradicted the theory that attributes the TRIM effect to WBC-derived soluble mediators that accumulate during storage.<sup>47,48</sup> Across nine RCTs transfusing RBCs WBC-reduced before storage to the WBC-reduced study arm,<sup>52,58,60,63,66-70</sup> no TRIM effect was detected (summary odds ratio, 1.06; 95% CI, 0.91-1.24;  $p > 0.05$ ).<sup>47</sup> If the TRIM effect were mediated by WBC-derived soluble mediators, prestorage filtration should have abrogated an increased infection risk associated with non-WBC-reduced ABT, because it would have removed the allogeneic WBCs from the components given to the WBC-reduced arm of the studies before WBCs could release mediators into the supernatant fluid. Accordingly, a deleterious TRIM effect associated with non-WBC-reduced ABT would have been expected in this analysis, but the meta-analysis detected no such effect (Fig 45-4).

In contrast, across four RCTs<sup>49,54,58,59</sup> that transfused RBCs filtered after storage to the WBC-reduced arm, there was a more than twofold increase in the risk of infection in association with non-WBC-reduced ABT (summary odds ratio, 2.25; 95% CI, 1.12-4.25;  $p < 0.05$ —Fig 45-5). If the TRIM effect were mediated by WBC-derived soluble mediators, poststorage filtration should not have abrogated an increased infection risk associated with

**Figure 45-5.** Risk of postoperative infection after transfusion of poststorage-filtered WBC-reduced RBCs or whole blood. Randomized controlled trials (RCTs) of ABT and postoperative infection administering poststorage-filtered allogeneic RBCs or whole blood to the WBC-reduced study arm.<sup>49,54,58,59</sup> The figure shows the odds ratio (OR) of postoperative infection in recipients of non-WBC-reduced vs WBC-reduced allogeneic RBCs or whole blood, as calculated from an intention-to-treat analysis of each study; and the summary OR across the depicted RCTs, as calculated from a meta-analysis.<sup>47</sup> A deleterious ABT effect (and thus a benefit from WBC reduction) is demonstrated by an OR >1, provided that the effect is statistically significant ( $p < 0.05$ ; ie, provided that the associated 95% CI does not include the null value of 1).

non-WBC-reduced ABT, because it would not have removed such mediators from the supernatant fluid of the stored RBCs given to the WBC-reduced arm of the studies. Thus, the large TRIM effect detected in this analysis (Fig 45-5) may be the result of the inclusion of three early RCTs<sup>49,54,59</sup> that had reported an unusually large TRIM effect.<sup>48</sup> These RCTs involved blood components no longer used in Western Europe or North America (allogeneic whole blood,<sup>49</sup> poststorage-filtered allogeneic whole blood,<sup>49</sup> or poststorage-filtered allogeneic RBCs<sup>54,59</sup>).

### TRIM Effects Mediated by Allogeneic Mononuclear Cells

The only established TRIM effect (ie, the beneficial effect of pre-transplant ABT on renal allograft survival) appears to require viable WBCs. Patients awaiting renal transplantation derive less immunologic benefit from pretransplant RBC transfusions that are WBC-reduced, washed, or frozen-thawed than from

non-WBC-reduced ABT. Mincheff et al<sup>135</sup> implicated the dendritic APCs of the allogeneic donor in the induction of a state of anergy in the recipient, proposing that during refrigeration APCs lose their ability to deliver costimulation. These investigators hypothesized that, following ABT, the recipient's T cells are stimulated by allogeneic donor APCs in the absence of costimulation, and this interaction induces a state of anergy in the recipient's T cells.

### Evidence from Animal Models

Animal data suggest that the TRIM effects are most likely mediated by transfused allogeneic mononuclear cells.<sup>136</sup> Kao<sup>137</sup> induced immune suppression in mice receiving donor WBCs free of plasma and platelets. A recent theory<sup>138</sup> proposes that donor dendritic cells expressing both alloantigen and the OX-2 (CD200) costimulatory molecule are required for the production of the TRIM effect.

CD200 is a transmembrane protein of the immunoglobulin superfamily that is expressed on various cell types, including a subpopulation of dendritic cells and some T and B cells.<sup>139</sup> Its receptor (CD200R or OX-2R) appears only on myeloid dendritic cells and some T cells. The interaction between CD200 and its receptor provokes a tolerance signal that leads to suppression of classical T-cell-mediated responses and the generation of  $\gamma\delta$ -suppressor T cells. Thus, CD200-deficient mice have reduced ability to downregulate activation of APCs. The absence of downregulatory signals in such mice results in exaggerated inflammatory responses and increased susceptibility to autoimmune encephalitis and collagen-induced arthritis. The interaction between CD200 and its receptor suppresses macrophage function, prolongs allograft survival, and prevents allogeneic fetal loss in a mouse model of cytokine-triggered abortions.<sup>140</sup>

Clark et al<sup>138</sup> demonstrated ABT-induced tumor growth in a murine model that employed BALB/c mice as allogeneic donors and C57Bl/6 mice as blood recipients. The recipient mice received a tail vein injection of syngeneic FSL10 fibrosarcoma cells, followed by transfusion of 50 to 200  $\mu$ L of allogeneic blood. Pulmonary tumor nodules were counted 3 weeks after the FSL10 cell infusion. There was a dose-response relationship between the volume of transfused allogeneic blood and the number of pulmonary tumor nodules, along with proliferation of TGF- $\beta$ -positive suppressor T cells in the spleen.

The tumor-growth-promoting effect of ABT was mediated by donor myeloid dendritic cells that expressed both CD11c and CD200 on their surface, because it could be blocked by monoclonal antibodies to either CD11c or CD200. (The effect could not be blocked by antibodies to CD200R, or by antibodies to other molecules participating in these interactions, an observation that implicated the subset of donor myeloid dendritic cells expressing both CD11c and CD200 in the pathogenesis of TRIM.) The interaction between the donor CD200 and its receptor on the recipient's T cells induced proliferation of  $\gamma\delta$ -suppressor T cells that released cytokines, especially TGF- $\beta$ . Physiologic concentrations of TGF- $\beta$  stimulated proliferation of FSL10 fibrosarcoma cells in vitro. Because TGF- $\beta$  can also suppress host

defenses against infectious agents,<sup>141</sup> it could be the basis of the TRIM effect with regard to both postoperative infections and tumor growth, at least as regards sarcomas.

Bordin and Blajchman<sup>142</sup> reviewed the findings of animal models of ABT and cancer recurrence and reported that 17 published models had found stimulation of tumor growth by ABT, as compared with three models that had reported inhibition of tumor growth and four models that had found no effect. Data from both inbred and outbred animal models have indicated that ABT accelerates tumor growth and enhances formation of metastatic nodules.<sup>132,143-146</sup> Allogeneically transfused mice inoculated intramuscularly with either syngeneic malignant melanoma (B16) or mastocytoma (P815) cells developed larger tumors than did syngeneically transfused mice.<sup>143</sup> Similar results were obtained when syngeneic B16 tumor cells were infused intravenously and the numbers of pulmonary nodules enumerated.<sup>143,144</sup> Experiments performed to investigate the effect of the tumor-cell dose showed that the ABT effect was only evident when small numbers ( $1.25\text{--}2.5 \times 10^5$ ) of tumor cells were inoculated into the host animal. The effect was not evident when large numbers of tumor cells were inoculated, suggesting that the tumor burden had a strong bearing on whether the ABT effect became manifest.

The influence of the timing of ABT in enhancing pulmonary-nodule formation has also been examined. Studies in both inbred (mice) and outbred (rabbits) animals have shown that ABT has a tumor-growth-promoting effect when administered before the infusion of syngeneic tumor cells.<sup>132,145</sup> In the murine model, male C57Bl/6J mice (MHC type H-2b) were blood recipients; Balb/c mice (MHC type H-2d) were allogeneic donors; and the tumor cells were syngeneic (H-2b) methylcholanthrene-induced fibrosarcoma cells.<sup>145</sup> As already discussed, to better replicate the situation seen clinically, the enhancement of tumor growth by ABT has been investigated in animals (mice and rabbits) that received such syngeneic and allogeneic transfusions subsequent to the inoculation of the tumor cells, and the data indicated that ABT enhanced tumor growth also in animals with established tumors.<sup>132</sup> Using inbred animals (mice) only, another series of investigations provided similar evidence indicating that ABT given after tumor-cell engraftment enhanced tumor growth.<sup>146</sup> It was also shown that animals with either nonestablished or established tumors receiving non-WBC-reduced ABT developed significantly larger numbers of pulmonary nodules than did animals given WBC-reduced ABT.<sup>132,145</sup>

Finally, the tumor-growth-promoting effect of ABT can be adoptively transferred to naive animals by spleen cells harvested from allogeneically transfused animals.<sup>145</sup> In these experiments, the number of pulmonary nodules observed in animals that had received spleen cells from allogeneically transfused animals was significantly higher than that observed in animals that had received spleen cells from animals transfused with syngeneic blood. However, the ABT effect could not be adoptively transferred to naive animals that received spleen cells derived from animals transfused with prestorage-WBC-reduced allogeneic blood.

The clonal deletion seen in recipients of ABT refers to the removal of lymphocytes that promote the clearance of transfused alloantigens. Interactions between Fas and FasL are involved in the clonal deletion of T cells and the downregulation of cytotoxic T-cell activity. In a murine model, Hashimoto et al<sup>147</sup> investigated the possibility of splenic-lymphocyte deletion secondary to ABT-related augmentation of apoptosis. These investigators demonstrated that non-WBC-reduced ABT upregulated the expression of Fas and FasL on CD4+ as well as CD8+ splenic T cells and could thereby promote their apoptosis. The ABT-related immune alterations could be partially prevented by WBC reduction of the transfused blood, as CD8+ splenic cells from mice receiving non-WBC-reduced ABT showed higher expression of Fas and FasL than cells from mice receiving WBC-reduced ABT.

The data regarding the TRIM effect and infection in animal models are contradictory. Moreover, a variety of experimental conditions such as anesthesia, shock, trauma, type of surgery, blood volume, as well as timing and transfusion frequency have all been reported to have an impact on the results.<sup>148-152</sup> In a series of studies in experimental animal, Waymack et al<sup>148-151</sup> have demonstrated that allogeneically transfused animals had immune impairment and a poorer response to a septic challenge than did syngeneically transfused animals. In a burn model, these investigators observed that rats given ABT had higher mortality than did rats given syngeneic blood or saline.<sup>152</sup> In a rat bacterial-peritonitis model, a significant adverse effect on survival was associated with ABT.<sup>149</sup> In another study, ABT was associated with marked immune impairment to a bacterial challenge immediately after the transfusion.<sup>153</sup>

Moreover, ABT and, in particular, transfused allogeneic WBCs adversely affected host resistance to a gut-derived infection with *Escherichia coli* in a murine model.<sup>154</sup> In addition, in a cecal ligation and puncture murine model, ABT greatly increased susceptibility to infection. These studies also indicated that spleen cells of allogeneically transfused mice produced increased quantities of the Th-2 cytokines (IL-4 and IL-10 and lesser amounts of IL-2), probably leading to increased antibody production and a decreased cell-mediated response.<sup>155</sup> In contrast, in murine experiments using a bacterial-peritonitis model that compared syngeneic with allogeneic transfusion, the latter was shown not to influence overall survival of animals challenged with *E. coli*.<sup>156</sup> Similarly, while a clear negative effect of shock was detected, no adverse effect of transfusions, either syngeneic or allogeneic, was observed in a rat model.<sup>157</sup>

### Microchimerism

HLA compatibility between donor and recipient may result in the persistence of allogeneic donor WBCs, including dendritic APCs, in the recipient. Such long-term engraftment and survival of small numbers of donor cells (microchimerism) has been proposed as a possible mechanism of TRIM.<sup>158</sup> Microchimerism could cause the downregulation of the recipient's immune response, resulting in tolerance to donor alloantigens and allograft survival. Microchimerism results in the release of IL-4,

IL-10, and TGF- $\beta$  from T-helper type 2 (Th-2) lymphocytes.<sup>159</sup> These cytokines have been shown to inhibit the production of T-helper type 1 (Th-1) cells and to deactivate cytotoxic T cells, thereby suppressing allograft rejection. Along similar lines, ABT was shown to cause a shift in peripheral T-cell cytokine secretion toward that of the Th-2 phenotype, and to downregulate Th-1 cytokine secretion. Impairment of Th-1 cytokine secretion results in impairment of various functions of cellular immunity (including antigen processing, macrophage activation, the T-cell cytotoxic function, and the neutrophil and monocyte cytotoxic activity) that are supported by Th-1 cytokines, such as IL-2, IL-12, and interferon- $\gamma$ .<sup>160</sup>

In 1995, Lee et al<sup>161</sup> employed quantitative allele-specific polymerase chain reaction methods to demonstrate a thousand-fold expansion of allogeneic donor WBCs in the recipient's circulation 3 to 5 days following transfusion in otherwise healthy adults undergoing elective orthopedic surgery. The allogeneic WBCs were cleared from the circulation within 2 weeks. The finding was verified in a canine transfusion model and—as expected—irradiation of blood products abrogated the allogeneic donor WBC expansion phase. However, in 1999, the same group documented high-level and long-lasting WBC microchimerism among selected victims of traumatic injury who had received a large number of very fresh units of blood during resuscitation.<sup>162</sup> In some of these trauma patients, up to 3% to 4% of circulating WBCs were of donor origin as long as 2 years following transfusion. Analysis of lymphocyte subsets using immunomagnetic bead enrichment showed that both lymphoid and myeloid lineages were represented.

Long-term transfusion-associated microchimerism appears to be a common, albeit only recently recognized, complication of ABT<sup>163</sup> that has hitherto been demonstrated only in trauma patients.<sup>162</sup> Injury produces an immunosuppressive and inflammatory milieu in which very fresh blood components, containing WBCs capable of replication, are often transfused in large quantities. Transfusion-associated microchimerism is present in approximately half of transfused, severely injured patients at hospital discharge.<sup>163</sup> In approximately 10% of the patients, the chimerism associated with a single blood donor may increase in magnitude over months to years, representing up to 2% to 5% of circulating WBCs.<sup>162,163</sup> Nonetheless, in other patient populations, such as those infected with HIV, ABT-induced microchimerism appears to be transient.<sup>164</sup>

If microchimerism does lead to the downregulation of the host's immune response, it is important to note that microchimerism is detected also following administration of WBC-reduced allogeneic RBCs.<sup>165</sup> Utter et al<sup>166</sup> examined a subgroup of the trauma patients enrolled in the RCT of Nathens et al<sup>70</sup> that had randomly assigned patients to receive non-WBC-reduced or WBC-reduced allogeneic RBCs filtered before storage. Nine of 32 (28%) patients in the non-WBC-reduced group developed microchimerism, as compared with 13 of 35 (37%) patients in the WBC-reduced group ( $p = 0.43$ ).<sup>166</sup> Several months after the transfusion, subjects with transfusion-associated

microchimerism were no more likely than subjects without transfusion-associated microchimerism to have at least one symptom suggestive of chronic graft-vs-host disease (64% vs 76%, respectively), indicating that transfusion-associated microchimerism is prevalent in this patient population but unlikely to be associated with symptoms.<sup>166</sup>

Similarly, Fresland et al<sup>167</sup> reported that microchimerism after ABT could be induced by transfusion of RBCs that were WBC-reduced by prestorage filtration. Moreover, in that study,<sup>167</sup> microchimerism was not dose dependent, and it could be induced even by RBC units that had been stored for more than 3 weeks.

### Evidence from RCTs

The authors know of only one RCT<sup>62</sup> that had been specifically designed to test a possible TRIM effect of allogeneic mononuclear cells. The Viral Activation Transfusion Study (VATS)<sup>62</sup> transfused unmodified allogeneic RBCs stored for <2 weeks (and thus containing relatively undamaged allogeneic mononuclear cells) to the non-WBC-reduced arm. Also, the two study arms were controlled for comparable duration of storage of the transfused RBCs. There was no difference between the study arms in the HIV or CMV viral load or the length of survival. Median survival was 13.0 months in recipients of prestorage-filtered allogeneic RBCs, as compared with 20.5 months in recipients of non-buffy-coat-reduced allogeneic RBCs ( $p = 0.12$ ). Thus, the VATS results have impugned the theory attributing the TRIM effect to allogeneic mononuclear cells. It should be noted, however, that no other RCT transfusing fresh components to the non-WBC-reduced study arm has been reported, and the effect of fresh components has not been studied in the context of more “traditional” TRIM effects (ie, cancer recurrence or postoperative infection).

Despite the convincing evidence provided by animal models for a relationship between transfusion of allogeneic mononuclear cells and tumor recurrence, no RCT of ABT and cancer recurrence has transfused fresh non-WBC-reduced RBCs to the non-WBC-reduced study arm to test for the effect of immunologically competent allogeneic mononuclear cells seen in animal models. Moreover, no RCT of ABT and cancer recurrence has enrolled patients with sarcomas—tumors whose growth is stimulated by TGF- $\beta$ <sup>138</sup>—or patients with tumors for which the immune response plays a major role. (These include skin tumors—such as melanomas, keratoacanthomas, squamous and basal-cell carcinomas—and certain virus-induced tumors—notably Kaposi’s sarcoma and certain lymphomas.<sup>168</sup>) Instead, the three available RCTs<sup>50,52,71</sup> of ABT and cancer recurrence enrolled patients with colorectal cancer—a tumor that is not sufficiently antigenic to render an impairment of the host’s immunity capable of facilitating tumor growth, and whose cells have not been shown to be stimulated by TGF- $\beta$ .

Thus, these three RCTs<sup>50,52,71</sup> permit very limited inference with regard to the biologic significance of the TRIM mediators discussed in this chapter. No adverse TRIM effect of ABT on cancer recurrence is detected across the three

**Figure 45-6.** Cancer recurrence after transfusion. Randomized controlled trials (RCTs) investigating the association of non-WBC-reduced allogeneic blood transfusion (ABT) with cancer recurrence.<sup>50,52,71</sup> For each RCT, the figure shows the odds ratio (OR) of cancer recurrence in recipients of non-WBC-reduced vs WBC-reduced allogeneic or autologous RBCs or whole blood, as calculated from an intention-to-treat analysis; and the summary OR across the depicted RCTs, as calculated from a meta-analysis.<sup>167</sup> Each OR is surrounded by its 95% confidence interval (CI). A deleterious effect of ABT (and thus a benefit from autologous transfusion or WBC reduction) is demonstrated by an OR > 1, provided that the effect is statistically significant ( $p < 0.05$ ; ie, provided that the associated 95% CI does not include the null value of 1).

studies (Fig 45-6). The summary odds ratio of cancer recurrence in recipients of non-WBC-reduced allogeneic compared with autologous or WBC-reduced allogeneic RBCs is 1.04 (95% CI, 0.81-1.35;  $p > 0.05$ ).<sup>169</sup>

### Summary and Conclusions

TRIM encompasses the laboratory immune aberrations that occur after ABT (Table 45-1) and their established or purported clinical effects. TRIM is a real biologic phenomenon resulting in at least one established beneficial clinical effect in humans (the enhanced survival of renal allografts), but the existence of deleterious clinical TRIM effects has not yet been confirmed. Initially, TRIM encompassed effects attributable to ABT by immunomodulatory mechanisms (eg, cancer recurrence, postoperative infection, or virus activation); more recently, TRIM has also included effects attributable to ABT by proinflammatory mechanisms (eg, multiple-organ failure or mortality).

The mechanism(s) of the TRIM effect(s) remain(s) elusive, and it is possible that a large number of biologic mechanisms may underlie these effect(s). The infusion of foreign antigen in either soluble or cell-associated form has been shown to induce immune suppression and anergy, as well as clonal deletion in studies in experimental animals. However, most studies evaluating proposed mechanisms have been conducted in rodents, and the findings may not be applicable to the human immune system.<sup>170</sup> Dzik<sup>171</sup> suggested that there may be two categories of a TRIM effect: one that is HLA-dependent and directed against adaptive immunity and another that is nonspecific and directed against innate immunity. The nonspecific effect might result from the infusion of WBCs that undergo apoptosis during refrigerated storage. Immunosuppression resulting from the infusion of apoptotic cells may be linked to TGF- $\beta$ .

Support for the theory that TRIM is caused by the allogeneic WBCs has come mainly from data from animal models. These have shown that animals receiving allogeneic buffy-coat leukocytes develop significantly more pulmonary tumor nodules than do animals given either plasma or prestorage-WBC-reduced whole blood.<sup>132</sup> It is possible that prestorage WBC reduction may prevent the accumulation of soluble mediators that are actively synthesized and released by WBCs during RBC storage, and that such WBC-derived soluble mediators are involved in the immunomodulation observed following ABT. However, storage lesions of RBCs and platelets occur even when the units have been WBC-reduced before storage (WBC removal only slightly improves these storage lesions—see Chapters 4 and 12).

The totality of the evidence from RCTs does not demonstrate the kind of deleterious TRIM effect that would justify universal WBC reduction specifically for prevention of this effect (ie, a TRIM effect manifest across all clinical settings and transfused RBC products), although universal WBC reduction may be justified on the basis of other WBC-related adverse effects.<sup>136</sup> Non-WBC-reduced ABT is associated with an increased risk of short-term (up to 3 months after transfusion) mortality from all causes specifically in cardiac surgery. Even in this setting, the reasons for the excess deaths attributed to non-WBC-reduced ABT remain elusive. The initial hypothesis suggested that non-WBC-reduced ABT may predispose to MOF which, in turn, may predispose to mortality.<sup>58</sup> However, no cardiac-surgery RCT has demonstrated an association between non-WBC-reduced ABT and MOF.

The TRIM effect seen in cardiac surgery deserves further study to pinpoint the cause(s) of the excess deaths, but—now that the majority of transfusions in Western Europe and North America are WBC-reduced—the undertaking of further RCTs comparing recipients of non-WBC-reduced vs WBC-reduced RBCs in cardiac surgery is difficult. Until further studies are conducted, whether to opt for WBC reduction of all cellular blood components transfused in cardiac surgery (in the absence of information on the specific cause or causes of death that can be ascribed to non-WBC-reduced ABT) is a policy decision that will have to be made on the basis of available data (Fig 45-3). The authors believe that WBC reduction of all cellular blood

components transfused in cardiac surgery is appropriate based on the accumulated evidence.

It must be emphasized that, at least in the case of some adverse TRIM effects, the evidence for the existence of such effects may not be available because the requisite studies have not been conducted. An effect of the transfusion of allogeneic mononuclear cells would be expected to occur on tumor recurrence for example, based on the convincing findings from experimental animals. However, no available RCT has transfused fresh non-WBC-reduced RBCs to the non-WBC-reduced study arm to specifically study the effect of allogeneic mononuclear cells. Moreover, no available RCT has enrolled patients with a tumor whose growth would be expected to be stimulated by ABT. A possible adverse TRIM effect of allogeneic mononuclear cells has similarly not been adequately investigated in the areas of postoperative infection and mortality.

Indeed, in many cases, the preclinical studies were conducted and the hypotheses about mechanisms formulated after clinical studies (including RCTs) had already presented data-derived hypotheses to account for unexpected ABT effects. Because it has not been possible to conduct further RCTs after the hypotheses about TRIM mediators (Fig 45-1) were crystallized, whether some adverse TRIM effects exist (or not) in humans may remain a mystery. Moreover, it is possible that the available RCTs have targeted outcomes that did not capture the true nature of the ABT effect. If this effect were “proinflammatory” rather than “immunomodulatory,” it would have been expected to result not in clinical impairment of the recipient’s immunity, but in multiple-organ dysfunction. MOF and related outcomes were not studied in most completed RCTs.

New data continue to appear,<sup>172-177</sup> and the controversy on the purported deleterious TRIM effects continues to persist.<sup>45-48,178-182</sup> Because the use of WBC-reduced allogeneic RBCs and platelets is becoming widespread, the opportunity to conduct RCTs to establish the existence of adverse TRIM effects mediated by allogeneic WBCs is removed. Despite the widespread acceptance of WBC reduction as a standard of care in many countries, however, it remains unclear whether deleterious clinical TRIM effects of ABT truly exist, and—in the event that they do—whether they are mediated, directly or indirectly, by allogeneic WBCs. The uncertainties and hypotheses discussed here underline the need for further research!

## Transfusion-Transmitted Hepatitis

**Harvey J. Alter<sup>1</sup> & Juan I. Esteban-Mur<sup>2</sup>**<sup>1</sup>Chief, Clinical Studies, and Associate Director for Research and Department of Transfusion Medicine, Warren Grant Magnuson Clinical Center, National Institutes of Health, Bethesda, Maryland, USA<sup>2</sup>Section Head, Liver Unit, Department of Medicine, Hospital Universitari Vall d'Hebron, Universitat Autònoma de Barcelona, Centro de Investigaciones Biomédicas en Red (Ciberehd), Instituto de Salud Carlos III, Barcelona, Spain

Hepatitis B virus (HBV) infection, originally called serum hepatitis, was definitively shown to be a serious, and sometimes fatal complication of blood transfusion when unscreened blood and plasma were massively transfused during World War II. Despite this clinical recognition, little was known of the causative agent until the 1960s when the serendipitous finding of an antigen in the serum of an Australian aborigine (Australia antigen)<sup>1</sup> ultimately led to the linkage of this antigen to human hepatitis.<sup>2</sup> Further investigation revealed that the Australia antigen represented the surface protein of a viral particle (Dane particle) that was later shown to be the hepatitis B virion. Once this relationship was understood, the Australia antigen was renamed the hepatitis B surface antigen (HBsAg) and tests to detect this antigen in blood donors were introduced in the United States in 1970. This screening measure, plus the universal adoption of an all volunteer donor system, resulted in a near 70% reduction in total posttransfusion hepatitis and a greater than 85% reduction in transfusion-associated hepatitis B.<sup>3</sup> Improvements in test sensitivity for HBsAg and the addition of screening assays for the detection of antibody to the hepatitis B core (nucleocapsid) protein (anti-HBc) in 1987 further reduced transfusion-associated hepatitis B to a calculated incidence of approximately one infection in every 150,000 transfusions. Rarely do these infections result in clinical disease and  $\geq 95\%$  of HBV infections in adults are spontaneously cleared. Hence, the current disease burden of transfusion-transmitted hepatitis B infection is very small.

Following the development of assays for HBsAg detection, it became apparent that HBV was not the primary causative agent of transfusion-associated hepatitis (TAH) and that some additional agent or agents accounted for at least 75% of cases.<sup>4</sup> It was initially thought that some or all of these non-B cases might be caused by the hepatitis A virus (HAV), the only other human hepatitis virus known at that time. However, HAV was definitively

identified in 1973<sup>5</sup> and when prospectively followed non-B hepatitis cases were retrospectively tested for antibody seroconversion to HAV, it was shown that none were HAV related. Thus, it became apparent that there was a third human hepatitis virus and this received the exclusionary designation, the non-A, non-B (NANB) agent, pending its further characterization. Although the NANB agent was shown to be transmissible to chimpanzees and was partially characterized in that model, it took more than a decade before the true nature of the NANB agent was revealed by the sophisticated approaches of the emerging field of molecular biology. In 1988, Houghton and coworkers at Chiron Corporation cloned the primary agent of NANB hepatitis, unraveled its molecular sequence, and expressed epitopes that now serve as the basis for highly specific serologic assays routinely used for blood donor screening.<sup>6</sup> The NANB agent was then renamed the hepatitis C virus (HCV) and was found responsible for at least 90% of cases of TAH.<sup>7</sup> The introduction of screening assays to detect antibody to HCV and subsequently the detection of amplified HCV RNA has resulted in a dramatic reduction in the incidence of transfusion-associated hepatitis C that is now calculated to be approximately one infection per 1.5 to 2.0 million transfusions.<sup>8</sup> In addition, virus inactivation procedures for pooled plasma products, including clotting factor concentrates, has rendered these formerly high-risk products virtually hepatitis-free. Efforts are now under way to develop virus inactivation procedures for cellular blood components. Although this will be more difficult, such an accomplishment would presage the end of TAH, as well as many other transfusion-transmitted infections.

**Incidence of Transfusion-Associated Hepatitis**

The incidence of TAH in the United States was formerly based on data from prospective studies, but as the incidence decreased to rates less than 1%, it became logistically and economically unfeasible to conduct prospective studies with sufficiently large numbers of subjects to achieve a statistically valid incidence. The incidence of TAH is now derived from mathematical modeling

based on 1) the incidence of HBV and HCV infections among repeat blood donors and estimates of the window period between exposure to these agents and the first detectable marker of infection in recipients (incidence-window period model) or 2) the yield of new infections based on detection of nucleic acid in the absence of antibody [nucleic acid amplification test (NAT)-yield model]. The need to utilize mathematical models is a reflection of the success of blood bank programs in interdicting donors with high-risk behavior and in detecting those with serologic or molecular markers of hepatitis virus infection.

Before mathematical modeling, determination of the incidence of TAH required prospective studies to detect biochemical evidence of liver disease because 75% of cases of TAH are clinically inapparent and because fewer than 10% of overt cases are reported to the transfusion service. Before 1970, a prospective study of patients undergoing open-heart surgery at the National Institutes of Health (NIH)<sup>9</sup> showed that the incidence of TAH exceeded 30%. The introduction of an all-volunteer donor system and first-generation assays for HBsAg dramatically reduced the incidence of TAH to the range of 10% to 12%.<sup>3</sup> That incidence persisted through the 1970s despite increasingly sensitive tests for HBsAg, but declined from 10% to 6% from 1980 to 1987.<sup>9</sup> By 1989, the cumulative effect of more stringent donor questioning regarding high-risk behaviors, the introduction of human immunodeficiency virus (HIV) and anti-HBc assays as surrogate markers for NANB hepatitis, the routine virus inactivation of plasma products, and the more judicious use of blood in the wake of the AIDS epidemic served to decrease the incidence of TAH to approximately 4%. The introduction of specific anti-HCV assays in 1990 led to a further marked decline in the incidence of TAH to approximately 1%.<sup>9</sup> Testing of stored donor and recipient serum revealed that first-generation anti-HCV assays could have prevented 80% of cases of TAH that occurred before 1990 and that second-generation assays, introduced in 1992, could have prevented 90% of cases.<sup>7</sup> On the basis of the prevalence of HCV in the donor population just before anti-HCV testing, it is estimated that the introduction of serologic tests for anti-HCV prevented 40,500 cases of TAH per year (111 cases per day) in the United States alone.

Mathematical modeling conducted before the implementation of routine NAT testing of donor blood estimated the risk of HCV transmission to be 1 case per 100,000 transfusions and the risk of HBV transmission to range from 1 in 65,000 to 1 in 150,000 transfusions.<sup>8</sup> After the implementation of minipool (MP)-NAT testing, the calculated risk of HCV infection was reduced to 1 in 1.5 million transfusions.<sup>8</sup> Individual donor (ID)-NAT testing could decrease that risk further, but the benefit would be marginal given the already low frequency with minipool donor testing. The current risk of transfusion-transmitted HBV infection is still calculated to be relatively high (approximately 1:150,000 to 1:175,000), but that is based on anti-HBc seroconversions and an adjustment for missed HBsAg detection and does not represent clinical or even biochemical hepatitis.<sup>8</sup> Actual transfusion-associated hepatitis B cases appear to be quite

rare. Nucleic acid testing for HBV has not been implemented as of this writing, but individual NAT for HBV would decrease the current seronegative window by 7 to 25 days, depending on the sensitivity of the HBsAg assay, and might bring the risk of HBV infection into the same range as the risk of HCV infection.<sup>8</sup> Blood transmission of hepatitis A or hepatitis E in the developed world is so rare as to be reportable. It is still unclear whether there is a human hepatitis beyond the identified agents for hepatitis A to E. This is addressed later in this chapter.

## Hepatitis B Virus

### Historical Perspective

The first reported outbreak of percutaneously transmitted hepatitis was described more than a century ago, when 15% of German dockyard workers developed jaundice after smallpox vaccination with lymph derived from convalescent persons.<sup>10</sup> Although HCV cannot be excluded, the most likely responsible agent was HBV. However, HBV infection probably has afflicted humankind since ancient times, judging by the extraordinary prevalence of the virus in Asia and Africa, where it has been perpetuated by perinatal and percutaneous transmission.

In the third and fourth decades of the last century, with the widespread use of syringes, percutaneous spread of viral hepatitis regained notoriety. Reports followed describing jaundice among persons attending venereal disease<sup>11</sup> and arthritis<sup>12</sup> clinics. Because the disease seemed to be associated with the sharing of inadequately sterilized needles, it became known as “postinoculation jaundice.” Further support for a link between needle exposure and infection came from reports of severe hepatitis among children and British troops inoculated with convalescent measles and mumps sera<sup>13,14</sup> and among recipients of yellow fever vaccine.<sup>15,16</sup>

During World War II, viral hepatitis research increased dramatically. Not only was “epidemic” hepatitis once again found to be common, but also the widespread use of blood transfusion led to the emergence of TAH first reported in 1943.<sup>17,18</sup> Subsequent investigations, including experimental human transmission studies, initially pointed to the existence of two viruses, with different modes of transmission, incubation periods, severity, and outcome.<sup>19-21</sup> Hepatitis B virus was held responsible for all cases of hepatitis following transfusion (“serum hepatitis” or “post-transfusion hepatitis”). The current terminology, *hepatitis B*, was proposed in the late 1940s and adopted by the World Health Organization (WHO) in the mid-1970s.

Proof that HBsAg was associated with a transmissible infectious agent came from the earliest studies, employing an insensitive immunodiffusion test.<sup>22</sup> Approximately 75% of recipients of HBsAg-positive donor blood were found to have either hepatitis or serologic markers of HBV infection, although hepatitis also was noted in recipients of HBsAg-negative donor blood. Testing for HBsAg evolved from agar gel diffusion to counter-electrophoresis, to radioimmunoassay and finally, to enzyme

immunoassay (EIA). Testing of all blood donations for this serum marker was made mandatory by federal regulation in July 1972 and third-generation HBsAg testing was mandated in 1975.

Prospective studies of TAH conducted during the 1980s and 1990s in the Far and Middle East, Europe, Canada, and Australia<sup>23-27</sup> showed that despite hepatitis frequencies ranging from 3% to 19%, few cases could be attributed to HBV. In the majority of studies, no cases of hepatitis B were identified, and hepatitis B accounted for 7% or fewer of total cases in three studies.<sup>23,26,28</sup> Widespread implementation of more sensitive assays for HBsAg and adoption of all-volunteer donor programs in developed countries has virtually eliminated clinically significant transfusion-associated hepatitis B.

## Molecular Virology

Hepatitis B virus is a 42-nm DNA virus composed of an outer shell (7 nm in width) and an inner core (27 nm in diameter). It belongs to a novel genus, *Hepadnavirus*, within the *Hepadnaviridae* family; HBV is designated hepadnavirus type 1. The outer coat material (or envelope), is composed of three virus-encoded polypeptides, collectively designated the hepatitis B surface antigen, and host-derived lipid components. The HBV envelope proteins can be detected in serum, not only as a part of the intact virus, but also as separate 22-nm spherical or tubular subvirus particles, that circulate in amounts that outnumber complete HBV particles by a factor of  $>10^4$ , that do not contain DNA, and that are highly immunogenic, but noninfectious. They, in fact, constituted the source for the first generation of plasma-derived HBV vaccines. Clinically, HBsAg is detected in serum by serologic assays, visualized in the cytoplasm of hepatocytes by electron microscopy, and identified in liver tissue of infected persons by its ground-glass appearance and by antigen-specific immunohistochemical staining.

The inner icosahedral nucleocapsid core of HBV is composed of the nucleocapsid protein known as the hepatitis B core antigen (HBcAg), the viral genome, and the viral DNA polymerase. The genome of HBV is a relaxed circular, partially double-stranded DNA, with a complete negative DNA strand (3200 nucleotides) and an incomplete positive DNA strand. The genomic information of the virus, present on the long strand of the DNA, comprises four highly overlapping (67%) open reading frames (referred to as *S*, *C*, *P*, and *X* genes), encoding the envelope (pre-S/S), core (pre-core/core), polymerase, and X proteins, respectively (Fig 46-1).

The *S* gene has three in-frame start codons and a common stop codon, dividing the gene into the preS1, preS2, and *S* regions encoding the *large* (L), *middle* (M), and *small* (S) envelope proteins, respectively, depending on where translation is initiated. The product of the *S* region is the HBsAg (major protein).<sup>29</sup> The M and S envelope proteins are found in both virions and subvirus particles, whereas the L proteins are found mostly in complete virions.

The *C* gene has two in-frame start codons. The core protein (HBcAg) is translated from the second start codon and expressed on the surface of the nucleocapsid. Translation from the precore

start codon produces a precore polypeptide that is posttranslationally cleaved into a soluble nonparticulate protein known as the hepatitis B e antigen (HBeAg).

The *P* gene, which encompasses 80% of the viral genome, encodes a single multifunctional protein with four distinct domains: a protein primer, a spacer, a reverse transcriptase (RT)/DNA polymerase, and an RNase H domain.

The *X* gene encodes a multifunctional transactivator of transcription (HBxAg), of both viral and cellular genes.<sup>30,31</sup> It has pleiotropic effects on the transcriptome of the infected cell, including signaling pathways, protein degradation, cell cycle checkpoints, cell death, and carcinogenesis.<sup>30</sup>

The HBV genome contains four promoters (preS1, preS2/S, C and X) that control transcription by the cell RNA polymerase II of six functionally co-terminal viral mRNAs.<sup>32</sup> The C promoter has a basic core promoter (BCP) sequence that acts as a binding site for a variety of cellular transcription factors (ie, HNF3, HNF4, SP1).<sup>33,34</sup>

HBV infects hepatocytes by binding a domain in the large surface protein to an unknown receptor and enters the cytoplasm by endocytosis. Once delivered to the nucleus, the plus-strand DNA is completed by the DNA polymerase and the HBV genome is converted into a covalently closed circular DNA (cccDNA) that acts as the template for transcription of five viral RNAs. These comprise two 3.5 kb precore (translated into the precore polypeptide, which is further processed at both ends to the HBeAg) and pregenomic RNAs, two 2.4 and 2.1 kb mRNAs for the surface proteins and a 0.7 kb mRNA for the X protein.

The pregenomic RNA, which functions as the messenger RNA for translation of the HBcAg and the polymerase, is also the template for reverse transcription. A stem-loop near the 5' end of the pregenomic RNA contains a packaging signal ( $\epsilon$ ) and is used by the RT domain of the viral polymerase to prime minus-strand DNA synthesis with concomitant packaging by the nucleocapsid protein into immature cores. Inside the immature cores, a new minus-strand HBV DNA is produced through reverse transcription of the pregenome followed by the synthesis of a new plus-strand DNA. Maturation of the nucleocapsid before plus-strand synthesis is complete results in the partially double-stranded genome.

The cccDNA persists as a stable chromatinized episome in the cell nuclei, appears to have a very long half-life, and is very resistant to antiviral therapy. Its stability along with the long half-life of hepatocytes implies that once HBV infection has occurred it may continue for life, even after apparent resolution.<sup>35</sup>

## Genetic Variation of HBV

HBV can be classified into eight genotypes (A to H) based upon an inter-group divergence of  $\geq 8\%$  in the complete nucleotide sequence.<sup>36</sup> There is growing evidence suggesting that HBV genotypes influence clinical outcomes, HBeAg seroconversion rates, mutational patterns in the precore and core promoter regions, and response to antiviral therapy.<sup>37,38</sup> The prevalence of specific genotypes varies geographically, with genotype A found mainly

**Figure 46-1.** Genomic structure and translated proteins of HBV. The inner circles represent the full-length minus-strand DNA, with the terminal protein attached to its 5' end, and the incomplete plus-strand DNA of the HBV genome. The shaded lines represent the four overlapping open reading frames (ORF) S, C, P, and X and their corresponding encoded proteins and detailed structure of the main HBV antigens encoded (HBcAg, HBeAg, and HBsAg). The outermost thin black lines represent the 3.5, 2.4, 2.1, and 0.7 kb mRNA transcripts, which are all terminated near the poly-A signal. Details of the HBcAg dimers that assemble into the inner core and the structure of the HBsAg domain, common to all HBV surface proteins, containing the main "a" are also shown (see also text).

in Northern Europe, North America, India, and Africa; genotypes B and C in Asia; and genotype D in Southern Europe, the Middle East, and India. All known genotypes have been found in the United States, with prevalence of genotypes A, B, C, and D of 35%, 22%, 31%, and 10%, respectively, while genotypes E to H represent 2%.<sup>39</sup>

The HBV viral polymerase lacks proofreading activity, resulting in an estimated error rate of  $10^{-4}$  to  $10^{-5}$  nucleotide substitutions per site/year. Combined with a high turnover rate (up to  $10^{11}$  virions/day), this leads to the accumulation of a swarm of closely related genomic sequences, referred to as quasispecies. Although mutations occur randomly along the genome, the overlapping open reading frames limit the number and location of viable mutations.<sup>40-42</sup> Mutants may become selected according to their relative fitness when environmental conditions change

[ie, during antiviral treatment or hepatitis B immune globulin (HBIG) prophylaxis]. Most common and clinically relevant HBV mutants have been well characterized and affect the precore/core promoter, preS/S, and polymerase genes.<sup>40</sup>

#### Precore and Core Promoter Variants

HBeAg, which is not required for virus replication, seems to act as a decoy for the immune system, inducing tolerance. Viral clearance is usually associated with decreased HBeAg production followed by seroconversion to anti-HBe. However, documented severe liver disease in anti-HBe-positive patients with chronic hepatitis B (CHB), (HBeAg-negative CHB), led to the recognition of mutations in the precore region that prevent HBeAg synthesis. By far the most common of these mutations is a transition (G1896A), that creates a stop codon blocking translation of the

precore protein and HBeAg production. Less frequently, point mutations in the start codon can also abrogate HBeAg production. In the United States, precore variants have been found in 27% of patients with chronic HBV infection.<sup>39</sup> The most common core promoter variant involves a dual mutation A1762T, G1764A (TA change). In the United States, these variants have been found in 44% of patients with chronic HBV infection, and may also be associated with HBeAg-negative CHB.<sup>39</sup> Most patients with HBeAg-negative CHB harbor HBV variants in the precore or core promoter regions, have lower serum HBV DNA levels, and are more likely to run a fluctuating course.<sup>43,44</sup>

HBeAg-negative CHB has been estimated to account for 7% to 30% of patients with CHB worldwide, being predominant in Mediterranean countries and Asia.<sup>45,46</sup> The most common HBV variant associated with HBeAg-negative CHB, G1896A, usually occurs in HBV genotype D infection (more prevalent in the Mediterranean basin) and is rare in genotype A infections (more common in the United States and northwestern Europe).

Although increasing data support an association between core promoter variants and more severe liver disease, hepatic decompensation and hepatocellular carcinoma (HCC), large-scale longitudinal studies are needed to clarify this association. Precore and core promoter variants have also been described in association with fulminant acute hepatitis B, and have been associated with higher resistance to interferon and nucleoside analog therapy.

### Pre-s/s Variants

The major B-cell neutralizing epitope of HBsAg resides in the “a” determinant region located at amino acid positions 124 to 149. Antibodies to the “a” determinant confer protection against all HBV serotypes. HBV S gene mutants have been described in infants infected with HBV despite an adequate anti-HBs response to HBV vaccination (vaccine escape mutants). The most common mutation involves an amino acid substitution at codon 145 (G145R) in the “a” determinant of HBsAg. Recurrent hepatitis B after liver transplantation despite HBIG prophylaxis has also been associated with this mutation. Finally, in rare instances, mutations in the HBV genome downregulate S gene expression or produce aberrant surface proteins undetectable by conventional HBsAg assays, despite ongoing HBV replication. Such “occult” HBV infections may have an impact on blood transfusion, organ transplantation, and diagnosis of cryptogenic liver disease.

### Polymerase Gene Mutations

The RT/DNA polymerase region has five conserved domains: A, B, C, D, E, with the putative catalytic domain believed to reside in the YMDD locus in domain C. Naturally occurring polymerase gene mutations are rare, but many mutants are selected in patients receiving treatment with oral nucleos(t)ide analogs.

### Profile of Serologic and Molecular Markers During Hepatitis B Virus Infection

Infection with HBV is associated with characteristic changes in the serum levels of hepatitis B antigens and antibodies and HBV

DNA, which define different clinical states.<sup>47</sup> Acute infection is characterized by the appearance of HBsAg, HBeAg, and HBV DNA 1 to 10 weeks after exposure, followed soon thereafter by anti-HBc (initially of the IgM and then the IgG class). After exposure, there is a phase, lasting approximately 3 weeks (1 to 6 weeks), in which serum HBV DNA is intermittently detectable at low levels, followed by a “ramp-up” phase during which HBV DNA increases rapidly with an estimated doubling time of 2.56 days.<sup>48</sup> The period between exposure and first appearance of detectable HBsAg is referred to as the *window period* (WP). During this WP, the duration of which depends on the sensitivity of the serologic assay, HBV DNA is the only marker of HBV infection. Hepatitis is defined by the observed onset of increased alanine aminotransferase (ALT) activity, 25% or fewer of the cases being associated with jaundice. Usually, HBeAg and HBV DNA, detectable by hybridization assays with limits of  $10^5$ - $10^6$  copies/mL, disappear early, and HBsAg titers decline as the ALT peaks. Soon thereafter, the enzyme values begin to decline. What remains is IgM anti-HBc, which, after 6 months or longer, is replaced by IgG anti-HBc, the latter persisting for life in decreasing titers. During the interval between loss of HBsAg and development of anti-HBe and anti-HBs, which may extend for weeks or months, IgM anti-HBc may be the sole marker of acute HBV infection. The usual recovery sequence begins with the loss of replicative markers (HBeAg and HBV DNA), seroconversion to anti-HBe and disappearance of HBsAg, return of ALT levels to normal, and, finally, appearance of anti-HBs, which conveys immunity to reinfection [Fig 46-2(A)]. Although recovery is associated with disappearance of serum HBV DNA as determined by insensitive assays; when very sensitive assays [polymerase chain reaction (PCR) or transcription-mediated amplification (TMA)] are used, HBV DNA may remain detectable (sometimes intermittently) for many years.<sup>49</sup>

Persistence of HBsAg and usually of HBeAg beyond 6 months defines chronic infection (which occurs with variable frequency depending on the age at infection and immune status of the host). HBV DNA is usually detectable with insensitive assays (levels  $\geq 10^5$ - $10^6$  copies/mL) as well as anti-HBc. HBeAg may persist for years or decades during chronic infection and its presence is usually associated with high levels of serum HBV DNA and active liver disease. Over time during chronic infection, spontaneous or treatment-induced seroconversion to anti-HBe occurs, usually associated with a marked decrease in serum HBV DNA and remission of liver disease. Some patients with mutations that prevent HBeAg production, however, continue to have active liver disease despite anti-HBe seroconversion (HBeAg-negative CHB) [Fig 46-2(B)].

There exists a subset of patients with “occult HBV infection” defined as being HBsAg negative with persistent HBV DNA detectable by PCR, in the presence (80%) or absence (20%) of anti-HBc with or without anti-HBs. Most of these patients have very low or only intermittently detectable serum HBV DNA levels; although HBV DNA is usually present in the liver. Infection with preS/S HBV variants accounts for a small number of these cases. HBV transmission from recently infected blood donors

**Figure 46-2.** Clinical, serologic, and virologic course of acute and chronic HBV infection. (A) Schematic profile of serologic and virologic markers of a typical acute resolving hepatitis with the average timing of detection of serum HBV DNA, HBsAg, and HBeAg and their corresponding antibodies, with respect to the ALT elevation reflecting immune-mediated liver cell destruction after HBV replication (as reflected by serum HBV DNA levels) has been mostly controlled by noncytolytic mechanisms. (B) Course of chronic hepatitis B after perinatal or early-childhood-acquired infection. The four distinct phases shown are: immune tolerance (high-level HBV replication with normal ALT levels), immune clearance (high ALT level, lower HBV DNA levels and frequent hepatitis flares, depicted with dashed lines for both HBV DNA and ALT, which may lead to loss of HBsAg and anti-HBe seroconversion), inactive carrier state (normal ALT, presence of anti-HBe and low or even undetectable HBV DNA), and reactivation phase after many years of inactive carrier state (lower and fluctuating HBV DNA and ALT levels in the presence of anti-HBe), commonly associated with selection of core or precore HBV variant (see text for further details).

with precore mutants, who never developed detectable HBsAg, has been described in Japan.<sup>50</sup> Most cases of occult HBV infection represent late stages of persistent HBV infection associated with a strong immune response from the host, and/or viral interference because of coinfection with HCV.<sup>51</sup> Among blood donors and the general population in developed countries cryptic HBV infection is rare,<sup>52</sup> but it is frequently detected in countries that have a high prevalence of HBV (~10%-15%).<sup>53</sup>

### Epidemiology and Prevention

According to WHO estimates, 2 billion people have been infected with HBV, of whom 350 million are chronic carriers,

and 4 million new infections occur annually. HBV is readily transmitted by percutaneous or transmucosal transfer of blood or body fluids (eg, semen, cervicovaginal fluid, saliva). Three patterns of infection exist. In developing countries of Asia and sub-Saharan Africa, the disease is transmitted predominantly during the perinatal period by carrier mothers or, less commonly, through horizontal household transmission during infancy or early childhood. In developed countries, infection occurs mainly in adolescents and young adults through intimate (usually sexual) contact with chronic carriers or by percutaneous exposure (injection drug use, tattoos, multiple transfusions, accidental needlestick exposure, etc). There is a striking inverse

relationship between age at infection and the risk of chronicity<sup>54,55</sup>; the chronicity rate is ~90% for perinatal infection, 20% to 50% for infection acquired before 5 years of age and 1% to 5% for adult acquired infections. Hence, the prevalence of HBV carriers varies from 0.1% to 2% in low-prevalence areas (United States, Canada, Western Europe, Australia), to 2% to 5% in intermediate-prevalence regions (Mediterranean countries, Japan, Central Asia, Eastern Europe, Middle East, and Latin America), to 7% to 20% in high-prevalence areas (Southeast Asia, China, sub-Saharan Africa).

Several studies undertaken soon after the implementation of HBsAg screening showed that it was more common in males, in African and Asian Americans, and in paid donors. In addition, the HBsAg prevalence was higher among certain population groups (injection drug users and promiscuous men who have sex with other men).<sup>56</sup> A study of the risk of blood-borne viral infections at five blood donor centers from 1991 to 1996, involving 1.9 million donors showed no reduction in the frequency of HBV infection (0.2% HBsAg-positive first-time donors during this 6-year period).<sup>57</sup> A more recent study has shown a progressive decline from 1995 to 2002 to a prevalence of 0.07% among first-time donors.<sup>58</sup> However, changing blood donor demographics as a result of immigration of people from areas of moderate to high endemicity may increase HBV prevalence again.

Among the preventive measures for HBV infection, adequate information to HBV carriers about transmission mechanisms and counseling to avoid spread should be provided (use of condoms during sexual intercourse with occasional partners; not sharing toothbrushes and razors; covering open cuts and scratches; cleaning blood spills with bleach; not donating blood, sperm, or organs; and vaccinating regular sexual partners and household members). A highly effective HBV vaccine (recombinant HBsAg), confers protection to all HBV genotypes and subtypes in >95% of immunocompetent individuals. In high- or intermediate-prevalence areas vaccination campaigns of all newborns (along with HBIG in children born to HBV carrier mothers) and children under 12 years of age, have been widely implemented during the last 10 to 20 years so that, in many countries most individuals <25 years old are protected from HBV infection. Recommendations for vaccination have been established in recent Centers for Disease Control and Prevention (CDC) and Advisory Committee on Immunization Practices (ACIP) guidelines.<sup>59,60</sup>

## Screening Tests and Detection Systems

### Serologic Assays

After the donor selection process, testing for HBsAg remains the first-line screen for HBV. Since its introduction in 1970, HBsAg assays have increased their sensitivity by more than 2 log<sub>10</sub>. During the 1970s, extensive prospective studies (undertaken to evaluate the frequency of hepatitis and the efficacy of immune globulin prophylaxis) that coincided with the appearance of serologic tests for HBsAg, documented the impact of screening tests with greater assay sensitivity. For example, in a study

performed at the blood bank of the NIH, the frequency of transfusion-associated hepatitis B was 4.8% with the gel diffusion test, 3.7% with counter-electrophoresis (CEP) screening, and 0.6% after screening by radioimmunoassay (RIA) became available.<sup>3</sup> Currently licensed tests are third-generation EIA or chemiluminescent immunoassays (ChLIA), with analytical sensitivities varying from 0.13-0.62 to 0.07-0.12 ng/mL, respectively, as assessed in seroconversion panels.<sup>48,61</sup> The infectious WP for licensed EIA tests has been estimated at 37 to 50 days, and 33 to 44 days for the recently licensed ChLIA tests.<sup>62</sup> Aside from the WP, HBsAg immunoassays may fail to detect HBV DNA positive donors infected with some preS/S mutants, acutely infected donors with transient antigenemia and chronic carriers with occult HBV infection.<sup>50, 51</sup>

Testing for anti-HBc, originally introduced in 1986 as a surrogate marker for NANB infection, was retained because of its potential value for the detection of HBV-infected donors. The effectiveness of screening for anti-HBc as a means to reduce HBV transmission may be very low, because of its low specificity, and the deferral of a large proportion of otherwise eligible donors; the vast majority of repeatedly reactive anti-HBc-positive units also carry high-titer anti-HBs and are consistently negative for HBV DNA. Although cases of hepatitis B infection have been described in recipients of HBsAg-negative, anti-HBc-positive-only blood, their prevalence is quite low (and often represent false-positive test results) thus limiting the value of anti-HBc screening in low-prevalence populations.<sup>63</sup> Furthermore, in contrast to studies from high-prevalence regions, where HBV DNA has been identified by PCR in 5% to 25% of anti-HBc-only donors,<sup>64,65</sup> in low-prevalence areas (United States, Canada, Western Europe), HBV DNA has been detected in only 0.5% to 3.5% of anti-HBc-only blood donors<sup>66-68</sup> and infectivity of these low-level HBV DNA-containing units has not been well established. Nonetheless, anti-HBc screening has been implemented in several low-prevalence countries (United States, Germany, United Kingdom, France, Canada, New Zealand), often along with HBV DNA testing, because HBV infection continues to pose the greatest residual risk of transmission of all major blood-borne viruses.

### Molecular Assays for HBV DNA

Qualitative and quantitative tests for HBV DNA in serum (and liver tissue) have been developed to assess HBV replication. The sensitivity limit and dynamic range of these assays depends upon the techniques used. These vary from several hybridization assays (detection limit 10<sup>3</sup>-10<sup>6</sup> copies/mL) to the most sensitive amplification procedures such as real-time PCR and TMA assays. Commercial assays based on the latter procedures are available and have excellent performance with low-end detection limits of 5 to 50 IU/mL (25-250 copies/mL).<sup>48,69,70</sup> Although the main clinical utility of quantitative tests for HBV DNA is the selection and monitoring of patients for antiviral treatment, sensitive (quantitative or qualitative) tests have also been developed in semiautomated or automated platforms for HBV NAT of large numbers of blood donors, often in multiplexing formats for

simultaneous detection of HCV RNA, HIV RNA, and HBV DNA in MP-NAT (minipool) or ID-NAT (individual donor).<sup>71</sup> The use of NAT testing of blood donors for HBV DNA is intended to shorten the infectious WP and to detect occasional cases of occult HBV infection. Transmission from occult late-stage chronic carriers may contribute little to HBV transfusion risk in countries performing routine anti-HBc screening, but might be more relevant in areas with intermediate prevalence where anti-HBc screening is not performed. Nonetheless, the infectivity of such donors (3% in a look-back study conducted in Japan),<sup>50</sup> and the clinical significance for the donors remain largely unknown and are being actively investigated.<sup>72</sup> Most of the residual risk (RR) of transfusion-transmitted HBV comes from recently infected individuals who donate during the infectious WP and this risk, in the absence of NAT, has been estimated to range between 0.75 and 200 per million donations from repeat donors in areas where anti-HBc screening has not been implemented and between 0.91 and 8.5 per million donations in areas screening for anti-HBc (3.6 per 10<sup>6</sup> donations in the United States).<sup>73</sup> However, implementation of NAT for HBV remains controversial because of uncertainties in the length of the infectious WP on the incidence of infection among first and repeat donors and on the minimum inoculum size required for transmission. In addition, the new HBsAg tests may be 10-fold more sensitive than current EIA tests and may have already shortened the WP significantly. A mathematical model to estimate the potential impact of HBV NAT testing in reducing WP and relative risk according to the analytical sensitivity of NAT assays, pool size, doubling time of the virus, the incidence rate and back-extrapolation to a putative infectious dose of one DNA copy per 20 mL (the plasma volume of an additive solution red cell concentrate) has been proposed.<sup>62</sup> According to this model, ID-NAT for HBV would reduce the WP to 20 days (a 50% reduction from current estimates).

### Pathogenesis and Mechanisms of Viral Persistence

HBV is not directly cytopathic and both liver injury and control of HBV replication appear to involve HBV-antigen-specific cytolytic T cells (CTL) and CD4+ T cells, as well as cytokines released by both virus-specific T cells and nonspecific lymphocytes.<sup>74,75</sup> The early immune response to HBV does not appear to involve a significant direct innate immune response during the first weeks of infection.<sup>76</sup> Nonetheless, HBV DNA can be cleared from serum and liver before detectable T-cell infiltration and liver injury. Downregulation of HBV replication, with removal of both single-stranded intermediates and cccDNA from the cytoplasm and nucleus, is mediated primarily by interferon- $\gamma$  (IFN- $\gamma$ ), presumably released by HBV-specific CD8+ T cells as well as other activated cells.<sup>77,78</sup> Clearance of most HBV DNA from blood and liver is followed by development of multispecific CD4+ and CD8+ T cells, cytolysis of HBV-infected hepatocytes, and ALT elevation. A broad and vigorous multispecific CD4+ and CD8+ T-cell response is essential for recovery as evidenced by in-vivo depletion studies in the chimpanzee model.<sup>79</sup>

Viral persistence occurs mainly in vertically transmitted HBV infection (>90% of newborns to HBeAg-positive carrier mothers with high HBV DNA levels) presumably because the immune system of neonates is not fully developed, allowing development of immune tolerance to nucleocapsid proteins induced by HBeAg. The mechanisms of chronicity in settings other than perinatal transmission may involve qualitative and quantitative differences in both innate and adaptive immune response.<sup>80</sup> The T-cell immune response not only plays a role in viral control and recovery, but also contributes to liver damage in acute and chronic hepatitis. Flares of disease activity during the immune clearance phase of CHB coincide with increased serum interleukin (IL)-12 levels, increased HBV-specific CD4 and CD8 T-cell responses, and recruitment of large numbers of neutrophils, natural killer (NK) cells and activated bystander lymphocytes. These nonspecific immune cells are believed to mediate most of the liver damage.

### Clinical Spectrum and Natural History of HBV Infection

#### Acute Hepatitis B

The spectrum of clinical manifestations of acute HBV infection varies, depending on host factors (age, immune status, and underlying liver disease), ranging from subclinical or anicteric hepatitis to icteric hepatitis and, in some cases, fulminant hepatic failure.

After an incubation period of 1 to 3 months, approximately 70% of patients with acute HBV infection have subclinical hepatitis. In those with symptomatic disease, the clinical picture is indistinguishable from that of other viral hepatitis with symptoms and jaundice lasting 1 to 3 months. The disease may be more severe in patients coinfecting with other hepatitis viruses or with underlying liver disease. Fulminant hepatitis is unusual (0.1 to 0.5%). Laboratory testing during the acute phase reveals elevation of aminotransferases (values up to 1000-2000 IU/L), and bilirubin, which usually return to normal within 1 to 4 months in patients who recover. Despite clinical, analytic, and serologic recovery from acute infection, traces of HBV DNA remain detectable in blood and/or liver tissue by PCR for many years, suggesting that eradication of HBV rarely occurs and that latent infection is kept under control by the immune system.

Data from several prospective studies conducted during the early 1970s indicate that transfusion-transmitted hepatitis B begins after an average incubation period of 11 to 12 weeks.<sup>81</sup> In general, the clinical symptoms of the different types of viral hepatitis are indistinguishable from one another, although symptoms are more frequently absent among persons with HCV than among those with HBV infections. The biochemical dysfunction also tends to be more severe with HBV disease than with transfusion-transmitted HCV, with higher mean ALT values (705 vs 471 U/liter) and a higher frequency of jaundice (60% vs 25%).<sup>81</sup> It is difficult to assess the disease course after transfusion because of the scarcity of well-defined cases studied prospectively. Although non-transfusion-related acute hepatitis B in immunocompetent adults leads to chronicity in 1% to 5%

of cases, too few large-scale, prospective studies have been conducted to establish whether the frequency of chronicity in transfusion-associated cases is similar. The frequency of chronic HBV infection is clearly influenced by the age at onset (neonates and infants vs adults or elderly people) and the immune status of the patient; it is debated as to whether the size of the inoculum (transfusion vs needlestick or sexual) also affects the likelihood of evolution to chronicity.

### Chronic Hepatitis B

Persistence of HBsAg beyond 6 months after acute infection is the hallmark of CHB. The overall view of the natural course of chronic HBV infection has changed with the recognition that HBV replicates throughout the course of CHB, that the immune response plays a major role in liver damage, and that the balance between immune response and viral replication is a dynamic process.<sup>82,83</sup>

The natural course of CHB consists of four phases [Fig 46-2(B)]. The first phase of immune tolerance is classically seen in patients infected at birth by vertical transmission and is characterized by the presence of HBeAg and high-level HBV DNA in serum but with normal ALT levels and minimal or absent liver inflammation. It may last 1 to 4 decades, a period during which spontaneous HBeAg seroconversion is infrequent. In childhood or adult-acquired HBV infection this phase is short-lived or absent. The second phase (immune clearance/HBeAg-positive CHB) is characterized by HBeAg persistence, high or fluctuating HBV DNA levels, persistent or intermittent ALT elevation, and active hepatic necro-inflammation. A hallmark of this phase is the occurrence of hepatitis flares, often accompanied by transient increases in serum HBV DNA, that are sometimes severe enough to lead to hepatic decompensation. The duration of the “immune clearance” phase, and the frequency and severity of the flares, correlate with the risk of cirrhosis and HCC.<sup>84</sup> An important outcome of this phase is spontaneous HBeAg clearance accompanied by anti-HBe seroconversion; clearance of HBeAg correlates with, but is not limited to, older age, higher ALT levels, and infection with HBV genotype B. The third phase (inactive HBsAg carrier state) is characterized by the presence of anti-HBe, normal ALT levels, low serum HBV DNA ( $<10^5$  IU/mL), and mild hepatitis with variable fibrosis, depending on the duration and severity of the prior immune clearance phase. The inactive carrier state may persist indefinitely, in which case the prognosis is generally favorable. This is supported by a long-term follow-up study of 296 HBsAg-positive, healthy blood donors in Italy,<sup>85</sup> whose survival was similar to that of 157 uninfected controls over a 30-year period, and in whom no episodes of hepatic decompensation occurred. However, 4% to 20% of inactive carriers have episodes of reversion to HBeAg positivity and 10% to 30% of inactive carriers have spontaneous reactivation of HBV replication and liver disease activity after years of quiescence. The fourth phase (HBV reactivation of inactive carrier state/HBeAg-negative CHB) is characterized by positive anti-HBe, detectable HBV DNA, elevated ALT, and active liver

disease.<sup>86</sup> Most cases represent reactivation after a period of the inactive carrier state of variable duration, but some progress directly from HBeAg-positive to HBeAg-negative CHB. Because this is a later phase in the course of CHB, patients are usually older and have more advanced liver disease. Most patients with HBeAg-negative CHB harbor precore or core promoter HBV variants and tend to have lower serum HBV DNA levels than during the immune clearance phase. A clinical course characterized by fluctuating ALT and HBV DNA levels. HBeAg-negative CHB, originally reported in Mediterranean countries,<sup>86,87</sup> is now being recognized with increasing frequency in all parts of the world.<sup>88,89</sup> Prevalence varies according to the predominant HBV genotype in different geographic regions.

Spontaneous clearance of HBsAg occurs in 0.5% to 1% of patients with CHB per year, usually in association with undetectable serum HBV DNA, normalization of ALT, and absence of liver disease activity. In the absence of cirrhosis or HCV coinfection, loss of HBsAg conveys a good prognosis. CHB is usually asymptomatic until the evolution to cirrhosis or HCC and the ensuing complications. Collectively, among patients with CHB, 40% develop cirrhosis, liver failure, and/or HCC. Cirrhosis develops during CHB with an annual incidence of 2% to 6% in HBeAg-positive and 8% to 10% in HBeAg-negative patients. Certain cofactors increase the risk, such as alcohol, HCV or HIV coinfection, high HBV DNA levels, and HBV genotype C.<sup>45,89,90</sup> Among patients with cirrhosis, persistent, high-level HBV DNA is associated with increased risk of hepatic decompensation and mortality. The annual incidence of HCC has been estimated to be  $<1\%$  for noncirrhotic carriers and 2% to 3% for patients with cirrhosis. Factors associated with increased risk of HCC include male gender, older age, a family history of HCC, core promoter mutation, HBV genotype C, HCV coinfection, and the presence of cirrhosis. Although preexisting cirrhosis is a strong risk factor, 30% to 50% of HBV-associated HCC occurs in the absence of cirrhosis.<sup>91</sup>

### Treatment

The aims of treatment of CHB are induction of sustained suppression of HBV replication and remission of liver disease activity, with the goal to prevent cirrhosis, hepatic failure, and HCC. Currently, six therapeutic agents have been approved for the treatment of adults with CHB in the US (IFN- $\alpha$ , and nucleoside or nucleotide analogs: lamivudine; adefovir; entecavir; and telbivudine), while other analogs are still undergoing trials (emtricitabine, tenofovir, and clevudine). Responses to treatment are categorized as biochemical (normalization of ALT levels), virologic (loss of HBV DNA and anti-HBe seroconversion), and histologic (reduction in activity and halting of fibrosis progression). Standard and pegylated IFN- $\alpha$  (which are given for finite periods, by subcutaneous injection), are associated with substantial side effects and have limited efficacy in inducing virologic response (35% in HBeAg-positive and 70% in anti-HBe-positive CHB). Despite its low initial efficacy, the advantage of pegylated IFN- $\alpha$  is that the virologic response in HBeAg-positive patients

who achieve anti-HBe seroconversion is sustained after discontinuation of therapy in up to 90% of cases and hence long-term therapy is not required. However, a sustained virologic response occurs in only 20% of HBeAg-negative CHB patients treated with pegylated IFN- $\alpha$ . Drug resistance does not occur in patients treated with IFN. In contrast to IFN, nucleos(t)ide analogs are given orally, have minimal side effects, and are more potent inhibitors of viral replication. However, they usually require long-term or indefinite administration (because of the low rate of sustained remission after withdrawal) and 30% to 70% develop resistant mutants after 2 to 5 years of treatment (<1% after 2 years with entecavir monotherapy).

Although there is no doubt that antiviral therapy modifies the natural history of chronic HBV infection—reducing liver-related morbidity, mortality, and HCC incidence—the current complexity of treating CHB (criteria for selection of candidates, choice of antiviral agent, monitoring of response, diagnosis and management of resistant mutants) has necessitated the development of evidence-based treatment guidelines for the management of CHB.<sup>91-93</sup> These guidelines will continuously evolve as new medications are added and as new drug interactions and resistance patterns emerge.

### HBV Summary

Hepatitis B virus, a hepadnavirus, causes acute and chronic infection, the latter evolving to cirrhosis, end-stage liver disease and HCC in 40% of cases, unless properly treated. It is transmitted perinatally and by blood and secretions and was a major cause of posttransfusion hepatitis until the risk was reduced by elimination of paid donors and by screening for HBsAg. A highly effective vaccine is available and vaccination campaigns in high and intermediate prevalence areas have been widely implemented in the last two decades. The near elimination of the risk of HBV transmission by transfusion has been a major part of the success of contemporary transfusion medicine. The small residual risk of HBV infection by blood transfusion will be further reduced with more sensitive serologic and molecular assays with the ultimate goal of eradicating this transmission mechanism from the epidemiology of HBV infection.

## Hepatitis D

Hepatitis D virus (HDV), also known as hepatitis delta virus, is a 35- to 37-nm defective RNA virus that contains a 1700-nucleotide RNA genome similar to that of plant satellite viruses and viroids. Hepatitis D virus is a hybrid virus that relies on HBV for its surface coat (HBsAg), which surrounds a nucleocapsid core expressing HDV antigen. HDV requires concurrent infection with HBV to support its replication and clinical expression.<sup>94</sup> Hepatitis B virus and HDV infections can occur simultaneously, or a patient with chronic HBV infection can become superinfected with HDV. Ultimately, the duration of HDV infection is determined by the duration of HBV infection because HDV invariably relies on HBV for its growth and expression. A diagnosis of HDV infection can be made by demonstrating antibody

(IgM or IgG) to HDV (anti-HDV), identifying HDV antigen (HDAg) in liver nuclei by immunohistochemical staining, or by detecting HDV RNA in serum by PCR or in liver by cDNA hybridization. The detection of HDAg in serum is difficult and therefore not a practical diagnostic marker.

Hepatitis D tends to segregate into two different epidemiologic patterns. In endemic areas, such as Mediterranean countries, HDV infection appears to be transmitted from person to person. In contrast, in nonendemic areas, such as northern Europe and North America, transmission of HDV infection appears to be confined to specific percutaneously exposed populations, such as drug users and hemophiliacs. Occasionally, even in nonendemic areas, protracted outbreaks of hepatitis D occur either by HBV-HDV coinfection or HDV superinfection. In nonendemic areas, such outbreaks have a tendency to amplify HDV infection in the community and to blur the epidemiologic distinction between endemic and nonendemic areas. The frequency of HDV infection, even in endemic areas of the world, has been declining.

The clinical features of hepatitis D are similar to those of hepatitis B, and most of the more severe outcomes of hepatitis B are caused by hepatitis D coinfection. In particular, superinfection of chronic hepatitis B with HDV often leads to more serious and rapidly progressive liver disease and can transform asymptomatic or mild chronic hepatitis B into severe chronic hepatitis and cirrhosis. In addition, fulminant hepatitis can follow HBV-HDV coinfection or HDV superinfection of an HBV carrier.<sup>95</sup>

Because HDV infection cannot occur in a patient who is immune to HBV, prevention of HDV infection is accomplished readily by HBV vaccination in persons susceptible to hepatitis B. For those already infected by HBV, prevention of superinfection is limited to mechanical efforts to avoid intimate contact with HDV-infected persons or HDV-contaminated needles or blood components.

### Hepatitis D and Blood Transfusion

Because, under ordinary circumstances, HDV infection cannot occur in the absence of HBV infection, the chance that a blood donor screened and found to be negative for HBsAg and anti-HBc could harbor HDV is exceedingly small. Before the advent of current screening techniques, transmission of HDV undoubtedly occurred and contributed to the previously identified high frequency of HDV infection in multitransfused persons, including those with hemophilia and thalassemia.<sup>96</sup> In a study of American patients with hemophilia A, 75% had a serologic marker of previous HBV infection, and 13% of them had antibodies to HDV.<sup>97</sup>

Although HDV is a blood-borne viral agent, contemporary, highly sensitive screening methods used in blood banks should be effective in reducing the frequency of transfusion-associated HDV hepatitis to a negligible level, at least in HBsAg-negative blood recipients. There is a very small residual risk for HBsAg-positive blood recipients because rare donors have occult HBV infection in which HBsAg is nondetectable despite the presence of HBV DNA. Theoretically, such donors could carry low levels

of HDV, though some level of HBsAg production would have to exist in order to support replication of HDV. Even this remote possibility of a donor with coexistent occult HBV infection and HDV infection would be interdicted in regions that screen donors for anti-HBc antibody.

## Hepatitis C Virus

### Historical Perspective

Before hepatitis C virus (HCV) was cloned, considerable knowledge of this agent was garnered from experiments in chimpanzees. In 1978, it was found that serum from patients with acute or chronic NANB hepatitis and from asymptomatic carriers could transmit infection to chimpanzees.<sup>98,99</sup> Although chimpanzees did not develop clinical illness, they had transaminase elevations and liver biopsy evidence of hepatitis after an appropriate incubation period. Animals inoculated with serum from patients with NANB hepatitis did not develop HBV markers, emphasizing the clear distinction between HBV and the agent of NANB hepatitis. In addition to elevations in transaminase levels, electron microscopy revealed that infected chimpanzees generally had characteristic tubular ultrastructures in hepatocyte cytoplasm.<sup>100</sup> These tubular structures, consisting of an electron-dense center and a double-unit membrane, represent proliferation of the rough endoplasmic reticulum, a change now shown to be induced by interferon. The tubules are an epiphenomenon of NANB/HCV infection and are useful indicators of such infection in chimpanzees because of their relative specificity. They are not induced during the course of HAV or HBV infection in chimpanzees and are not seen in human NANB/HCV infection.

The findings of elevated transaminase levels, light microscopic changes of hepatocellular damage, and electron microscopic evidence of cytoplasmic tubules made it possible to define NANB hepatitis in chimpanzees, even in the absence of a specific serologic marker. Using the chimpanzee as an infectivity model, it was shown that the cytoplasmic tubule-inducing NANB agent was sensitive to chloroform and other lipid solvents and thus that it contained essential lipid, presumably in its surface membrane.<sup>101,102</sup> Filtration studies subsequently showed that the NANB agent was 30 to 60 nm in diameter.<sup>103</sup> Among known viruses, only the flaviviruses and the hepadnaviruses (HBV, woodchuck hepatitis virus, duck hepatitis virus) are lipid encapsulated and fall into this size range. It was predicted that the NANB agent was a flavivirus and the subsequent cloning and characterization of HCV<sup>6</sup> proved this prediction correct.

Flaviviruses are a large and diverse family, formerly known as arboviruses (arthropod-borne viruses) and togaviruses. They include the dengue and yellow fever viruses, the rubivirus (rubella), and the pestiviruses (bovine diarrheal virus, hog cholera virus, and other mucosal disease viruses of animals). HCV represents a new genus in the family *Flaviviridae* and is most closely related to pestiviruses. Although there is only limited homology with the pestiviruses, the genomic structure and

hydrophobicity patterns are similar. The pestiviruses, like HCV, are characterized by blood-borne transmission and by lifelong viremia. Unlike dengue and yellow fever viruses, they do not have a mosquito vector.

### Cloning and Molecular Characterization

In the mid-1980s, a long series of experiments conducted by Houghton et al at the Chiron Corporation, in collaboration with Bradley at the CDC, culminated in the cloning and serologic characterization of HCV.<sup>6</sup> Using large volumes of plasma derived from a chimpanzee with chronic NANB hepatitis, these investigators extracted whole nucleic acid and made complementary DNA (cDNA) from RNA and single-stranded DNA templates. The cDNA was inserted into a gt11-phage expression vector and used to infect *Escherichia coli*. Expressed proteins were blotted and overlaid with serum from patients with NANB hepatitis. A single clone was identified that expressed an antigen reactive with chronic- and convalescent-phase serum from persons with NANB hepatitis, but not with serum from control subjects without infection or from patients with type A or type B hepatitis.<sup>6</sup> Cloned nucleic acid was used to generate probes that were shown to hybridize with RNA derived from the starting plasma, thus closing the loop between the cloned agent and the infectious plasma. Once the cloned agent of NANB hepatitis was molecularly characterized, it was designated HCV. Amplification of the reactive clones and expression of the genome in large cultures of yeast produced sufficient antigen to formulate radioimmune and enzyme-linked assays for the detection of antibody to HCV.

Characterization of HCV shows that the viral genome consists of single-stranded, linear RNA of 9.6 kb that is positively stranded and hence can serve directly as message for the synthesis of viral proteins.<sup>6,104</sup> The viral proteins are encoded from a single, large open reading frame that produces a polyprotein that is posttranslationally cleaved.<sup>104</sup> The genome (Fig 46-3) is characterized by a highly conserved, untranslated region at the 5' terminus (5'UTR) that is now used as the primary target for molecular amplification assays to detect HCV RNA and for viral genotyping. The 5'UTR contains an internal ribosomal entry site that is essential for viral protein synthesis and that initiates translation at the start codon of the large open reading frame.<sup>104</sup> Downstream of the 5'UTR are the coding regions for envelope proteins designated E1 and E2, followed by the coding region for the viral core (nucleocapsid). In the terminal portion of the E1 region is a hypervariable segment (HVR1), which is the most highly mutable region of the genome, presumably because its position in the viral envelope places it under a high degree of immune pressure. It is presumed that this region is the target for neutralizing antibody responses. Downstream from the structural genomic regions are a series of nonstructural coding regions designated NS2, NS3, NS4, and NS5. The full function of these regions is not known, but they have been shown to code for critical enzymes, including an NS3 protease, an NS3 helicase, and an NS5 polymerase.

**Figure 46-3.** Proposed genome of hepatitis C virus (HCV). Functional equivalents and major antigens used in antibody detection assays. The structural organization of the HCV genome has been deduced from genomic sequencing and from parallels with other flaviviruses. The entire genome contains approximately 9500 bases coding for approximately 3000 amino acids. The 5' end has a highly conserved noncoding region, the one generally used for polymerase chain reaction amplification and presumed to have important regulatory functions. Downstream of the noncoding region are the regions coding for the structural elements, including the core or nucleocapsid (C) and the envelope (E1, E2/NS1). It is unclear whether NS1 is part of the envelope region or the first nonstructural gene. The 5' end of E2/NS1 contains a hypervariable (HV) region that mutates rapidly

There are six major genotypes of HCV that are designated in Arabic numerals 1 through 6 and each has been subtyped as designated by lowercase lettering. The genotypes differ from each other in nucleotide sequence by at least 15%. Genotypes 1a and 1b are the most prevalent forms in the United States, Europe, and Japan. In the United States, genotypes 1a and 1b are found in almost equal frequency, whereas in Japan genotype 1b predominates. Genotypes 2 and 3 are found as minor populations in the United States (10% genotype 2 and 6% genotype 3) and Europe. Genotype 3 is the predominant genotype in Southeast Asia. Genotype 4 appears isolated to Northern Africa (especially Egypt), and the Middle East, whereas genotype 5 has been localized to South Africa. Genotype 6 is rare and found predominantly in Japan. Although useful as epidemiologic tools and predictors of treatment response, the clinical significance of HCV genotypes is uncertain. Although many studies have claimed that patients with genotype 1 have more severe histologic outcomes and clinical disease, an equal number of studies have failed to show this association. The primary use of HCV genotypes is in the prediction of response to interferon-based therapies. In general, patients with genotypes 1 and 4 have an approximate 45% to 50% sustained virologic response to interferon plus ribavirin, whereas patients with genotype 2 or 3 infection have an

and probably plays a key role in the ability of the virus to escape neutralization. There follow a series of nonstructural genes (NS2-NS5) with enzymatic or membrane-binding functions. The initial clone discovered was from the NS4 region; the derived protein was designated 5-1-1. This was expanded to form the c100-3 antigen, the basis of the first-generation anti-HCV assay. Second-generation assays added the c22 core antigen and the c33c antigen from the NS3 region. These antigens increased the sensitivity of the second-generation assay approximately 20% over the first-generation test. The third-generation assay (pending licensure in the United States) adds an NS5 protein and reconfigures some of the earlier antigens. (Used with permission from Alter.<sup>105</sup>)

approximate 80% sustained virologic response rate that is akin to “cure” (see below).

## Detection Systems

### Surrogate Tests

Mounting evidence for the role of blood transfusion in the induction of chronic liver disease and continuing frustration in the development of a specific assay for the agent of NANB hepatitis prompted the adoption of surrogate (nonspecific) tests for the detection of NANB hepatitis virus carriers. These surrogate tests, ALT and anti-HBc, were implemented for routine donor screening early in 1987. Use of these tests evolved from retrospective analyses of prospective studies of TAH conducted by the Transfusion Transmitted Virus Study Group<sup>106,107</sup> and by the department of transfusion medicine at the NIH.<sup>108,109</sup> These studies found a threefold to fourfold increase in hepatitis risk among recipients of ALT-elevated or anti-HBc-positive blood compared to the rate among recipients of blood negative for these two indices. It was predicted from these studies that the adoption of ALT and/or anti-HBc tests for donor screening might result in a 30% to 40% reduction in TAH. The value of surrogate assays as an interim measure was validated when it was later shown that approximately one-third of donors with

confirmed anti-HCV were also positive for one or both of these surrogate markers.<sup>110</sup> A controlled prospective study conducted in Canada further validated the use of surrogate assays for the prevention of TAH.<sup>111</sup>

### Serologic Assays

Humoral responses to HCV are vigorous and are directed to a multiplicity of antigenic sites.<sup>104,112</sup> As shown in Fig 46-3, the original clone produced a protein designated 5-1-1, which was then expanded and fused to form the c100-3 antigen that served as the basis for first-generation anti-HCV assays. This early assay was highly effective in interdicting HCV carrier blood donors, but anti-c100-3 did not appear for a protracted period after exposure, creating a window of infectivity that ranged from 12 to more than 26 weeks. Some patients with HCV infection never developed antibody that was reactive in the first-generation assay. The second-generation assays added two critical epitopes to both the screening EIA and the confirmatory recombinant immunoblot assay (RIBA). These were a core protein, designated c22-3, and an NS3 protein, designated c33c. Antibodies to these new epitopes generally appear much earlier than anti-c100-3, and the window period in which a donor might be seronegative has considerably narrowed. In an NIH prospective study, 41% of persons with HCV infection had specific antibody detected with second-generation assays within 10 weeks of exposure, 80% had antibody within 15 weeks, and all patients had antibody within 6 months.<sup>113</sup> Third-generation EIA tests added an HCV antigen from the NS-5 region and have shown a marginal increase in sensitivity with a further reduction of the window period of approximately 1 week compared with second-generation assays. Because this increment in sensitivity would have minimal benefit in disease prevention, the use of third-generation anti-HCV assays has not been mandated by the US Food and Drug Administration (FDA).

Antibodies, particularly to 5-1-1, c100-3, and E1, may disappear spontaneously, during immunosuppression, or after successful antiviral therapy. Antibodies to c22-3 and c33c rarely disappear from persons with chronic infection and only infrequently disappear even from persons with apparent recovery. However, a minority of patients who clear HCV RNA also lose anti-HCV over time and are termed seroreverters; in most persons, some HCV antibodies persist for long periods, perhaps for a lifetime. The prevalence of HCV antibody, found with second-generation EIAs and confirmed with RIBA, among US blood donors ranges from 0.2% to 0.4%. Similar rates have been observed in Europe and higher rates are seen in Japan and other Eastern nations. These rates among highly selected blood donors are underestimates of the prevalence in the general population, which is estimated to be around 1%.

Because of nonspecific reactivity, it is important to confirm EIA reactivity with a supplemental assay. The only licensed supplemental test is a recombinant immunoblot strip assay that displays the key epitopes in a linear format on a nitrocellulose strip. With second-generation assays, approximately 40% of

EIA-reactive samples are confirmed by RIBA in a low-risk blood donor setting. Among high-risk populations or EIA-reactive donors who have elevated ALT levels, the confirmation rate is much higher (60% to 80%). In the initially licensed supplemental assay, approximately 30% of EIA-positive samples were classified as indeterminate because only one band appeared on the strip. A third-generation RIBA replaces the recombinant proteins c22-3 and c100-3 with synthetic peptides representing only a portion of the respective coding regions and replaces 5-1-1 antigen with recombinant NS5. This format resolves many RIBA-2-indeterminate patterns. Approximately 60% of RIBA-2 indeterminates are negative with RIBA-3, whereas 20% are RIBA-3 positive and 20% remain indeterminate. Thus RIBA-3 resolves approximately 80% of RIBA-2 indeterminate results. There is good, but not absolute, correlation between a positive RIBA result and NAT documentation of HCV RNA. Patients who have resolved HCV infection are RIBA positive, but repeatedly NAT negative. In contrast, almost all anti-HCV-positive persons who are HCV RNA positive also are RIBA positive. An alternative to RIBA testing is to go directly from a positive EIA screening assay to amplification of the viral genome by NAT or other technique. If HCV RNA is detected, there is no need to perform RIBA. However, if HCV RNA is negative, the RIBA assay should be performed to distinguish HCV-recovered subjects from those with false-positive EIA reactivity.

### Molecular Assays for Detection of HCV RNA

The most sensitive way to detect HCV is measurement of HCV RNA by means of NAT or another gene amplification technique. The NAT has shown that HCV RNA is almost universally detected in the early phase of HCV infection, generally within 1 to 3 weeks of exposure. Thus, HCV RNA detection precedes the increase in serum ALT level, sometimes by as much as 10 to 12 weeks. It also has been shown by means of quantitative NAT or branched DNA assay that the highest levels of HCV RNA appear early in the course of infection, generally preceding or coinciding with the first significant elevation in ALT level.<sup>105</sup> In persons who appear to recover from HCV infection, HCV RNA generally declines or disappears near the time of the peak in ALT elevation. However, in at least 75% of persons, HCV RNA persists, generally with associated fluctuating ALT elevations, but up to 30% of infected individuals have persistently normal serum ALT. These relationships imply that infectivity is probably greatest before signs or symptoms of acute hepatitis develop, that chronic HCV infection is more frequent than is indicated by ALT elevations alone, and that a proportion of persons with HCV infection may be true asymptomatic carriers with normal serum ALT levels and minimal histologic abnormalities in the liver.

The extreme sensitivity of NAT techniques and the long seronegative window between the first detection of virus and the first detection of anti-HCV has prompted the introduction of NAT into routine donor screening. NAT testing has been universally implemented in US blood establishments and in most blood centers in developed nations. Nucleic acid testing is being performed by two primary methods—standard

reverse-transcription PCR and TMA. Transcription-mediated amplification offers two advantages in the blood bank setting because extraction and amplification take place in the same tube under isothermal conditions and because the test lends itself to a duplex configuration, whereby HIV and HCV RNA can be measured simultaneously. A triplex TMA assay that also detects HBV DNA has been developed, but testing for HBV DNA is not mandated by the FDA at this time. As indicated earlier, the routine use of NAT has generated a better understanding of the dynamics of HCV and HBV viremia. With serial stored collections from commercial plasma donors who subsequently are found to be HCV-infected, it has been shown that HCV RNA usually is undetectable until the level increases precipitously to reach peak levels over a brief interval. This phase of rapid acceleration has been termed the ramp-up phase, and it usually occurs 2 to 4 weeks after exposure. During ramp-up, the doubling time of the virus has been calculated to be 13 to 17 hours.<sup>114</sup> The pattern of HBV viremia differs in that the ramp-up is more delayed and not as steep and in that the ramp-up is preceded by a persistent low-level of viremia. During the period of low-level HBV viremia before the ramp-up phase, possibly infectious donations can be missed at MP-NAT testing, but detected with ID-NAT testing. The doubling time for HBV during the ramp-up phase is calculated to be 2.8 days.

Another distinction between HBV and HCV testing is that MP-NAT dramatically decreases the infectious window for HCV (60 days, an 85% reduction) compared with detection of antibody to HCV. In contrast, MP-NAT (minipool) testing for HBV DNA reduces the window by only 6 days (13%) compared to detection of HBsAg; ID-NAT (individual donor) for HBV would decrease the window by to 25 days (55%) compared to current HBsAg detection,<sup>114</sup> but newer, more sensitive HBsAg assays will narrow the window between detection of HBV RNA and detection of HBsAg to as little as 1 week. In essence, to have a significant effect on HBV transmission compared to current practice, one would have to implement ID-NAT testing. For HCV, MP-NAT testing seems sufficient in most instances. A serologic test for HCV core antigen has been developed<sup>115</sup> and has shown sensitivity similar to that of HCV MP-NAT testing. This test may be an option for blood establishments that have not committed to NAT technology.

### HCV Cell Culture

The holy grail of HCV research has been to develop an in-vitro culture system. After 15 years of failure, this crusade now has come to fruition, spearheaded by the groundbreaking work of Wakita and collaborators in Japan<sup>116</sup> and subsequently expanded by several investigative groups.<sup>117,118</sup> The groundbreaking event was the isolation of a clone, designated JFH-1, derived from a single patient in Japan with fulminant hepatitis caused by HCV genotype 2a infection.<sup>116</sup> This full-length genome replicated without modification in a hepatoma cell line designated Huh-7. Replication was indicated by the finding of HCV RNA and HCV antigens within cultured liver cells, the secretion of intact viral particles, and the ability to passage the virus in culture and to

chimpanzees. Thus far, only this single JFH-1 isolate or its chimeras have been shown to grow in Huh-7 and other hepatoma cell lines. No genomic or structural difference has been identified to account for JFH-1's unique growth characteristics, nor is it known whether its high replicative capacity in vitro relates to the development of fulminant hepatitis in the infected patient. In regard to the latter, clones from other patients with fulminant hepatitis have not grown in tissue culture, nor did JFH-1 cause fulminant hepatitis in the chimpanzee. Building on the discovery by Wakita et al, Rice and coworkers<sup>117</sup> constructed chimeras comprising the core to NS-2 region of the related genotype 2a clone, J6, and the nonstructural regions from JFH-1. This chimera grew very well in Huh-7.5 cells, spreading more rapidly and reaching higher infectivity titers ( $10^5$ ) than JFH-1. Serial passage was achieved without the loss of infectivity. Further, it was shown that virus replication was inhibited by interferon and by protease and polymerase inhibitors, demonstrating the value of this culture system for drug testing. Zhong,<sup>118</sup> in the Chisari lab, took this a step further by deriving an "interferon-cured" cell line designated Huh 7.5.1 that allowed very efficient release of virions with sustained infectivity titers of  $10^4$  to  $10^5$  IU/mL, about 50-fold higher than in the original Wakita experiments. It is postulated that a defect in the RIG-1 pathway of innate immunity may be the reason these cells are so permissive.

In sum, these three landmark studies published in 2005 demonstrated that 1) HCV virions could replicate in human hepatoma cell lines, could be serially and efficiently passaged, and that particles produced in vitro could transmit infection to chimpanzees at reasonably high titer; 2) the HCV virion is 50-60 nm in diameter, as previously predicted, but now directly visualized; 3) infectivity could be blocked by monoclonal antibodies to E2 and by patient sera, confirming that neutralizing antibodies to HCV exist and that E2 contains a key neutralizing epitope; 4) CD81, a membrane tetraspanin, is a critical component of the HCV entry pathway; and 5) infectivity could be blocked by interferon and protease/helicase inhibitors, demonstrating the suitability of this system for evaluation of candidate antiviral agents.

Because most HCV infections are genotype 1, it was critical to establish a culture system for this dominant genotype. In 2006, Yi and Lemon<sup>119</sup> produced adaptive mutations in the nonstructural regions of the prototype genotype 1 strain, H77, and transfected this adapted genome (H77-S) into Huh 7.5 cells. Although infectivity titers with H77-S were two logs lower than with JFH-1, the system is viable and now allows study of genotypic differences in an in-vitro system. Sera from genotype-1a-infected individuals neutralized H-77S virus, but could not neutralize genotype 2a virus, a finding that has implications for the development of therapeutic hyperimmune globulins and HCV vaccines.

### Mechanisms of Viral Persistence

#### Viral Quasispecies

The most striking feature of HCV is its ability to persist in the host. Measurements of HCV RNA in serum and liver suggest that the prevalence of persistent infection is higher than the

prevalence of chronic hepatitis and may be in the range of 75% to 85%. The mechanism of persistence appears to involve the ability of the virus to mutate rapidly under immune pressure and to exist simultaneously as a series of related but immunologically distinct variants, any one of which can become the predominant strain when a coexistent strain comes under immune pressure. This coexistence of multiple genetic variants has been termed "quasispecies." It provides an efficient and rapid mechanism for the virus to escape the host immune response. Although mutations occur throughout the HCV genome, most occur in a relatively short hypervariable segment of the envelope (E2) domain. This hypervariability suggests that this region contains important target epitopes that are under intense immune attack. Among HCV isolates, the average mutation rate is  $10^{-3}$  to  $10^{-4}$  base substitutions per genome site per year.<sup>120</sup> This high rate of mutation, reflected in the quasispecies nature of the virus and in the ability of HCV to rapidly evolve escape mutants, appears to be the primary mechanism underlying the absence of effective neutralization and the development of persistent infection. A study by Farci et al<sup>121</sup> showed that early in HCV infection, patients who ultimately recover have a decreased degree of viral diversity after the appearance of anti-HCV. In these persons, antibody or coexistent cell-mediated immune responses seem to contain viral replication and quasispecies formation such that the virus becomes increasingly homogeneous and is eventually cleared. In contrast, in most patients, the development of antibody appears to drive viral diversity until the population becomes so heterogeneous that it cannot be fully contained by the immune system.

Hepatitis C virus has evolved to become an efficient machine for survival. In this survival scheme, a master strain is accompanied by a series of subservient strains that under immune pressure can themselves become the master. Defective particles are formed that can protect replicative particles, and a low level of replication can allow the virus to both hide from the host and protect its environment by inducing disease so indolent that the cells that nurture the virus are well maintained or only incrementally destroyed. These efficient mechanisms for self-survival have allowed HCV to chronically infect approximately 1% of the world's population.

### Neutralizing Antibody and Cell-Mediated Immunity

There is little evidence that HCV is directly cytopathic. It is generally believed that liver damage is the result of the host's immune response, including CTLs, cytokines, and apoptotic factors. The immune response to HCV infection is brisk and yet generally ineffective in viral clearance. High titers of antibody coexist with high levels of virus. Antibodies broadly directed across the entire genome rarely have neutralizing potential. Those directed at the critical neutralizing epitopes in the viral envelope more often tend to drive viral diversity than to eradicate the agent. Nonetheless, neutralizing antibodies to HCV have been found in mixing experiments in which chimpanzee infectivity was used as the endpoint. These neutralizing responses, however, have been shown to be transient and highly

strain-specific.<sup>122</sup> Recently, pseudoviruses, consisting of a retroviral core, HCV envelope proteins and a green fluorescence protein marker, have been developed and allow for in-vitro measurement of neutralizing antibodies to HCV.<sup>123</sup> In this system, pseudoviruses infect an HCV susceptible hepatoma cell line (Huh-7) and infected cells fluoresce green. By premixing the pseudoviruses with serum suspected to contain antibody, neutralization can be measured by diminution of green fluorescence compared to controls. This system has shown that neutralizing antibodies are formed in HCV infection, but that they appear late in the acute infection and probably play a minimal role in viral clearance.<sup>124</sup> Paradoxically, neutralizing antibodies increase over time during chronic infection and also become more broadly reactive against multiple genotypes<sup>125</sup>; this broad, cross-reactive neutralization has now been demonstrated in virus culture assays as well as in the pseudovirus system.<sup>126</sup> It is presently unclear whether these neutralizing antibodies play a role in containing chronic infection even though they are incapable of clearing the virus. It is also unknown whether these late-developing neutralizing antibodies can be harvested to produce a clinically effective HCV-specific hyperimmune globulin. A protective HCV immune globulin would be a major weapon in preventing infection of transplanted HCV-naïve livers; reinfection of transplanted livers, presumably from extrahepatic HCV reservoirs, is now universal.

An expanding array of assays to measure in-vitro lymphoproliferative and cytotoxic (CTL) responses, including enzyme-linked immunospot (ELISPOT) assays, and tetramer assays, have elucidated the cellular immune responses to HCV infection.<sup>127</sup> It has been found that cell-mediated immune responses occur early (1 to 2 weeks) after the onset of infection. These initial responses involve innate immunity, primarily effected by CD56+ NK cells. Although the liver is particularly rich in NK cells, HCV has evolved mechanisms to bypass innate immunity. It is now clear that specific HCV proteins, particularly core and NS3, directly inhibit critical steps in the transcription cascade of the innate immune response, blocking upregulation of interferon regulatory factors and the generation of natural interferons.<sup>128</sup> This impaired innate immune response allows the virus to gain an early foothold such that HCV reaches very high levels of replication before generation of the adaptive immune response, forcing the cellular immune system to combat a massively expanding and rapidly evolving viral antagonist.

Results suggest that the Class II major histocompatibility complex restricted helper T-cell ( $T_H$ ) response is particularly important in determining the outcome of acute HCV infection.<sup>129</sup> Patients with acute, self-limited hepatitis C have been shown to mount an early, vigorous, and multispecific  $T_H$  response that can be measured in the peripheral blood. In contrast, if this  $T_H$  response is weak or poorly sustained, persistent infection and chronic hepatitis ensue. It appears that in most patients with HCV infection, the  $T_H$  response is blunted. In addition to the early stimulation of  $T_H$  responses, there is a corresponding HCV-specific CD8+ CTL response that is probably driven by cytokines (IFN, IL-2) released by  $T_H$ 1 lymphocytes.

Early, vigorous, and multispecific CTL responses have been associated with viral clearance and recovery from HCV infection. Conversely, in patients with persistent HCV infection, CTL responses are weak and targeted against fewer HCV epitopes.<sup>129</sup> Although patients with chronic HCV infection have blunted CTL responses to HCV, they have normal CTL responses to other viruses such as influenza and Epstein-Barr virus (EBV). Hence, there is no generalized immunodeficiency state, but rather a specific tolerance to HCV. The net effect is that the adaptive cell-mediated immune response appears to be blunted or exhausted in those destined to become chronic carriers. It has been debated whether the exhaustion of T cells is the result of, or the cause of, viral persistence, but recent data<sup>130</sup> have demonstrated that diminished HCV-specific T-cell responses occur early in HCV infection, suggesting that the failure of this critical immune response is central and causal to viral persistence.

Thus, several mechanisms are at play in the development of persistent HCV infection including the high mutability of the virus, inhibition of innate immunity induced by viral proteins, and the blunting or exhaustion of HCV-specific adaptive T-cell responses. Further, although the total number of virions produced is large, the number of viruses per cell is small. This small intracellular viral burden may decrease the display of viral antigens on the cell surface, blunt the lymphoid immune response, and protect the cell from immune destruction. There is little evidence that HCV is directly cytopathic, so it is probable that CTL and other immune responses while attempting to contain the virus also cause liver cell damage through a variety of mechanisms, including Fas-ligand apoptosis, cytokine-induced injury (including that from tumor necrosis factor  $\alpha$ ), and perforin-induced injury.<sup>127</sup> It has been shown that Fas is upregulated on HCV-infected hepatocytes and on uninfected bystander cells and that Fas ligand is expressed on activated liver-infiltrating T cells.<sup>127</sup> Such apoptotic cell death may account for liver cell destruction that is sometimes out of proportion to the number of cells actually infected. In contrast, IFN- $\gamma$  produced by CTLs can result in intrahepatic viral clearance without accompanying liver cell injury. The T-cell-mediated attack on the HCV-infected liver may lead to sufficient inflammation and fibrotic repair that cirrhosis develops. However, in most patients with HCV infection, an equilibrium develops in which ongoing viral replication and T-cell- and cytokine-mediated cell destruction are balanced by controlled hepatic regeneration such that chronic hepatitis develops without progressive fibrosis and without impairment of liver function.

## Epidemiology

Although HCV was discovered through investigations of transfusion-transmitted hepatitis, transfusion was never the primary source of transmission and currently is only a minor mechanism for dissemination of this agent. Nonetheless, therapeutic blood transfusion is the prototype for parenteral (percutaneous) transmission of viral agents. Such percutaneous spread is defined by the intravenous infusion of contaminated blood

components or drugs or by the shared use of contaminated needles or other sharp instruments. Studies of HCV-infected blood donors showed that 27% were infected as the result of blood transfusion in the pretesting era before 1990, whereas 42% were infected by intravenous drug use (IVDU) with shared needles.<sup>131</sup> It is noteworthy that none of the blood donors in this study were drug addicts, but rather persons who experimented with drugs in their youth and generally for intervals of less than 5 years. Sharing of needles was almost universal. It is also noteworthy that there was an independent cohort who snorted cocaine and repeatedly denied IVDU. While the veracity of this denial cannot be proved, the statistical association of cocaine snorting with HCV infection is exceedingly high and substantiated in a multivariate analysis.<sup>131</sup> Further, approximately 25% of cocaine snorters provided a history of experiencing nosebleeds while snorting or observing nosebleeds in those with whom they shared snorting devices, thus providing a rationale for blood transmission by this covert route. Other routes of overt or covert blood transmission include improperly sterilized, reusable needles and dental instruments, particularly in developing nations, but also in the developed world in the decades before 1970. Although it is now difficult to prove, tattooing with shared needles or inks undoubtedly contributed to viral spread as did ritual scarification practices in native populations. Although rare transmissions have been traced to chronically infected health-care workers, the main health-care burden has been the reutilization of unsterilized needles and contaminated instruments, including early dialysis machines and inadequately sterilized diagnostic instruments such as colonoscopes and bronchoscopes. It is important to keep in mind that HCV infection requires only one exposure to result in a lifelong infection and that most of those now found to be HCV-infected were actually exposed 20 to 50 years ago when health care and transfusion practice were markedly different than they are today. Thus, our current HCV-related disease burden is primarily the residual of past parenteral spread that, except for IVDU, essentially has been interdicted in the developed world. IVDU, however, remains unchecked and has been the primary source of HCV infection since proliferation of the drug culture in the 1960s. It is conceivable that if the practice of shared-needle IVDU was eradicated, HCV infection would ultimately disappear among populations in developed countries.

Although parenteral routes are the predominant modes of HCV transmission, a parenteral source cannot be identified in up to one-third of infected individuals. This does not rule out covert parenteral exposures, but has raised the possibility of nonparenteral modes of acquisition. The CDC has conducted comprehensive epidemiologic studies of community-acquired HCV infection in four selected (sentinel) counties in the United States.<sup>132</sup> The sentinel counties studies initially revealed that among patients with clinically overt NANB hepatitis, only 15% gave a history of blood transfusion, 25% used intravenous drugs, fewer than 10% were in health-related fields or had a presumed sexual or household contact, and more than 50% had no known route of exposure to this agent. More recent evaluations<sup>133</sup> have

shown that fewer than 1% of cases of community-acquired hepatitis are related to transfusion, further demonstrating the effectiveness of donor screening measures implemented since 1990. The precise routes of nonparenteral transmission of hepatitis C remain an enigma even in the face of sensitive serologic and molecular assays for HCV. There is evidence that HCV, like HBV and HIV, has a sexual and perinatal, as well as parenteral, route of transmission. However, HCV is much less efficiently spread by these nonparenteral routes than are HBV and HIV. The CDC has implicated sexual transmission in up to 10% of acute, clinically apparent hepatitis C cases based on the absence of an identified parenteral source and on a history of having had sex with more than two sexual partners in the preceding 6 months or having had sex with a prostitute or having a recent history of a sexually transmitted disease. In contrast, the sexual partners of patients with chronic HCV infection are very rarely infected despite years of unprotected sex.<sup>131</sup> This paradox might be explained by the fact that HCV may be more transmissible early in HCV infection when viral titers are higher and when the virus is more likely to exist as free virions rather than complexed to antibody. In the final analysis, it is probable that HCV can be spread sexually, but that such spread is very inefficient and more likely to occur early in the course of infection. Because sexual transmission is rare, particularly during chronic infection, there is no mandate that committed, monogamous partners should routinely use condoms or other protective devices; rather, the probabilities and potential risks should be presented to affected couples and the decision for condom use left to their discretion. Perinatal transmission of HCV is also inefficient, but has been documented to occur in about 5% of cases where the mother is HCV RNA positive at the time of delivery.

## Clinical Spectrum of Hepatitis C Virus Infection

### Acute Manifestations

Only 25% of acute hepatitis C cases present with jaundice or substantial clinical symptoms; subclinical cases generally remain undetected until uncovered by the incidental finding of elevated ALT levels or anti-HCV during the course of blood donation or general medical/surgical evaluation. Long-term observation in prospective studies has revealed that asymptomatic acute hepatitis has the same propensity to evolve into chronic liver disease, including cirrhosis, as do the more overt cases. Thus, silent TAH may have major clinical significance. Although patients with HCV rarely have sufficient symptoms to seek medical care, individual cases can be acutely severe and even fulminant. However, fulminant hepatitis is an exceedingly rare complication of hepatitis C.

Three major patterns of elevation of ALT level have been observed in hepatitis C—monophasic, polyphasic (fluctuating), and plateau.<sup>134</sup> The monophasic pattern involves a single acute phase peak followed by complete normalization of ALT level. The polyphasic pattern is the most characteristic and includes dramatic fluctuations of ALT level over brief intervals. Over time, the amplitude of the fluctuation diminishes, but the periodicity persists into chronicity. In the plateau pattern, a relatively constant and generally low-level ALT abnormality is observed in the

acute and chronic phases of the disease. Such patients often have biopsy evidence of chronic liver disease early in the posttransfusion course. These patterns have prognostic implications. In one study,<sup>134</sup> 42% of patients with a monophasic peak progressed to chronic hepatitis, compared with 87% of patients with the fluctuating pattern and 95% of patients with the plateau pattern. Levels of ALT occasionally normalize for prolonged intervals that suggest recovery, but are followed months to years later by secondary elevations that indicate the presence of chronic liver disease. This prolonged normalization of ALT level followed by recrudescence makes it difficult to ascertain when, or if, biochemical recovery from HCV infection has occurred. The best current assessment of recovery from HCV infection is serial measurement of HCV RNA. Three negative determinations of HCV RNA over the course of 3 to 6 months generally connote sustained clearance of the virus and full recovery from the infection.

### Chronic Sequelae

The most important component of HCV infection is its ability to evolve into chronic hepatitis, cirrhosis, and more rarely, HCC. Long-term follow-up evaluation of transfusion-associated cases indicates that at least 50% of patients contract chronic hepatitis as evidenced by elevations in ALT level that persist longer than one year. More recent data indicate that chronic hepatitis may occur in nearly 70% of cases. Similar frequencies of chronic hepatitis have been documented among community-acquired cases of hepatitis C.

In eight early studies, 339 patients with transfusion-associated NANB hepatitis underwent prospective observation; 47% had biochemical evidence of chronic hepatitis.<sup>81</sup> Of 102 patients who underwent biopsy, 41% had chronic active hepatitis and 20% had cirrhosis; five of the 20 patients with cirrhosis died of liver disease. Subsequent studies in which serial liver biopsies were performed provided unequivocal documentation of the progression of histologic abnormalities from acute to chronic hepatitis to cirrhosis.<sup>135-138</sup> In summary, numerous studies of transfusion recipients have revealed the following: 1) at least 50% of patients with acute hepatitis C eventually have biochemical evidence of chronic hepatitis; 2) approximately 20% of patients with chronic hepatitis C have biopsy evidence of cirrhosis; 3) progression from acute hepatitis to cirrhosis can be documented histologically and generally evolves slowly over the course of decades but sometimes can occur more rapidly, the mean time to the development of cirrhosis being approximately 20 years; 4) the progression to cirrhosis is enhanced in patients with HCV infection who abuse alcohol—the cumulative effect of alcohol and HCV infection is more than additive, and the risk of cirrhosis may be 15-fold higher among persons who abuse alcohol than among persons with HCV infection alone<sup>139</sup>; and 5) when HCC occurs, it is almost always in patients with established cirrhosis—the risk of development of HCC among patients with cirrhosis has been estimated to be 1.7% per year.<sup>140</sup>

The foregoing considerations allow a schematic depicting the typical course of acute resolving and chronic hepatitis C (Fig 46-4). The essential features of viral replication, humoral immune responses, hepatocellular inflammation, and clinical

**Figure 46-4.** Biochemical, serologic, and molecular biologic profile of acute and chronic transfusion-associated hepatitis C virus (HCV) infection. Acute, resolving hepatitis C is shown in (A) and chronic hepatitis C in (B). Resolving disease cannot be differentiated from progressive disease by the time of onset of detectable HCV RNA by means of polymerase chain reaction (PCR), the magnitude of HCV RNA elevation as measured by means of branched DNA assay, the interval to the first elevation in the level of alanine aminotransferase (ALT), the magnitude of ALT elevation in the acute phase, or the interval between exposure and the first appearance of antibody. Progression to chronic disease cannot be predicted in the acute phase, and the only distinguishing features in these patterns are the persistence of ALT elevation and the persistence of HCV RNA in persons with chronic hepatitis C. The acute, resolving pattern (A) occurs in 10% to 15% of patients with transfusion-associated hepatitis C and the chronic pattern (B) in 85% to 90%. Note: 1) HCV RNA is detectable soon after exposure. Here the PCR results was positive 2 weeks after exposure, but it can become positive even sooner. 2) HCV RNA may be detected by means of branched DNA assay coincident with PCR reactivity, but the reaction may be delayed, as shown here. 3) The major

peak of viral replication (assessed with HCV RNA level) occurs before the first increase in ALT level and before any clinical or biochemical evidence of hepatitis; it is presumed that persons might be most infectious in this interval before the acute phase. 4) In acute resolving infection, HCV RNA levels increase rapidly before the decline in serum ALT level. 5) In chronic infection, HCV RNA level diminishes and can remain low, fluctuate, or become undetectable; HCV RNA levels sometimes show a periodicity that parallels the fluctuations in ALT level; in (B) the level of HCV RNA increases a short time before ALT level does and decreases before the decline in ALT. 6) Second-generation anti-HCV assays shorten the seronegative window in HCV infection much more than do first-generation assays; nonetheless, anti-HCV was not detectable for 12 to 15 weeks after exposure and for 6 to 7 weeks after the first significant rise in ALT level. Antibody to HCV (detected with second-generation assays) almost always persists in chronic cases and generally persists in acute resolving cases. Antibodies detected with the first-generation assay (anti-C100, anti-5-1-1) generally disappear in resolving cases. (Used with permission from Alter.<sup>105</sup>)

outcome are described earlier and in the legend to Fig 46-4. These are representative diagrams of classic cases—there is considerable variability in these patterns from case to case. The most consistent features are that viral replication can be detected soon after exposure, that peak viremia occurs in the acute or preacute phase in patients who recover and in those who have chronic hepatitis, and that progression to chronic hepatitis cannot be predicted by the time of onset or the peak level of viremia.

Untoward occurrences among recipients of standard blood transfusion are exaggerated in recipients of clotting factor

concentrates. Before recent inactivation procedures were developed, such concentrates, derived from massive pools of paid blood donors, were invariably contaminated with HBV and HCV. Overall, more than 50% of patients with hemophilia have ALT elevations and serologic results that suggest chronic hepatitis C.<sup>141</sup> That proportion increases to 80% among patients with severe hemophilia who received clotting factor concentrates before virus inactivation.<sup>142</sup> In a landmark multicenter study,<sup>142</sup> liver biopsy specimens from 155 patients with hemophilia and chronic elevations in ALT level revealed cirrhosis in 15% and

severe chronic active hepatitis, likely to progress to cirrhosis, in an additional 7%. Similar severe outcomes were found in a subsequent prospective study in England<sup>143</sup> wherein 71% of 79 patients with hemophilia had persistent abnormalities in ALT level, 25% of the 34 patients who underwent biopsy had cirrhosis, and 12% had radiographic evidence of esophageal varices. One patient died of complications of portal hypertension. Before AIDS, chronic liver disease accounted for 5% to 11% of deaths in patients with hemophilia. The advent of AIDS has further complicated the course of hepatitis C in this population. It is now evident that HIV infection accelerates the course and increases the severity of coexistent HCV infection.<sup>144</sup> Now that patients with HIV infection have long survival because of highly active antiretroviral therapy, severe liver disease is emerging as a major cause of morbidity and mortality among patients with HCV and HIV coinfection.

In Japan, where hepatitis C is common and where a similar progression from acute to chronic hepatitis has been well documented, it has been possible to examine the role of blood transfusion in the development of chronic liver disease. Kiyosawa et al<sup>145</sup> found that among patients with chronic hepatitis and cirrhosis, presumably related to hepatitis C (then designated NANB hepatitis), 44% and 38% of patients, respectively, had a history of previous transfusion. In HCV-related chronic liver disease, a history of transfusion was 6 to 12 times more frequent than in HBV-related disease. This finding suggested a causal relation in the former, but less so in the latter, where the virus tends to be transmitted more readily by sexual and maternal-fetal routes. Another important observation in the study of Kiyosawa et al was the long interval between transfusion and the first clinical manifestations of chronic liver disease. The mean interval from transfusion to the clinical recognition of chronic hepatitis was 11.3 years; to the development of overt cirrhosis, 21.2 years; and to the development of clinically apparent HCC, 29.0 years.<sup>145</sup> These long intervals may account for the apparent disparity between the number of expected cases of transfusion-associated cirrhosis and the number of cases actually detected; because patients who undergo transfusion tend to be elderly, many die of an underlying illness before chronic liver disease becomes clinically evident. Such intercurrent deaths obscure the course of this slowly evolving disease and mask the possible effect of HCV-related chronic hepatitis and cirrhosis on younger blood recipients.

Infection with HCV can unequivocally lead to HCC.<sup>146</sup> In a composite of prospective studies, it appears that the overall incidence of HCV-associated HCC is 1% to 5%. However, once cirrhosis develops in chronic hepatitis C, the risk of developing HCC is about 4% per year. Currently, the rate of HCV-related HCC is relatively low in Western nations and relatively high in Japan. Okuda et al<sup>147</sup> conducted a study of 113 patients with nonalcoholic HCC and found that 69% of the cases of HCC were HBsAg negative and presumably related to HCV infection, as subsequently documented by serologic testing.<sup>148</sup> The disparity between the frequency of HCV-related HCC in the United States and Japan probably reflects the duration of infection in the

respective populations. Calculations using the molecular clock methodology suggest that the major spread of HCV in Japan preceded that in the United States by 30 to 40 years.<sup>149</sup> Hence, the infected population in Japan is decades older and their duration of infection places them at increased risk of HCC evolution. It is anticipated that as the duration of infection in Western populations increases, the rates of HCC will increase concomitantly and hence that many more cases will be observed in the next 2 to 3 decades unless chronic HCV carriers can be successfully treated in the interim.

The long-term consequences of TAH were comprehensively studied by Seeff et al.<sup>150</sup> Patients who had TAH in five major prospective studies conducted in the 1970s were traced after a mean interval of 18 years and prospectively evaluated for evidence of chronic hepatitis. Over this interval, there was no increase in overall mortality among patients who sustained an episode of TAH compared with controls who underwent transfusion and did not have an episode of TAH. Although the mortality was not different, 35% of patients with previous episodes of hepatitis had biochemical and histologic evidence of chronic hepatitis compared to 1% of controls. The results of this study were subsequently updated to a mean follow-up period of 23 years.<sup>151</sup> Overall mortality was similar among patients with hepatitis and control subjects without hepatitis, but patients with hepatitis had a small, but significant increase in liver-related mortality (4.1% vs 1.3%;  $p = 0.05$ ). Among 103 patients with positive results for anti-HCV in 1974, 76% were still anti-HCV positive and HCV RNA-positive approximately 20 years later. An additional 17% had specific anti-HCV but no longer had viremia, suggesting they had spontaneously cleared the infection. A surprising finding was that 7% of patients had no residual markers of HCV infection, suggesting they not only had cleared the virus, but also had lost anti-HCV. Hence, prevalence estimations based on serologic status may underestimate the extent of HCV infection in the population. More important, this study showed that the spontaneous clearance rate of HCV infection may exceed the commonly accepted estimate of 15% and actually be between 20% and 25%. In a separate study of longer duration, Seeff et al<sup>152</sup> found that only 1 of 17 persons with chronic HCV infection had died of liver disease in the nearly 50 years after their HCV infection was first documented.

Milder outcomes of HCV infection have been observed in studies of asymptomatic blood donors found to be anti-HCV positive at the time of donation. In an NIH study,<sup>131</sup> 15% of donors appeared to have spontaneously cleared HCV infection on the basis of the presence of RIBA-confirmed anti-HCV and repeatedly negative determinations for HCV RNA. Among those with persistent HCV infection, the peak ALT level exceeded two times the upper limit of normal in only 16%, and clinical symptoms were minimal. Liver biopsy was performed on 94 patients. No patients had severe inflammatory changes, 13% had stage 3 or 4 fibrosis, and only 2% had cirrhosis after an average duration of infection of 19 years on the basis of a defined parenteral exposure. Repeated liver biopsies were performed 5 years later on

60 of these patients. Fibrosis progression over that interval was minimal; no new cases of cirrhosis were found even when the follow-up was extended to a mean of 24 years.<sup>153</sup>

Three additional long-term outcome studies also suggest relatively mild outcomes in chronic HCV infection. Kenny-Walsh<sup>154</sup> performed a 17 year follow-up study of 376 women with HCV infection from a contaminated lot of Rh Immune Globulin (RhIG). Liver biopsies were performed on 363 patients a mean of 17 years after exposure; only 4% had moderate to severe grades of inflammation. Periportal fibrosis (stage 1) was found in 34% of patients; bridging fibrosis (stage 3) in 15% and cirrhosis in only 2%; 49% had no fibrosis. Two of seven patients with cirrhosis also had a history of alcohol abuse. A similar study in Germany<sup>155</sup> enrolled 152 women with HCV infection traced to contaminated lots of RhIG and found that none had cirrhosis or severe fibrosis after a mean follow-up period of 15 years. Further supporting mild outcomes of HCV infection, a 20-year follow-up study<sup>156</sup> of children who were infected at the time of heart surgery revealed that 45% had spontaneously recovered based on the findings of RIBA-confirmed anti-HCV and persistently negative assays for HCV RNA. Among the children with viremia who underwent biopsy, only two of 17 had portal fibrosis and only one had cirrhosis 20 years after exposure. The one patient with cirrhosis also had chronic HBV infection.

There is a paradox in the course of HCV infection. If one studies patients who already have evidence of severe liver disease, it is evident that HCV is responsible for the majority of cases. From this perspective, HCV projects as a frequent cause of cirrhosis, end-stage liver disease, and HCC. On the other hand, if one prospectively evaluates cohorts of persons with HCV infection, a more balanced picture emerges. First, as indicated above, a minimum of 15%, and possibly as high as 25% of infected adults spontaneously recover from HCV infection, usually within the first year after onset. The rate of recovery among children with HCV infection is even higher, reaching 45% in a retrospective-prospective study conducted in Germany.<sup>156</sup> It is now also apparent that in the absence of alcohol abuse or coexistent HIV infection, chronic hepatitis C is generally an indolent process in which severe outcomes may never occur or may take decades to evolve. Most adults who undergo transfusion die of the disease for which they were transfused or of an intercurrent illness before the potentially fatal complications of chronic hepatitis C become manifest. Nonetheless, over the span of 20 or more years, 20% to 30% of patients with HCV infection may have histologic evidence of cirrhosis that can ultimately lead to liver failure and the need for liver transplantation. That the majority of patients with HCV infection spontaneously recover or have a nonprogressive form of chronic liver disease gives hope to the individual patient; however, this does not diminish the global impact of HCV infection engendered by the sheer magnitude of the population that is infected. On a global scale, the absolute number that face life-threatening events related to HCV is staggering even if the proportion that encounter these events is encouragingly small.

## Treatment

The last decade has seen marked advances in the treatment of hepatitis C and new classes of drugs are in the pipeline. The foundation of therapy since the inception of treatment has been IFN- $\alpha$ , but the introduction of combination therapy with ribavirin and subsequently, the use of pegylated interferon have been the innovations that have increased sustained efficacy from approximately 10% in the early 1990s to near 50% at present.<sup>157</sup> The efficacy of treatment is assessed by the sustained loss of HCV RNA. During treatment, four patterns of HCV RNA response are observed: 1) **Non-response** wherein HCV RNA levels do not fall or are only minimally reduced during therapy; 2) **Breakthrough** wherein a good initial response is followed by a return of HCV RNA to original levels despite continued therapy; 3) **Relapse** wherein HCV RNA becomes undetectable during therapy, but then rebounds to initial levels soon after therapy is discontinued; the main benefit of ribavirin is its ability to prevent this virologic relapse; 4) **Sustained virologic response (SVR)** wherein HCV RNA becomes undetectable during therapy and remains undetectable at least 6 months after the cessation of therapy. Considerable evidence now shows that a sustained virologic response is tantamount to “cure” because long-term follow-up studies have not shown recrudescence of infection beyond 6 months after therapy is terminated. Serial measurements can be used early after initiation of therapy to assess the likelihood of response. Those who have a more rapid early response are more likely to have a sustained response.<sup>157</sup> There are several parameters that predict treatment outcome, but none are absolute. In general, higher response rates are seen in females, in those less than age 40, in those of European ancestry compared to those of African ancestry, in the nonobese and in those with viral loads less than 2 million copies/mL. In addition, persons with severe liver disease, particularly cirrhosis, and those with immunodeficiency, particularly HIV infection with CD4 counts  $<200 \text{ mm}^3$ , are less likely to respond. However, none of these parameters are a contraindication to treatment and their value lies in predicting the probability of response. The main determinant of virologic response is the viral genotype; SVR in persons who test positive for genotype 1 or 4 approximates 45% to 50% with combined IFN- $\alpha$  and ribavirin, whereas patients with genotype 2 or 3 infection have an approximate 80% sustained virologic response. In addition, patients with genotype 2 or 3 infection have to be treated for only 6 months compared to a 1-year course for those with genotypes 1 and 4.<sup>157</sup> Hence, it is essential to obtain a viral genotype before initiating therapy. Another important treatment guideline is that treatment can be stopped after 3 months in persons whose viral load has failed to become undetectable by that time; the continued presence of virus in the peripheral blood 3 months after initiation of therapy is highly predictive of treatment failure.

In summary, the combined use of pegylated IFN- $\alpha$  (180  $\mu\text{g}$ /wk, subcutaneously) and weight-based dosing of ribavirin (800–1200 mg/day, orally) will result in an approximate 50% SVR for genotypes 1 and 4 and an approximate 80% SVR for genotypes 2 and 3. These treatments have multiple side effects that are

often poorly tolerated. Interferon can cause flu-like symptoms, marked fatigue, mood changes (particularly depression and irritability), hair loss, anorexia, nausea and vomiting, thyroid dysfunction (generally hypothyroidism) and cytopenias, particularly thrombocytopenia and leukopenia. All these side effects, except those involving the thyroid, are reversible upon cessation of therapy. Cytopenias may necessitate dose reduction or cessation of interferon therapy. The primary serious side effect of ribavirin is hemolytic anemia. This can be offset by administration of erythropoietin, but often requires dose reduction or discontinuation of this arm of the therapy. The mechanisms of interferon's and ribavirin's antiviral effects are diverse and not completely understood, but they are general antiviral agents and not HCV-specific therapies. Under development are several drugs that are specifically directed to critical steps in the HCV life cycle, including inhibitors of HCV protease and helicase enzymes. Early evidence indicates that this class of virus-specific enzyme inhibitors are very potent and can decrease viral loads rapidly.<sup>158</sup> However, as with similar inhibitors for HBV and HIV, resistance develops rapidly and hence these drugs will not be given singly, but rather in combination with interferon, interferon plus ribavirin, or with each other. It is probable that interferon will remain the backbone of HCV therapy and that these new designer drugs will be additive rather than replacements. It is anticipated that under these new combination regimens, treatment efficacy will increase significantly, but the substantial side effects of interferon will remain and side effects of the new agents will be added. It is hoped that the anticipated additive efficacy of these new therapies will offset their side effects and resistance patterns, especially because the drug cocktails may need to be given for only 6 months. Many other therapeutic approaches, including small interfering RNAs, are under investigation and the ability to study new agents has been enhanced, not only by increased knowledge of the structure of the virus, but also by the recent availability of in-vitro culture systems<sup>116-119</sup> and the chimeric severe combined immunodeficiency (SCID) mouse model that harbors human hepatocytes.<sup>159</sup> Last, the potential for liver transplantation is increasingly available for those who fail antiviral therapy and progress to end-stage liver disease. Although the transplanted liver is universally reinfected, the 5-year survival for liver transplantation now approximates 70%.<sup>160</sup> Nonetheless, in a subset of transplant recipients, recurrent hepatitis C is severe and cirrhosis may develop in as little as 3 to 5 years.<sup>161,162</sup> The main impediment to liver transplantation is not graft or patient survival, but rather cost and the inability to procure a sufficient number of viable livers for the very large population that has developed, or subsequently will develop, HCV-related end-stage liver disease that is not amenable to current drug therapies.

### Non-A, Non-B, Non-C Hepatitis

Within the spectrum of TAH, cases were identified that met the biochemical and exclusionary definition of NANB hepatitis,

but were subsequently shown to be negative for serologic and molecular markers of HAV, HBV, and HCV infection. Such cases have been termed non-A, non-B, non-C hepatitis and have been assumed to be the consequence of another, as yet undiscovered, human hepatitis virus. However, such cases could also be the result of a known hepatitis agent present at levels below the detection limit of current assays, or be of nonviral origin. After more than a decade of intensive investigation, and despite many published and unpublished claims of discovery, a non-A, non-B, non-C human hepatitis agent has yet to be conclusively identified.

Evidence for the existence of more than one NANB hepatitis agent initially derived from the clinical observation of more than one episode of HBV- and HAV-negative hepatitis occurring in the same patient<sup>163</sup> and the observation that some episodes of NANB hepatitis among persons with hemophilia occurred after an unusually short incubation period.<sup>164</sup> Results of early chimpanzee cross-challenge studies further supported the existence of two NANB agents.<sup>165</sup> One of these agents proved to be HCV, and the other is still undefined. Confounding the issue of whether there are additional NANB agents is the observation that both humans and chimpanzees can sustain more than one episode of HCV infection.<sup>166</sup> Thus, what appeared to be two episodes of NANB hepatitis may instead have been two distinct episodes of hepatitis C. Nonetheless, 10% to 30% of cases of chronic NANB hepatitis cannot be accounted for by HCV infection, and most cases of fulminant hepatitis and hepatitis-associated aplastic anemia appear to be unrelated to hepatitis viruses A, B, or C, suggesting the existence of an additional agent of hepatitis in humans.

Encouraged by the blind cloning of HCV, investigators have used sophisticated molecular approaches to search for the agent or agents of non-A, non-B, non-C hepatitis. This has led to the sequential discovery of the GB virus<sup>167</sup> the hepatitis G virus,<sup>168</sup> the TT virus,<sup>169</sup> and the SEN virus.<sup>170</sup> None of these agents has yet been proven to be a hepatitis virus in humans, but each has been shown to be transmitted by transfusion and to result in persistent infection in some blood recipients. The GB agent derives from the blood of a surgeon (G.B.) who in the 1950s contracted acute icteric hepatitis. Inoculation of GB serum into marmosets reproducibly caused hepatitis, but controversy arose as to whether this represented transmission of a human hepatitis agent or reactivation of a latent marmoset hepatitis virus. The controversy was never resolved. Decades later, investigators at Abbott Laboratories analyzed frozen samples that had been collected during serial passages of the GB agent in the marmoset model. Using representational difference analysis to compare preinoculation and postinoculation marmoset serum,<sup>167</sup> the investigators identified unique nucleic acid sequences in the postinoculation specimens.<sup>171</sup> Sequencing of the full genome identified three distinct GB agents that were designated GBV-A, GBV-B, and GBV-C.<sup>171</sup> The genomic structure identified these agents as flaviviruses, but the agents showed little homology to HCV or other members of that family. Extensive population studies involving

patients with and without liver disease and studies of marmosets established that GBV-A was a primary marmoset agent, that GBV-C was a human virus, and that GBV-B might infect both species.

In independent investigations, Gene Labs (in collaboration with NIH) and the CDC, used sequence-independent single primer amplification to identify what was considered a novel hepatitis agent and called the hepatitis G virus.<sup>168</sup> Subsequent sequence comparisons revealed that GBV-C and HGV were essentially the same agent and represented strain variants of this new member of the *Flaviviridae* family. Although GBV-C/HGV was unequivocally found to be transmitted by transfusion, extensive clinical studies did not show a causal relation between the presence of the virus and the development of hepatitis.<sup>172</sup> The designation hepatitis G virus now appears to be a misnomer; it would be better to refer to this agent as the GB virus because that designation does not infer causality.

In 1997, Nishizawa et al<sup>169</sup> in Japan used representational difference analysis to compare pre- and posthepatitis sera from five patients with TAH. A unique viral clone was found in three of the five cases of TAH studied, and viral titers generally correlated with the ALT level. The presumed virus was designated TT virus after the initials of the index case. Biophysical characterization<sup>173</sup> suggested that TT virus was a novel, 3700 bp, nonenveloped, circular, single-stranded human DNA virus most closely related to the *Circoviridae*, a family of plant and animal viruses not previously associated with human disease.<sup>174</sup> The TT virus family is highly divergent and at least 16 genotypes have been identified.

The TT virus has been reported to replicate in the liver based on PCR detection and in-situ hybridization.<sup>175</sup> However, there were no morphologic changes in the liver cells that showed hybridization signals, and there was no correlation between the percentage of TT-virus-infected hepatocytes and the histologic activity index or its composite scores. Although the TT virus can infect liver cells, it may not cause hepatitis. Epidemiologic studies have shown that TT virus is transmitted by both parenteral and enteral routes. The original studies of TT virus suggested a relation to acute and chronic liver disease, but subsequent studies with inclusive primers that targeted conserved sequences showed an exceedingly high background prevalence (93%) and thus established that most persons with TT virus infection did not have hepatitis.<sup>176</sup>

Matsumoto et al<sup>177</sup> studied TT virus infection in the transfusion setting using the more restrictive primers used in the original publications. The background prevalence in the volunteer US donor population was 7.5%. The key finding of this NIH study was that the frequency of transfusion-associated TT virus infection was identical among patients with non-A–E hepatitis (see later) (23%) and control patients who did not have hepatitis (22%). Overall, fewer than 4% of TT virus infections were associated with hepatitis, and there was poor correlation between TT virus DNA levels and ALT levels. Hence, as had occurred in investigations of HGV, the NIH prospective series did not support a causal association between TT virus infection and

posttransfusion hepatitis. However, there are caveats to the interpretation that the TT virus lacks pathogenicity in that the agent may cause disease in only a small number of infected persons who have particular host susceptibility factors or there may be particular TT virus variants that are pathogenic while the wild-type virus is not.

Many other isolates subsequently were identified in the TT virus family, including agents designated SANBAN, YONBAN, and TLMV.<sup>178</sup> Each of these agents is phylogenetically distant from the prototype TT virus agent and shows only 50% to 60% sequence homology. Unlike HCV variants that primarily represent strain differences of 1% to 2% (quasispecies) or genotypes diverging by approximately 15%, in the TT virus family, sequence differences between variants frequently exceed 30% and sometimes exceed 50%. These differences are so great that the agents, although linked by common biophysical characteristics, may have totally different clinical spectrums and disease associations.

A virus detection program conducted by the Diasorin Corporation (Stillwater, MN) uncovered what was at the time considered a novel infectious agent and designated SEN virus for the initials of the patient in whom it was initially found. Like TT virus, SEN virus proved to be a small, nonenveloped, circular, single-stranded DNA virus.<sup>179</sup> The SEN virus represented a subfamily of very heterogeneous agents differing in nucleotide sequences by 15% to 50% from each other and by 40% to 60% from the prototype TT virus sequence. The SEN virus is now considered a member of the TT virus family in the genus *Circoviridae*.

The clinical significance of SEN virus is uncertain. Two SEN virus variants, designated SENV-D and SENV-H, have been extensively studied.<sup>179</sup> SENV-D and -H were found in 1.5% to 2% of volunteer US donors and were shown to be transfusion transmitted. They were present in 40% of 155 subjects who underwent transfusion but in only 3% of 97 control subjects who did not undergo transfusion ( $p < 0.0001$ ).<sup>179</sup> A significant relationship of infection to transfusion volume was observed, and donor-recipient linkage was established by means of sequencing. It is noteworthy that new SEN virus infections occurred in 3% of patients who did not receive transfusions. This finding suggested that, as with TT virus, there was nosocomial transmission or reactivation of latent virus.

In the NIH prospective study of TAH,<sup>179</sup> 13 cases of non-A–E hepatitis were found. One of these patients was infected with SEN virus before transfusion. Among the remaining 12 susceptible recipients, 11 (92%) became SENV-D or SENV-H positive after transfusion. There was a good, although imperfect, temporal association between the level of virus and the level of elevation of ALT value. In contrast, acute SEN virus infection was found in 24% of patients who underwent transfusion but did not have hepatitis ( $p < 0.0001$ ). Despite the strong statistical link to cases of transfusion-associated non-A-E hepatitis, it was projected that no more than 5% of cases of SEN virus infection were accompanied by biochemical evidence of hepatitis.

Further, there has been no significant association between SEN virus infection and acute liver failure or cryptogenic cases of chronic hepatitis, cirrhosis, or HCC. If SEN virus is a hepatitis agent, it causes disease in only a small number of infected individuals, the difference perhaps depending on host susceptibility, viral load, or immune responsiveness. A parallel might be drawn to viruses such as cytomegalovirus or EBV that also cause disease in only a small number of infected persons. Nonetheless, it is important to emphasize that the statistical association between SEN virus infection and TAH does not establish causality. There is currently no proof that either GB virus, TT virus, or SEN virus represents the elusive agent of non-A, non-B, non-C hepatitis.

An epidemic form of NANB hepatitis has resulted in massive outbreaks, most prominently in India, other parts of the Asian subcontinent, and South America.<sup>180,181</sup> These explosive outbreaks are waterborne and epidemiologically resemble HAV infection, but they are serologically and to some degree clinically distinct. Particles ranging from 27 to 38 nm have been associated with the epidemic form of NANB hepatitis and a specific serologic assay has been developed.<sup>182</sup> This form of hepatitis is now known to be caused by a distinct RNA virus designated hepatitis E virus (HEV) and to be classified in the family of *Caliciviruses*. Although HEV was first recognized in its epidemic form, it is endemic in many areas of the world and is probably maintained in animal hosts, particularly swine. An HEV vaccine has been developed, but not yet widely applied.

Thus, the characterized human hepatitis viruses range from A to E, including HAV (infectious), HBV (serum), HCV (former NANB), HDV ( $\delta$  agent), and HEV (enterically transmitted non-A, non-B). It is unclear at present whether a non-A, non-B, non-C transfusion-transmitted hepatitis agent exists or whether these biochemically defined cases represent cryptic (sero-silent) forms of hepatitis B or C or are of nonviral etiology. Viral discovery programs are ongoing, but their likelihood of success diminishes as the incidence of non-A, non-B, non-C hepatitis declines in the wake of enhanced blood donor screening. Clearly, the discovery of HCV and the introduction of molecular assays for HCV RNA coupled with increasingly sensitive assays for HBsAg has diminished TAH incidence to minuscule levels and proportionately reduced the clinical relevance of non-A, non-B, non-C hepatitis in this setting.

---

## Summary

A marked decline in the incidence of TAH was observed in the early 1970s as commercial blood supplies were phased out and the United States adopted an all-volunteer donor system. No subsequent interdictive measure has had such dramatic effect, although additional contributions were made by the development of sensitive assays for HBsAg and by the introduction of surrogate tests for the NANB hepatitis agent. Ironically, AIDS had the next most profound effect on the incidence of hepatitis.

The development of a highly sensitive test for antibody to HIV and the intensified donor screening initiated to exclude high-risk AIDS groups served to exclude the primary source of donors transmitting viral hepatitis. The overlap between groups at risk of AIDS and groups at risk of viral hepatitis is so marked that a single exclusionary process diminishes both occurrences. As the result of these indirect measures, the incidence of TAH had declined significantly even before the introduction of anti-HCV testing. In sequential prospective studies at the NIH, the incidence of TAH had decreased from 8% to 10% to approximately 4% just before the introduction of routine anti-HCV donor screening.

Implementation of anti-HCV testing resulted in an approximate 80% reduction in TAH incidence from pretesting levels, bringing the frequency down to less than 1%. It can be calculated from the prevalence of the HCV carrier state (0.3%), the number of units of blood components transfused (15 million annually), and the infectivity of anti-HCV-positive, RIBA-positive blood (90%) that the introduction of first-generation assays initially prevented 111 transfusion-associated HCV infections per day in the United States alone, or approximately 40,000 infections per year. A subsequent analysis showed that second-generation assays would find one additional true positive donor in every 1000 tested and thus could have prevented an additional 15,000 HCV transmissions per year. A prospective study at the NIH in which the second-generation anti-HCV assay was used for donor screening showed that the risk of transfusion-transmitted hepatitis C is now exceedingly low and, indeed, approaches zero—a remarkable achievement given that the incidence of hepatitis was 33% in the 1960s and 10% to 12% in the early 1980s. Mathematical modeling after the introduction of HCV-NAT places the risk of transfusion-associated hepatitis C at one case per 1.5 to 2.0 million transfusions. Although anti-HCV screening has been a critical determinant in risk reduction, it has been only one of many interventions since 1985 that have increased blood safety. Other measures include the more judicious use of blood components and derivatives by physicians and a concerned recipient population; the increasing use of autologous blood and blood management techniques; intensive donor questioning and interdiction based on high-risk behavior; the shift to apheresis platelets; the introduction of additional infectious disease tests; bacterial testing of platelet products; and virus inactivation of clotting factor concentrates. Under development are chemical pathogen reduction procedures for plasma, platelets, and red cells. These combined sociologic, serologic, molecular, and virus inactivation measures raise the realistic potential that transfusion-associated viral hepatitis will be totally eradicated and become a historical footnote in the practice of transfusion medicine.

**John A.J. Barbara<sup>1</sup> & Brian C. Dow<sup>2</sup>**<sup>1</sup>Emeritus Microbiology Consultant to National Blood Service, London, and Visiting Professor, University of West of England, Bristol, United Kingdom<sup>2</sup>Consultant Clinical Microbiologist and Head of National Microbiology Reference Unit, Scottish National Blood Transfusion Service, Glasgow, United Kingdom

Ever since the advent of the global human immunodeficiency virus (HIV) epidemic, transfusion medicine has maintained a heightened awareness of the potential risk of transmitting infection through blood transfusions. This awareness has paradoxically increased despite the actual infectious risks of blood transfusion being lower than ever in developed countries. The enhanced level of safety has resulted from a series of stepwise interventions and policies in blood services throughout the world. Microbial risks were once mainly related to persistent infections such as HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV), where viral carriage or latency were the key factors predisposing an agent to transmission by transfusion. More recently, several acute infections have posed a threat to blood safety when they have occurred at high incidence in certain populations. West Nile virus (WNV) in North America is a good example of this but other infections such as chikungunya and the specter of respiratory viruses such as pandemic influenza have made transfusion microbiologists widen their areas of vigilance. These issues are reflected in this chapter.

## Retroviruses

### Overview

Retroviruses are widely distributed in nature, with examples in insects, reptiles, and almost all mammals. There are four main pathogenic human retroviruses—namely, HIV-1 and HIV-2, belonging to the lentivirus group of the retrovirus family, and human T-cell lymphotropic viruses (HTLV-I and HTLV-II), belonging to the oncornavirus group. It is generally accepted that HTLV-I and HTLV-II evolved from simian T-lymphotropic retroviruses that were transmitted to humans centuries ago. HIV-1 is also thought to have derived from a simian ancestor, as simian immunodeficiency viruses are endemic in chimpanzees

in Central Africa.<sup>1</sup> HIV-2 originated from sooty mangabey monkeys in West Africa. It is thought that transmission to African natives may have occurred only over the last century.<sup>2,3</sup>

There are three groups of HIV-1, the main group (M) containing several genotypes A through K, new group (N), and the outlier group (O). Group M is widely distributed throughout the world and is the predominant cause of the AIDS pandemic. Many of the group M subtypes and most of the circulating recombinant forms have a limited geographic spread (Table 47-1). Genotype B is by far the most widespread HIV genotype in the developed world, whereas genotype C is the most common overall, accounting for 50% of HIV infections. The Democratic Republic of Congo has the largest degree of HIV-1 genetic diversity, suggesting that this geographic area is the source of the virus.<sup>4,5</sup> Groups O and N are confined to Cameroon in Central Africa. HIV-2 was originally thought to be confined to West Africa, but international travel has resulted in a wider distribution that represents 1% or less of all HIV infections.

Retroviruses are membrane-coated, single-stranded RNA viruses that require the essential enzyme, reverse transcriptase, to transcribe their viral RNA to complementary double-stranded DNA that will integrate into the host cell chromosome (Fig 47-1). The host cell enzymes aid the virus to complete its life cycle by synthesising virions that bud from the plasma membrane to infect other cells or organisms. More virologic and clinical details on retroviral infections can be accessed in the scientific literature.<sup>7-12</sup>

### Human Immunodeficiency Virus

Originally described in the early 1980s by both Montagnier and Gallo, respectively, as lymphadenopathy virus (LAV) and human T-cell lymphotropic virus type III (HTLV-III), HIV-1 (as it subsequently became known) was established as the cause of AIDS in 1984 (Fig 47-2). Shortly after infection, the virus integrates into the host cell DNA using reverse transcription. The infected individual may suffer a “glandular fever”-like “seroconversion” illness within 2 to 3 weeks of infection, then develops antibodies, and usually remains asymptomatic for many

**Table 47-1.** Human Immunodeficiency Virus Strains Found Worldwide\*

| HIV Strain    | Subclassification | Main Geographic Concentration                      | Worldwide Prevalence |
|---------------|-------------------|----------------------------------------------------|----------------------|
| HIV-1 Group M | A                 | Africa and former USSR                             | High                 |
|               | B                 | America, Western Europe, Australia                 | High                 |
|               | C                 | South and East Africa, India                       | High                 |
|               | D                 | East and West Africa                               | High                 |
|               | F                 | West Central Africa                                | Very low             |
|               | G                 | West Central Africa                                | Very low             |
|               | H                 | West Central Africa                                | Very low             |

**Figure 47-1.** Simplified replication cycle of a retrovirus. The virion containing two RNA genome copies enters the cell via a specific cell surface receptor. The single-stranded RNA genome is converted into a double-stranded RNA provirus by the virion enzyme reverse transcriptase. The provirus inserts into host chromosomal DNA in the same orientation as the original virion RNA. Transcription of RNA from the integrated DNA provirus is mediated by cellular RNA polymerases, and this RNA serves both as messenger RNA for the synthesis of viral antigens and as genomic RNA, which becomes packaged into progeny virion budding from the cell surface. Used with permission from Weiss et al.<sup>6</sup>

years. However, during this asymptomatic period, the latent virus commonly reactivates and actively replicates in lymphoid tissues, macrophages, and other tissues. The number of CD4<sup>+</sup> lymphocytes gradually decreases until the infected individual

becomes increasingly prone to opportunistic infections, indicating the start of clinically apparent AIDS. In the developed world the use of combination drug therapy can prolong life expectancy, but the majority of those denied such medication will inevitably reach the terminal stage of the disease.

### Incidence and Prevalence Among Blood Donors

Since 1983 men who have had sex with other men (MSM) have been permanently excluded from donation in most countries because the HIV prevalence was high in this population. With improvements in HIV serologic tests [including the introduction of HIV nucleic acid amplification testing (NAT)], the risk reduction measures have been subject to review following pressure from this population group. Although it is expected that potential donors will answer donor questionnaires honestly, it has been obvious from counseling HIV-positive donors that a significant proportion admit to a risk factor that would have resulted in deferral.<sup>14</sup>

The number of new cases of HIV infection (incidence) among blood donors should reflect the situation within the general heterosexual population. In the United Kingdom (UK) new cases of HIV have doubled in the general population during the past 5 years. This is a cause for concern and donor statistics have also shown a general increased trend to over twice the usual number of HIV-positive donors being detected in 2002 to 2003 compared with 2000 to 2001. The rate in new donors peaked in 2005 with nine cases per 100,000; the rate in repeat donors peaked in 2002 to 2003 with 0.8 case per 100,000.<sup>15</sup> The HIV-positive donor rate

**Figure 47-2.** Schematic of the human immunodeficiency virus type 1 (HIV-1) virion. Each of the virion proteins making up the envelope (*gp120<sup>env</sup>* and *gp41<sup>env</sup>*) and inner core (*p24<sup>gag</sup>*, *p17<sup>gag</sup>*, *p7<sup>gag</sup>*, and *p6<sup>gag</sup>*) is identified. The diploid RNA genome is shown associated with reverse transcriptase (*RT*), an RNA- and DNA-dependent DNA polymerase. Integrase (*IN*) and protease (*PR*) also are present in the mature HIV-1 virion. The auxiliary protein *Vpr* is incorporated into the HIV-1 virion through interaction with the *P6gag* protein, which composes the carboxyl terminus of the *p55gag* precursor protein. **Figure 47-3.** HIV window period detection by various HIV assays (generalized). Assuming that the first-generation HIV antibody test could detect early HIV seroconversion at Day 0, second-generation tests were able to detect seroconversion up to 23 days before, third-generation tests 34 days before, fourth-generation Ag/Ab assays 39 days before, HIV p24 antigen assays 40 days before, and HIV NAT 45 days before. This still leaves a period of around 11 days when a donor could be infective but is nonreactive in current tests.

has not increased further, although more HIV transmissions are being detected in the general population.

In the United States the incidence is reported to be 7.2 cases per 100,000 in new donors (1993 to 1996) and 2.9 cases per 100,000 in repeat donors.<sup>16</sup> In Western Europe 1.7 donations per 100,000 were HIV positive; in Eastern Europe (former USSR) this rose to 36.7 per 100,000 for the period 2000 to 2004. Ukraine had the highest prevalence with 128.4 HIV-positive donors per 100,000. The dramatic increase in the prevalence of HIV infection in Eastern European blood donors parallels the high ongoing transmission among the general populations, particularly in injecting drug users. This causes considerable concern over the safety of the blood supply in Eastern Europe.

### Donor Testing and Counseling

Shortly after the discovery of HIV as the cause of AIDS, serologic enzyme-linked immunosorbent assay (ELISA) tests for anti-HIV became commercially available during 1985 and most blood services in developed countries began screening every donation. HIV screening tests have gradually been improved over the years by replacing viral lysates with recom-

binant antigens, including HIV-2 proteins and HIV-1 group O components; using sandwich technology; and, more recently, incorporating simultaneous detection of both HIV antibody and HIV p24 antigen in the fourth-generation HIV antigen/antibody tests.<sup>17</sup> These improvements have led to a considerable shortening (almost fourfold) of the seronegative gap between potential infectivity following infection and reactivity in serologic tests (Fig 47-3). Numerous commercial HIV serologic assays exist; transfusion services select a suitable assay on the basis of sensitivity, specificity, and other criteria. Normally, the selected assay should be capable of detecting early seroconversion samples without any associated specificity problems.<sup>18</sup> External quality control samples<sup>19</sup> should be used to monitor the performance of routine screening kits and batches of test kits should also be checked to ensure sensitivity is maintained before general use.<sup>20</sup>

The advent of HIV NAT-based systems for screening blood donors (introduced in some countries in 1995) is thought to reduce the time by detection by only a few days compared with the latest fourth-generation HIV antigen/antibody test systems. Current commercial HIV NAT assays can detect 14 copies/mL

**Figure 47-4.** HIV Western blot (Genelabs HIV 2.2). Strip 30 shows a confirmed HIV-1 positive sample; strip 31 is a negative sample; strip 32 is an indeterminate (p24).

HIV-1 RNA (50% detection limit). The blood services in the United States, Canada, Germany, and France perform HIV NAT in minipools (MPs) of six to 24 donations and detect around 1 in 3 million as HIV-positive (by NAT only). Facilities in Italy observe around 1 in 450,000 and those in South Africa detect 1 in 25,000<sup>14</sup> as HIV-positive (by NAT only, serology negative). Look-back investigations on HIV MP-NAT-negative donations from donors who later were found to be confirmed HIV positive, have revealed a number of HIV transfusion transmissions,<sup>21</sup> leading to consideration of reducing the number of donations in minipools to the ultimate individual donation (ID)-NAT assay. HIV NAT should not replace serologic HIV donor screening assays, because there are occasional examples of HIV-seropositive donors with HIV viral loads below the threshold of HIV MP-NAT, being barely detectable even by HIV ID-NAT.<sup>22</sup>

Western blot testing of repeatedly reactive samples is often considered the “gold standard” for confirmation of reactivity, although reactivity in two or three alternative ELISAs of equal sensitivity is also a recognized confirmatory strategy in high-prevalence populations. Western blot displays a wide range of antibodies against various components of the virus with the identification of antibodies to p24 (core) and gp120 and gp160 (envelope) regions being essential to conclude HIV infection (Fig 47-4). However, Western blot testing has several drawbacks. It is incapable of confirming HIV infection in those who are recently infected and who may be HIV NAT-reactive or HIV p24 antigen-reactive. However, the assay invariably will produce a clear positive result on the follow-up sample from such a donor. It should be pointed out that many weak bands can appear in individuals who have never been infected. With the use of widely accepted criteria to interpret results, such “indeterminate” reactions can be considered as uninfected if no change in blot pattern is seen on follow-up samples. This position has been verified by extensive analysis of many such samples worldwide.<sup>23-25</sup>

The finding of sole HIV NAT reactivity in the absence of serologic activity requires confirmation by either an alternative HIV NAT assay or a sensitive HIV p24 antigen test (generally up to four times more sensitive than any of the combined assays).

In the absence of any confirmatory procedure, preliminary counseling of donors should be considered that includes the acquisition of another blood sample that would reveal any further development of serologic markers.

If HIV infection is confirmed, the donor should be invited to attend a clinic with a donor consultant who will advise the donor of his or her HIV status and ask for a follow-up sample for repeat testing to confirm identity. The donor would be probed regarding any potential risk situations that may have led to the infection. Use of a detuned assay on confirmed HIV-positive donors can aid in the determination whether new donors were recently infected.<sup>26,27</sup> Often donors will admit to a risk situation that they had denied when they gave their index donation. The infected donor would then be referred to the appropriate follow-up health department for clinical management.

#### Window Period and Risk of Transmission

Transfusion transmission has infected approximately 2% to 5% of those with HIV, with the vast majority of these transmissions occurring before the advent of HIV donor testing.<sup>28</sup> Around 90% of recipients of seropositive units became infected with HIV.<sup>29</sup> Since HIV screening commenced, HIV transfusion transmission has become a relatively rare event, usually associated with a blood donor in the early course of HIV seroconversion, ie, in the “window period.” This window period is defined as the time between exposure to the virus (or onset of infectiousness in the host) and the appearance of a diagnostic marker of the infection in the blood. In the late 1980s some well-documented cases of HIV-1 transmission from screening test-negative blood were reported.<sup>30,31</sup> This led to an estimate that five cases of transfusion-transmitted AIDS had occurred per year in the United States from anti-HIV-negative, early seroconversion donations. The residual risk has been estimated between 1 in 450,000 and 1 in 3 million before NAT; NAT screening has halved this risk.<sup>32</sup> The risk of transmission of HIV-2 has been estimated at less than 1 in 15 million and other subtypes are of even lesser concern. It is notable that the risk of HIV infection from blood has been reduced by almost four orders of magnitude in comparison with the transfusion AIDS epidemic of 1982 to 1984, which was responsible for around 2% to 5% of those infected

with HIV. Furthermore it has been suggested that the infectivity of a transfusion in the early 11-day window period (before HIV NAT detection) may be lower than later stages of primary infection because of the low level of virus in this eclipse phase.<sup>12</sup> It has been estimated that the doubling time of HIV is 20.5 hours in this period.<sup>33</sup> Nevertheless, despite the improvements in HIV testing, there have been reports of HIV-NAT-negative blood involved in transfusion-transmitted HIV.<sup>22,34</sup> This demonstrates that despite the employment of the most sensitive type of assay to screen blood donations, zero risk is presently still unattainable.

The residual risk of HIV transfusion-transmitted infection (TTI) has been estimated to be 0.14 per million donations for the UK blood supply during the period 1996 to 2003.<sup>15</sup> Despite improvements in testing (HIV antigen/antibody assays and HIV NAT in some centers) the residual risk has risen to 0.22 per million because the improvements in tests have been overshadowed by the gradual doubling of new infections in the general population. These new infections have been associated with heterosexual spread of genotype C and other non-B genotypes, whereas MSM spread is associated with genotype B. A similar increase in non-B HIV genotypes has been found in other European countries and, to a lesser extent, Asia and the Americas.<sup>35-38</sup> In the United States the proportion of non-B HIV-positive blood donors rose from 0.8% to 3.1% between 1993 and 2000.<sup>39</sup>

Worldwide it has been estimated that up to 13 million units are not tested for HIV, HBV, or HCV. The World Health Organization (WHO) has estimated that this would result in 160,000 TTI cases per year. More recently, the Global Database on Blood Safety stated that HIV testing is being conducted in all 152 surveyed countries, but poor quality test performance together with sporadic supply problems have contributed to HIV transmission.<sup>40</sup>

### Clinical Course

Although HIV can be inactivated by heat treatment of lyophilized products at 68°C for 72 hours, this became apparent only after a considerable number of hemophilia patients had already been infected through HIV-contaminated Factor VIII products. Indeed, around 50% of those treated with the non-heat-treated product experienced HIV seroconversion.<sup>41</sup> Initially it was hoped that those with anti-HIV were merely immunized rather than infected but studies proved that those with anti-HIV were also HIV-positive by polymerase chain reaction (PCR), indicating that they were indeed infected. This has been amply borne out by the clinical outcomes in such patients.

Because HIV can withstand the storage temperatures of blood components, it is to be expected that recipients of blood would be infected. The Transfusion Safety Study (TSS) in the United States was unique in actively tracing and enrolling recipients of known HIV-positive units. In this study 111 (89.5%) of 124 recipients of HIV-infected components experienced seroconversion to anti-HIV positivity.<sup>42-44</sup> It was noted that washed Red Blood Cell (RBC) units and RBC units stored longer than 26

days had lower transmission rates than other components. This would also suggest that leukocyte reduction might have a beneficial effect in reducing infectivity.<sup>45</sup>

Following infection with HIV, there is usually an asymptomatic period of around 2 to 3 weeks that progresses to an acute flu-like (seroconversion) illness in 40% to 90% of patients. Fever, enlarged lymph nodes, sore throat, rash, joint and muscle pains, headache, diarrhea, and vomiting are some of the signs and symptoms that can be experienced for a period of up to 2 weeks or longer. Correct diagnosis at this stage is usually unlikely unless symptoms are protracted. The infection will then become clinically latent but with active viral replication. The virus can be transmitted via blood and genital secretions during the asymptomatic and clinically latent period.

Persistent asymptomatic HIV infection lasts on average 10 years in the absence of treatment. Eventually there is a sharp decrease in the number of CD4 T lymphocytes, leading to immunosuppression and opportunistic infections that may prove fatal when not treated. When an HIV diagnosis has been made and treatment is undertaken, the many advances in HIV management can extend survival and delay the onset of AIDS. However, worldwide the majority of those infected live in developing countries where effective therapy is usually not available.

The 112 recipients enrolled in the TSS study provided valuable data as to the progression of the disease in those individuals infected through transfusion. Seven years following their transfusion, 37 (33%) had developed AIDS.<sup>46</sup> The transfusion recipients tended to have a faster rate of disease progression compared with both infected donors and infected hemophilia patients who were followed in parallel. This higher rate was mainly because the patients were older and with underlying clinical conditions.<sup>47</sup> Overall this study led to suggestions that the route of infection, size of inoculum, and other viral co-infections do not significantly alter the course of the disease. However, the importance of the viral virulence gene, *nef*, was demonstrated in an Australian cohort of a blood donor and eight transfusion recipients infected with an HIV strain lacking a functioning *nef* gene. The cohort members had a much milder illness with longer disease-free survival in the absence of therapy.<sup>48</sup>

Whether transfusion of AIDS patients is beneficial is debatable.<sup>49,50</sup> The results of the Viral Activation by Transfusion Study (VATS) showed no evidence that leukocyte reduction benefits this patient group.<sup>51</sup>

### Treatment

Antiviral treatment has evolved from monotherapy to cocktails of highly active antiretroviral therapy (HAART) that has achieved remarkable success in decreasing the mortality from AIDS and in prolonging useful active life in those with HIV infection. Three classes of antiretroviral drugs are available—nucleoside and nucleotide analogs (NRTIs); reverse transcriptase inhibitors (RTIs); and protease inhibitors (PIs). There is no cure for HIV or AIDS. It should be realized that where viral load is measured routinely, any increase may be associated with the development

of drug-resistant strains, necessitating a drug substitution in the patient's therapy.

### Human T-Cell Lymphotropic Viruses

Human T-cell lymphotropic virus (HTLV-I) was identified in 1978 when it was isolated from a Japanese patient. The virus was found to cause adult T-cell leukemia and lymphoma (ATL)<sup>52</sup> and tropical spastic paraparesis (TSP), otherwise known as HTLV-I-associated myelopathy or HAM.<sup>53</sup> The virus is now found globally but is endemic in Japan, the Caribbean, South America, and West and Central Africa, where infection rates are often above 1%. HTLV-II was originally identified in 1982 in a patient with hairy-cell leukemia. HTLV-I and HTLV-II show 65% homology. HTLV-II is found in American Indian populations and in some populations of intravenous drug users.

### Incidence and Prevalence Among Blood Donors

The overall incidence in first-time donors in the United States is around 40 per 100,000. In repeat donors a rate of approximately 1.6 per 100,000 person years was identified from 1991 to 1996. HTLV-II is found more often than HTLV-I among US first-time donors, reflecting the epidemic of HTLV-II among intravenous drug users. In the UK, routine screening of blood donations commenced in 2002 and has resulted in over 100 HTLV-positive donors being detected. However, in the UK there is a remarkable geographic variation in distribution, with southern England having an incidence as much as 10 times higher than northern regions.<sup>54,55</sup>

### Donor Testing and Counseling

Current HTLV donor screening assays are based solely on antibody detection by ELISA or chemiluminescent (ChLIA) format. The more sensitive assays have used recombinant HTLV proteins on both solid phase and conjugate in a sandwich assay format. Assays detect both HTLV-I and HTLV-II.

In the UK a lengthy pilot study was performed using anti-HTLV to test the residues of the pools of samples used for HCV NAT assays (pools of up to 95 donations).<sup>56</sup> It was estimated that this procedure was around 95% sensitive compared with individual donation testing. However, adjustment of the cut-off to enhance the test sensitivity together with reduction in the minipool size to no more than 48 donations led to an HTLV screening strategy that was comparatively inexpensive, around 98% sensitive, and with remarkable specificity (the almost ideal situation). Furthermore, the knowledge that all UK blood components were subjected to leukocyte reduction meant that this strategy carried even less residual risk of viral transmission by transfusion.

Confirmatory testing of reactive HTLV donations is more complex than confirmatory testing for HIV, partly because of the relatively poor Western blots that were commercially available. Modifications to those Western blots to include recombinant materials in addition to viral lysate and also the development of recombinant immunoblots (Fig 47-5) (similar to HCV immunoblot formats) have led to more accurate interpretations. Indeed, some of the immunoblots were capable of discriminating the

**Figure 47-5.** HTLV Immunoblot (Innolia). Strips 09 and 10 show confirmed HTLV-I specimens; strip 11 shows confirmed HTLV-II; strip 12 is a negative control; strip 13 is a positive control.

pooled donation samples (up to 95 donations) as either HTLV-I or HTLV-II positive. Nucleic acid testing as part of a confirmatory algorithm is still under development.<sup>57</sup>

Most UK HTLV-positive blood donors were shown to be of Afro-Caribbean ancestry or had been sexual partners of someone of Afro-Caribbean ethnicity. Therefore, it is important to ensure that sexual partners and other family members are also tested for HTLV in any clinical follow-up.

### Window Period and Risk of Transmission

A window period of 51 days has been calculated.<sup>58</sup> A study of US transfusion recipients estimated the risk of HTLV infection at 12 per 100,000 units before screening and 1.4 per 100,000 following the implementation of blood donor HTLV screening. Over time, this risk has changed to 0.16 per 100,000 screened donations. Generally, transfusion-transmitted HTLV has been associated with (fresher) cellular components so that plasma transfusions are thought to be of little risk. Furthermore, the use of leukocyte reduction procedures has lessened the risk considerably such that in combination with HTLV donor screening, virtual elimination of HTLV transfusion transmission has been claimed.<sup>59</sup>

### Clinical Course

Although the majority of HTLV-positive donors exhibit no clinical symptoms of disease, they should be made aware that a small percentage (2% to 4%) may develop ATL up to 40 years after infection. HAM/TSP is characterized by spinal cord degeneration and has a

Table 47-2. Human Herpesviruses

| Herpes Subfamily   | New Nomenclature | Common Name                       |
|--------------------|------------------|-----------------------------------|
| Alphaherpesvirinae | HHV-1            | Herpes simplex virus-1 (HSV-1)    |
| Alphaherpesvirinae | HHV-2            | Herpes simplex virus-2 (HSV-2)    |
| Alphaherpesvirinae | HHV-3            | Varicella zoster virus (VZV)      |
| Gammapesvirinae    | HHV-4            | Epstein-Barr virus (EBV)          |
| Betaherpesvirinae  | HHV-5            | Cytomegalovirus (CMV)             |
| Betaherpesvirinae  | HHV-6            | HHV-6                             |
| Betaherpesvirinae  | HHV-7            | HHV-7                             |
| Gammapesvirinae    | HHV-8            | Kaposi's sarcoma-associated virus |

much shorter incubation period, developing in a few (1.5% to 3%) patients infected with HTLV-I and HTLV-II. HTLV-I has also been associated with uveitis and may lead to eventual blindness.

Treatment

The management of asymptomatic HTLV infection generally should not involve drug therapy because of the low chance of clinical disease development. Chemotherapy for the treatment of ATL is often less effective than for other forms of leukemia or lymphoma. Therefore, there is a high mortality associated with this disease. HAM/TSP can be treated with systemic steroids or azathioprine immunosuppression with variable success.

Other Retroviruses

The finding of a high proportion of individuals with antibodies to the p24 core antigen on HIV Western blot is highly suggestive that these individuals may have been infected with other retroviruses. Testing sequential donations or samples from such individuals over many years has shown that their “indeterminate” banding patterns usually do not alter for a particular individual. In addition, PCR testing of such individuals has not identified any reactivity. Also, it is known that the human genome, like that of other species, harbors some ancient endogenous retroviral sequences. These observations have not resulted in any real proof of disease association.

However, there is some concern over the possibility that the use of animal-derived blood constituents could harbor such retroviruses that may re-activate following transfusion. Indeed, the latest fad of “bush meat cuisine” may also result in cross-species transmission of retroviruses.<sup>60,61</sup> Blood donor-recipient repositories in developed and developing countries will provide reassurance against such potential risks to blood safety.<sup>62</sup>

Herpesviruses

Overview

Herpesviruses are ubiquitous in nature, with practically every living creature known to be susceptible to some associated herpesvirus. Humans are known to have several herpesviruses (Table 47-2). All human herpesviruses (HHVs) have the

capability to lie dormant in tissues after an acute infection. With reference to transfusion, cytomegalovirus (CMV or HHV-5) is by far the most important herpesvirus infection. Herpes simplex (HHV-1 and HHV-2) and herpes varicella-zoster (HHV-3) have restricted tissue involvement, but CMV can manifest itself in many organs. Therefore, CMV is a major problem in immunosuppressed patients requiring transfusion therapy. Patients who should receive components that are selected or processed to minimize the risk of CMV infectivity include the following:

- Transplant recipients
- Patients with severe immunodeficiency
- Fetus (intrauterine transfusion)
- CMV-negative pregnant females
- Low birthweight premature infants and neonates

It is important to be able to distinguish between *CMV infection*, identified by means of serologic tests or viral isolation, and *CMV disease* identified by laboratory evidence of infection combined with specific symptoms associated with the virus.

Epstein-Barr virus (EBV or HHV-4) is responsible for infectious mononucleosis, is associated with Burkitt lymphoma and nasopharyngeal cancer, and can also be transfusion transmitted.

Human herpesvirus 6 (HHV-6) causes “roseola infantum” or “sixth disease”—a childhood rash. Primary infection of adults is rare.

Human herpesvirus 8 (HHV-8) has been found in Kaposi's sarcoma and other tumors such as Castleman disease and body-cavity-based lymphoma.<sup>63,64</sup> It has also been associated with polyneuropathy, organomegaly, and endocrinopathy. As with CMV and EBV, HHV-8 appears to cause a persistent infection with the viral genome, lying latent in host immune cells.

Incidence and Prevalence Among Blood Donors

Figure 47-6 shows the prevalence of CMV infection in a Scottish blood donor population with an apparent 2% CMV seroconversion rate per year. The prevalence figures for a similar population 20 years earlier showed figures that were considerably higher. Thus, it would appear that few donors had been infected in recent times (possibly because of improved hygiene and living conditions). Support for this hypothesis comes from a German study<sup>65</sup> in which an overall CMV seroconversion rate of 0.55% per year was observed.

**Figure 47-6.** Comparison of cytomegalovirus antibody status of West of Scotland blood donors according to age and samples 20 years apart.

**Figure 47-7.** Western blot for cytomegalovirus antibodies showing the various antibodies that are elicited.

EBV and HHV-6 have a very high prevalence in the general population (>80%). HHV-8 has a seroprevalence in blood donors between 0 and 20%. African populations have been reported to have a prevalence of 35% to 75%, with 10% to 50% showing evidence of HHV-8 DNA. In the UK, HHV-8 has been reported more frequently in MSMs attending sexually transmitted disease clinics and this was a contributory factor in the decision to maintain permanent deferral of this population group as blood donors.<sup>66</sup>

### Donor Testing

Most transfusion testing sites use ELISA-based assays to test blood donations for the presence of anti-CMV. Unlike mandatory marker assays, anti-CMV assays are not as strictly controlled by regulatory agencies. Validation and concordance of assays is hampered by the number of antibodies that CMV can elicit.<sup>67</sup> Most transfusion testing sites tend to use “total” anti-CMV assays that can detect both IgG and IgM class antibodies.

Hemagglutination assays are inherently capable of detecting both classes of antibodies and some commercial assays have now become available that can be performed on automated blood group analyzers. In contrast, diagnostic virology laboratories use both IgG and IgM antibody tests to differentiate acute from

recrudescant CMV infections. Although it is accepted that those donors with IgM reactivity are most likely to have CMV viremia, the capacity of CMV to lie dormant in white cells means that any antibody-reactive donation has the capability of infecting the recipient with CMV. Donors with reactivity in anti-CMV screening assays usually are flagged as “CMV positive” on donor databases so that they will not be retested and their blood will not be included in the preparation of CMV-negative components. Problems associated with specificity of some ELISA tests can lead to some donors being labeled falsely as CMV positive; transfusion services are hesitant to retest these donors because of operational constraints.

Recently, a CMV Western blot assay (Fig 47-7) has become available, allowing a check to be made on samples found to show discrepant reactivity with different manufacturers’ assays. Because CMV is a common infection and not clinically significant in immunocompetent individuals, there is no need to counsel donors. No routine tests are performed for EBV, HHV-6, or HHV-8 infection. Indeed, tests for HHV-8 frequently show discrepant results.<sup>68</sup>

### Window Period and Risk of Transmission

Although CMV is transmissible by transfusion, this is now relatively uncommon in developed countries, particularly those where

all blood components are leukocyte reduced. Despite the average 3 log<sub>10</sub> reduction in leukocyte concentration achieved by leukocyte reduction,<sup>69</sup> there has been no abandonment of CMV-seronegative blood bank inventories, particularly for the patient populations at high risk of CMV disease.<sup>70</sup> It is thought that only 1% to 5% of blood units found to be CMV seropositive will actually lead to infection of CMV-seronegative recipients. The incubation period of primary CMV infection varies between 4 and 8 weeks. The residual risk of transfusion-transmitted CMV infection from anti-CMV screened blood components (not leukocyte reduced) is around 1.2% to 1.6% per donation, whereas the risk is between 2.3% and 3.0% for leukocyte-reduced blood components.<sup>71</sup> The present use of CMV screened leukocyte-reduced blood would be expected to be associated with a risk of less than 1%.

Before leukocyte reduction, EBV infection occurred between 3 and 7 weeks following transfusion in around 33% to 46% of recipients lacking EBV antibodies. Such recipients are a small minority, especially in older individuals.

The transmissibility of HHV-8 by transfusion is still debatable. Studies in the United States provided evidence of seroconversion in two of 284 cardiac surgery patients from non-leukocyte-reduced blood between 1986 and 1990.<sup>72</sup> A Ugandan study showed a 6% frequency of seroconversion with non-leukocyte-reduced blood compared with 3.5% among recipients of HHV-8 seronegative blood.<sup>73</sup>

### Clinical Course

In marrow recipients, CMV is one of the most significant infections, responsible for 15% of mortality before the advent of good antiviral drugs. CMV matching of kidney recipients has a beneficial effect on clinical outcome more so than matching patients for HLA Class I status. The use of seropositive blood for seropositive patients can lead to reinfection of some CMV seropositive recipients; therefore, CMV-seronegative components are preferred (but not always available) for all immunocompromised patients. The leukocyte reduction of blood components has lessened the demand on CMV-seronegative components.

Transfusion-transmitted EBV infections usually are asymptomatic, but some appear as an infectious mononucleosis with mild fever, anorexia, and malaise. Most HHV-8 infection is benign with a low frequency of disease development.

### Treatment

Antiviral drugs that are effective against CMV (and also HHV-6) include ganciclovir, foscarnet, cidofovir, and valganciclovir. Drugs can be prescribed either for prophylaxis, suppression, or treatment.

## Other Viruses

Several viruses have had a considerable impact on blood services in certain parts of the world. These “other” viruses include parvovirus B19 (human erythrovirus), West Nile virus, chikungunya, and pandemic influenza.

### Parvovirus B19

Parvovirus B19 was so named because it was the 19th sample on a hepatitis B counter electrophoresis assessment panel that reacted; subsequently it was shown to contain parvovirus. Parvovirus is a single-stranded nonenveloped DNA virus of 5500 nucleotides that code for two capsid proteins (VP1 and VP2) and other proteins.<sup>74</sup> Parvovirus is the agent that causes “fifth disease” or “slap-cheeked syndrome” in young children. However, parvovirus can also cause serious, even life-threatening, disease in certain immunosuppressed individuals and women in the second trimester of pregnancy, where hydrops fetalis may result. Individuals lacking the P blood group globoside are naturally immune to parvovirus because the virus requires the globoside for binding to the cell. Various cell types contain this surface antigen and are susceptible to infection. The clinical manifestations of parvovirus are, therefore, widespread, involving fetal myocardium, placenta, liver, kidney, thyroid, megalokaryocytes, and erythroid progenitor cells.

Compared to some blood derivatives, blood components are only rarely associated with parvovirus B19 transmission. This may be because of a lack of recognition of an association of parvovirus infection with transfusion or, more likely, asymptomatic infection in the recipient. Nevertheless, recent studies suggest between 0.5% and 0.9% of individual blood donations are contaminated with parvovirus B19 by evidence of B19 DNA. It could be argued that other components containing antibodies may prevent infection in some recipients, but ongoing studies with an archive repository in the United States may reveal the true transmission rate. Various parvovirus serologic assays are now commercially available.<sup>75</sup> The Netherlands have reacted to the risk of parvovirus infection in selected patient groups by providing a “parvovirus-safe” panel of donors deemed to be safe from transmitting parvovirus by evidence of parvovirus antibodies for a period of at least 6 months. This panel was created by large-scale ELISA screening of the donor panel for parvovirus antibodies (against VP2) over a period of over a year. The demand for “parvovirus-safe” blood components has been limited. Recent studies<sup>76,77</sup> raise doubt over the strategy, as they describe low-level parvovirus B19 carriage in individuals with cocirculating antibodies.

In the past, parvovirus B19 transmissions have occurred through plasma-derived Factor VIII or IX blood derivatives. Although parvoviruses are generally stable and resist most physicochemical inactivation procedures, parvovirus B19 is more readily inactivated than the other parvoviruses using either dry or wet heat, extreme pH, ultraviolet C irradiation, photochemical reaction, or even nanofiltration procedures in blood derivative manufacture. Despite the incorporation of some of these inactivation procedures and the use of recombinant-derived clotting factor concentrates, reports of potential parvovirus B19 transmission with high-purity clotting factor concentrates, immunoglobulin preparations, and solvent/detergent-treated plasma still occurred. This led plasma fractionators worldwide to screen their source plasma for parvovirus DNA and use only pools with less than 10,000 copies/mL. This level of reactivity was ascertained by considering the level

of parvovirus antibodies that were also contained within these pools and its ability to neutralize small concentrations of the virus. A pilot study on parvovirus NAT testing was able to demonstrate some exceedingly high viral concentrations in maxipools of donations. The level of parvovirus mirrored the level of infection in the general population where epidemics appear every 3 to 4 years, usually in late spring.<sup>78</sup> The prevalence of parvovirus is age related, with most infections occurring in young children, who often then infect their (non-immune) siblings, parents, or grandparents. By the age of 15 years, 60% of the population will possess antibodies to parvovirus.<sup>79</sup> Most parvovirus assays detect three genotypes, Parvovirus 1, 2, and 3. Two new parvoviruses, Parvovirus 4 and Parvovirus 5, have been described with no known pathogenicity.<sup>80</sup>

### West Nile Virus

West Nile virus, a flavivirus, was first recognized in 1937 and now has a wide distribution in Africa, Europe, Asia, Australia, and, in the past decade, in Northern America. WNV mainly infects birds and is normally transmitted by mosquito. However, horses and also humans can be bitten by infected mosquitoes and subsequently can develop West Nile fever.<sup>81</sup>

In the United States, WNV was first identified in 1999 and over the next few years spread from the eastern seaboard to the Pacific states. Most human cases occur between July and November with a peak period in August and September, but viremic blood donors have been found throughout the year. Cases in the United States peaked in 2003 with 9862 cases and 264 deaths, but WNV is likely to continue to cause around 2000 cases and 100 deaths per year.

The incubation period is between 3 and 15 days in humans with over 80% of infections being asymptomatic or with a mild flu-like illness. In rare cases (fewer than 1% of those infected), a more severe disease results and fatal encephalitis can occur. Asking donors about predonation headache and fever was found to have no effect on blood safety.<sup>82</sup> The risk of transfusion transmission is associated with a period of viremia occurring around 3 days after infection and lasting around a week.<sup>32</sup> Since July 2003, the US and Canadian blood supply has been screened using WNV NAT assays that were developed quickly by two major diagnostic companies, Roche and Chiron.<sup>83</sup> Both assays can be used on minipools of six or 16 donations. However, following reported WNV transmissions from MP-NAT-negative donations, an algorithm was devised to switch to ID-NAT when there was demonstrable WNV activity in a region.<sup>84</sup> This strategy seems sensible, particularly because 294 (22%) of 1332 viremic blood donors tested during the period 2003 to 2005 were detected solely by ID-NAT.<sup>85</sup>

Following an outbreak in horses in southern France, a survey of 2157 blood donors in that region showed that 0.8% had evidence of antibodies to WNV.<sup>86</sup> Various outbreaks in Europe have not equalled the WNV epidemic in the United States. Perhaps the American WNV is more pathogenic, or alternatively, perhaps Europeans are less susceptible. European blood services have found that deferring donors from North America for a period of 28 days offers sufficient protection to their blood supply. Fresh frozen

plasma imported from the United States is currently pathogen inactivated (eg, with methylene blue) to combat any WNV risk.

### Chikungunya

Chikungunya virus (CHIKV) is an alphavirus of the *Togaviridae* family with a single-stranded RNA genome. The virus is transmitted by mosquitoes (*Aedes albopictus*) to humans, where after 1 to 10 days symptoms of chikungunya fever develop. Derived from the Swahili name for “that which bends up,” Chikungunya disease symptoms include arthralgia, myalgia, rash, headache, and fever. Three main genotypes exist associated with either West Africa, Central and East Africa, or Asia. More recently, there has been an epidemic associated with the Central and East African genotype that was first reported in 2005 in French Indian Ocean islands, but subsequently spread to cover most Indian Ocean islands and the Indian subcontinent. It has been estimated that at the height of the epidemic over 250,000 (35% of the population) had been infected on Reunion Island, with 250 deaths. French blood service authorities originally managed the problem by importing blood to the French territories as a short-term measure, with the implementation of chikungunya NAT testing and pathogen inactivation as longer-term measures.<sup>14</sup> Blood services outside the affected areas were able to defer (for a period of 28 days) those donors who had visited areas where chikungunya was known to be epidemic.

During 2007, European blood services realized that foreign travel can aid the spread of chikungunya not only as isolated cases in returning visitors but also as an outbreak (eg, chikungunya fever in an Italian province). The latter event occurred after a visit to the region from a foreigner incubating the disease, together with the spread of the disease by the *Aedes albopictus* mosquito within that region. This mosquito species is also capable of transmitting dengue virus and is found elsewhere in Italy, France, and Albania. This highlights the need for continued vigilance of emerging infections elsewhere in the world, particularly because world travel can quickly transfer disease from one area to another. In addition, the effects of global warming allow insect vectors to survive in what once were less temperate regions.

### Pandemic Influenza

Pandemic influenza has been a continuing threat arising shortly after the severe acute respiratory syndrome (SARS) outbreak. The lethal influenza viruses that have infected humans have been adequately managed so far by existing public health measures.<sup>87</sup> This has been helped by the relative inability of “bird flu” viruses to infect humans. However, concern exists that eventually a mutation or a mixed infection will occur that will allow one of these lethal viruses to spread among humans. Because there have been a number of bird flu cases in humans involving the influenza subtype H5N1, it is felt that any new emerging influenza threat is likely to be closely related. Vaccines have been prepared, but as with normal human influenza vaccines, they have good efficacy in immunocompetent individuals but are of limited use among those who are at greatest risk from such a pandemic (ie, the old and the very young). It is believed that transfusion-transmitted influenza is relatively rare,<sup>88</sup> but theoretically

possible. Thus, the deferral of donors from areas at the height of an epidemic may be the safest option, along with the backfilling of blood stocks from areas with few or no cases. At the height of any epidemic it is likely that the use of blood will be severely curtailed—partly because of cancellation of elective surgery, but also because of a lack of health-care personnel and, indeed, blood donors.

### Lymphocytic Choriomeningitis Virus

Lymphocytic choriomeningitis virus (LCMV) was first described in 1931 as one of the main causes of meningitis. Eight solid-organ transplant recipients have been infected with LCMV from two organ donors,<sup>89</sup> raising the concern that LCMV may also be transfusion-transmitted despite a lack of reported cases in the literature. A French study<sup>90</sup> ascertained a low (0.33%) prevalence in the blood donor population, suggesting that the risk of transmission is low. However, the researchers did suggest that history of recent rodent contact should lead to a temporary deferral of potential donors.

### Simian Foamy Virus

Strategies for limiting the spread of simian foamy virus are similar to those used to manage LCMV. Donors who have occupational exposure to primates have been deferred in Canada as a measure to prevent potential transmission.

---

## Emerging Nonpathogenic Viruses

The use of new powerful molecular genetic techniques to identify previously undescribed viruses has led to a plethora of “new” viruses that have yet to be shown to have any human pathogenicity.<sup>91</sup> Two such viruses have instigated much research and literature in the past 20 years—GB virus-C (GBV-C, once known as hepatitis G virus) and TT virus (TTV).

### GBV-C

GBV-C is an enveloped RNA virus and a member of the *Flaviviridae* family (which also includes HCV). The viral genome is structured similarly to HCV but has only 25% homology with it. Several genotypes exist, mainly confined to various continents.

Transfusion transmission of GBV-C has been demonstrated. The prevalence of GBV-C RNA in blood donors ranges from 1% to 5% dependent on geographic location. Antibody as measured by anti-E2 is usually found three to four times more frequently than is viral RNA.<sup>64</sup> GBV-C, and independently “hepatitis G virus (HGV),” was discovered in patients with sporadic “non-A, non-B” hepatitis, inferring that it was a causal agent of hepatitis. However, subsequent investigations have concluded that GBV-C was not the cause of viral hepatitis, nor had any hepatotropic or other pathologic role. It was merely a “passenger” virus, isolated by chance. Blood screening is therefore not necessary.

### TT Virus

As with GBV-C, TT virus was discovered during the search for the elusive cause of the minor (non-C) component of “non-A through

E” posttransfusion hepatitis. The virus was discovered in a post-transfusion hepatitis patient with the initials TT. TTV is a small (18-50 nm) DNA nonenveloped virus. TTV can be transmitted by transfusion and has a TTV RNA prevalence of between 5% and 80%; there is again a marked geographic variation in infection rates with higher prevalence in Africa (up to 80%).<sup>64</sup> It is thought that 50% of African children will have been infected by TTV by 1 year of age. More sensitive NAT assays detect higher rates of viral infection. The relevance of TTV in transfusion is limited because of the lack of any clinical symptoms. However, the fact that some current fractionated plasma product inactivation procedures are unable to prevent infection of recipients is of some concern.

---

## Conclusion

The pathogenicity of any virus is extremely important when considering the value of introducing specific blood safety interventions. Another issue is the difficulties of testing and excluding infected donations when the prevalence of an agent in the donor population is high. Nevertheless, there are pragmatic actions that can be taken to reduce the likelihood of “at-risk” recipients being given infected blood. The blood supply will never be deemed to have “zero risk,” but there is an expectation by the public for blood services to provide blood that is as safe as possible. This will include steps such as excluding “high-risk” donors temporarily or permanently, using serologic or NAT-based assays to identify donors infected with pathogenic blood-borne agents, or using pathogen inactivation/reduction techniques on particular blood components to ensure that there are considerable reductions in microbial infectivity (see Chapter 51). The latter intervention is likely to be a potential basis for blood safety strategies to avert the emerging diseases of the future. Effective microbial inactivation of the full inventory of blood components would be one prerequisite of such a strategy. The case to discontinue the use of any of the present arsenal of tests/procedures will be unlikely to succeed unless the inactivation procedure is extremely reliable and robust. Commercial companies promoting pathogen inactivation systems suggest that the cost savings realized with discontinuing CMV and bacterial testing will more than adequately compensate for the costs of introducing their systems, claimed to be effective against nearly all transfusion-transmissible agents.

Manager of Blood Research, American Red Cross—New England Region, Dedham, Massachusetts, USA

The risk that a blood recipient in the United States will receive a component contaminated with parasites is, in absolute terms, small but not negligible. Estimates covering nearly 20 years are that roughly one per million transfusions might transmit parasitic infection.<sup>1,2</sup> Given the large increase in international travel by US residents, the movement of large numbers of military personnel, and growing immigration, the opportunity for human trafficking of parasites that are endemic in tropical countries has never been greater. With the further development of molecular tools and improved diagnostics, these risks are being clarified. For some parasites, including *Babesia* and *Leishmania* species, the risk has probably been underappreciated given that transfusion transmission can easily go undetected, especially when the recipients are immunocompetent patients. The residual risk for some protozoan parasites appears to be on par with, or even greater than, transfusion-transmitted viral infections for which nucleic acid screening is performed. This chapter discusses the parasitic agents most likely to be found in blood donors, the risks from each, and the strategies for eliminating or diminishing these risks.

---

### Chagas' Disease

Concern for transfusion transmission of *Trypanosoma cruzi* infection has increased in recent years, concurrent with the growing Hispanic population in the United States. Endemic in Central and South America and in Mexico, this protozoan hemoflagellate is transmitted in nature by triatomines, or reduviid bugs (also called "kissing bugs" for their tendency to bite on the face). Trypanosomes are not injected through the bite of the insect vector; rather, the insect vector deposits the infective metacyclic forms of the trypanosomes in its excreta during or soon after the blood meal. The sleeping host, in scratching the wound, can rub the

parasite into the wound or transfer it to mucous membranes in the eye or mouth. Triatomids competent for transmitting *T. cruzi* are widespread, including in the United States, where rare autochthonous transmission has been documented.<sup>3</sup> The agent can also be transmitted readily by blood transfusion and solid-organ transplantation, and by congenital transmission.<sup>4</sup> Rare outbreaks from contaminated food or drinks have also been reported.<sup>5</sup>

The typical clinical course following infection is an acute phase lasting 4 to 6 weeks, characterized by mild symptoms including fever, malaise, and edema of the face, as well as lymphadenopathy and hepatosplenomegaly.<sup>6</sup> The fatality rate in the acute phase is usually less than 5%, and many cases go unrecognized. During this period, parasites are readily detectable in peripheral blood.<sup>4</sup> In the ensuing indeterminate phase, however, carriers remain asymptomatic, and parasitemia tends to be low grade and intermittent.<sup>7</sup> Up to decades later, 15% to 30% of carriers will develop serious sequelae involving the heart and gastrointestinal tract (mega-colon and mega-esophagus). Chagas' disease kills an estimated 13,000 people annually, mostly from cardiac complications.<sup>4,8</sup> Acute-stage treatment with benznidazole or nifurtimox is effective, but treatment during the chronic phase has only recently been shown to be effective. A 60-day course of benznidazole treatment eliminated infection in nearly two-thirds of chronically infected children,<sup>9</sup> while a study in Argentina suggested that chronic-phase treatment with benznidazole might slow or prevent progression to cardiac disease.<sup>10</sup>

Despite considerable success in reducing insect transmission in the last two decades, Chagas' disease remains a major public health problem in many countries, with an estimated 9 million infected and 25 million at risk for infection.<sup>11</sup> The Southern Cone Initiative, inaugurated in six South American countries in 1991, sought to eliminate domestic infection by *Triatoma infestans* (the primary vector in several countries) and to interrupt transfusion transmission through universal donor screening.<sup>7</sup> Estimated annual incidence of cases has declined by 90%, and Chile, Brazil, and Uruguay are all certified as having interrupted vector transmission.<sup>12</sup> The success of this initiative inspired similar efforts in four Andean countries,<sup>13</sup> Central America,<sup>14</sup> and, the Amazon

region.<sup>15</sup> Different species of vectors and different ecologic conditions apply across these regions, so no universal strategy can be applied uniformly.

The adoption of universal blood screening in Latin American countries has dramatically altered the risk for transfusion transmission in countries where *T. cruzi* is endemic. Whereas in the early to mid-1990s only four of 17 Latin American countries in which data were compiled had achieved universal donor screening, 10 of 17 were at or above 99% coverage by 2002.<sup>16</sup> During this period, estimates of cases of transfusion-transmitted *T. cruzi* in those countries dropped by nearly 75%, from 1996 to 536.<sup>16</sup> Mexico alone accounts for two-thirds of recent estimated cases because of its large number of donors and relatively low screening coverage (27%), despite a moderately low seroprevalence in donors. A recent evaluation in Mexico demonstrated four cases of transfusion transmission and estimated that up to 1800 such cases occur in Mexico annually, on the basis of state-specific prevalence rates and donation data.<sup>17</sup>

Clearly, the risk in the United States and other countries receiving Latin American immigrants depends on the immigrants' risk for acquisition of infection extending decades into the past. US census figures estimate that 41 million Hispanics live in the United States, of whom two-thirds are of Mexican origin,<sup>18</sup> 2.9 million are of Central American origin, and 2.2 million are of South American origin. Of these, an estimated 40%, 68%, and 70%, respectively, were foreign-born. Among the foreign-born, 40% or more arrived in the United States before 1990,<sup>18</sup> and the subsequent intensification of control programs in *T. cruzi*-endemic countries. This suggests that a very large number of Hispanic immigrants might have been exposed long before entering the United States. Recent estimates project that between 70,000 and 100,000 Hispanic immigrants in the United States may be infected with *T. cruzi*.<sup>19</sup> Canada and Australia are estimated to have more than 1000 *T. cruzi*-infected immigrants each, and Spain is estimated to have more than 10,000 undetected infections.<sup>20</sup> Within the United States, 50% of Hispanic residents live in California and Texas, and a total greater than 25 million live in those two states plus Florida and New York. In all, about 80% of Hispanics in the United States live in nine states, but risk for transfusion transmission of *T. cruzi* can be found countrywide.<sup>18</sup>

There have been seven reported cases of *T. cruzi* transfusion transmission in the United States and Canada,<sup>21</sup> and five cases of transmission associated with solid-organ transplantation.<sup>22,23</sup> The actual number of transfusion cases is undoubtedly higher, because all seven cases have been detected in immunocompromised patients.<sup>21</sup> Although platelet products have been implicated in six of these seven events, the study in Mexico<sup>17</sup> revealed that two of four recipients who became *T. cruzi*-positive following transfusion had received whole blood from radioimmune precipitation assay (RIPA)-positive donors. An in-vitro study confirmed survival of *T. cruzi* up to 3 weeks in Whole Blood and Red Blood Cell (RBC) units,<sup>24</sup> underlining that the risk is not limited to platelet products. The largest look-back study performed in the United States found zero positive

recipients of 18 tested; only three of the components were platelets.<sup>25</sup> It remains unclear whether the apparently higher risk from platelets results from greater parasite survival and infectivity in this component or from the greater likelihood that recipients of platelets might be immunocompromised. Overall, data are lacking on infectivity estimates for different components, but it is estimated that roughly 20% of contaminated Whole Blood units will result in transfusion transmission.<sup>7,26</sup> Preliminary look-back efforts following introduction of a screening test in the United States suggest infectivity as low as 10% for RBC units.<sup>27</sup>

There is no definitive estimate of the nationwide seroprevalence of *T. cruzi* antibodies in the United States, but a study of donors in Miami and Los Angeles indicated roughly 1 per 10<sup>4</sup> donations were from a seropositive donor, and in Los Angeles this risk appeared to be increasing over time.<sup>25</sup> More recently, nearly 150,000 donors were screened as part of the licensure of a new commercial enzyme-linked immunosorbent assay (ELISA) for *T. cruzi* screening of blood donors. Conducted in three sites across California and Arizona, the repeat-reactive rates ranged from roughly 1:2000 in Los Angeles to 1:6000 in Tucson with half of all repeat-reactive donations testing positive by RIPA, a confirmatory assay, which at that time was not licensed by the Food and Drug Administration (FDA).<sup>28</sup> Following FDA licensure of the screening test in December 2006,<sup>29</sup> blood collection centers representing two-thirds of the US collections reported at least 582 RIPA-confirmed donors through August 8, 2008. Post-licensure results from two large blood centers covering a broad geographic area suggest an aggregate donor prevalence around 1:21,100.<sup>31</sup> Figure 48-1 reflects that although the states of California and Florida account for the great majority of RIPA-positive donors, the risk for transfusion transmission of *T. cruzi* is evident countrywide. Follow-up studies will help clarify the relationship between serologic status and parasitemia in donors, and the infectivity of components. Regulatory guidance is pending regarding donor screening for Chagas' disease, but the FDA has in the past publicly declared its support for universal donor testing given the availability of appropriate screening tests.<sup>32</sup> Meanwhile, AABB has issued recommendations for product management, recipient testing, and donor referral for medical evaluation for those blood centers choosing to implement Chagas' screening in the absence of FDA requirements.<sup>32</sup>

Aside from testing, options for risk reduction include donor exclusion, pathogen removal, and pathogen inactivation. Canada has for years addressed risk by excluding donors on the basis of residence and travel history in areas where the disease is endemic, but intends to implement the newly licensed ELISA.<sup>33</sup> In any case, deferral of donors on this basis is likely to be feasible only where such donors constitute a small portion of the donor pool. Leukocyte reduction filters have been shown to lower the concentration of trypanosomes in blood,<sup>34</sup> but at least one case of transfusion transmission in platelets was from a leukocyte-reduced and irradiated product.<sup>21</sup> A variety of photochemical treatment methods in platelets,<sup>35</sup> plasma,<sup>36</sup> and red cell components<sup>37</sup> all show promise in reducing the parasite load by several logs.

**Figure 48-1.** Donors with confirmed *T. cruzi* infection are concentrated in states with high numbers of Hispanic residents, but the risk for transfusion transmission exists countrywide. Data through August 8, 2008.<sup>30</sup>

## Malaria

Human malaria is caused by one of four species of protozoan parasites: *Plasmodium falciparum*, *P. vivax*, *P. malariae*, and *P. ovale*. Malaria is a significant cause of global morbidity and mortality, responsible for an estimated 350 to 500 million clinical cases annually and over one million deaths; the disease is especially severe among young children in sub-Saharan Africa.<sup>38</sup> Natural infection with malaria typically occurs through the bite of an infective female anopheline mosquito. Less frequently, parasites might be transmitted through blood transfusion, organ transplantation, parenteral exposure, or mother-to-child transmission.<sup>39,40</sup> The United States recorded an average of three cases of transfusion-associated malaria per year between 1963 and 1989.<sup>41</sup> An average of about one case per year—less than 0.1 per million donations—was the rate of occurrence from 1990 to 2005.<sup>42</sup> This compares favorably to the historical estimate of zero to two cases per million donations in nonendemic areas, as contrasted with an incidence of 50 cases per million donations in areas where malaria is endemic.<sup>43</sup>

In malaria-endemic settings, where frequent boosting by infective mosquito bites help induce and maintain protective immune responses, severe infection is rare for those who survive beyond early childhood.<sup>44</sup> In a nonimmune population, such as that of the United States, clinical malaria presents as a febrile illness with paroxysms, possibly at regular intervals, with accompanying flu-like symptoms. Complications can include severe anemia, hepatic involvement, cerebral alterations, renal failure, and shock.<sup>40</sup> The case-fatality rate for malaria is generally

low—less than 1% in developed countries,<sup>45,46</sup> but can surpass 10% in recipients of blood components.<sup>41</sup>

Once endemic throughout large parts of the country, malaria in the United States is now almost exclusively caused by imported infections.<sup>47</sup> In a typical year, 1200 to 1500 malaria infections are diagnosed in the United States, more than 95% of which are found in US civilians who have visited malaria-endemic areas and in foreign civilians from malaria-endemic countries. A comprehensive review of transfusion-transmitted malaria in the United States indicates that many of these infections were preventable, with >60% having occurred because of deviations from the prevailing deferral guidelines.<sup>41</sup> Of the cases in which donor exclusion guidelines were followed, *P. malariae* is 15 times more prevalent than its share of imported malaria overall in US travelers: 65% to 4%, respectively. This fact reflects the ability of *P. malariae* to remain at subpatent levels for lengthy periods, even up to 40 years.<sup>48</sup> Indeed, because all malaria parasites remain viable in blood stored at 4°C for at least 1 week, there exists risk from all four species.<sup>39</sup> *P. falciparum* malaria has been transmitted in blood stored for 19 days, as well as in units of platelets.<sup>49</sup> Interval to onset in transfusion cases is likely to vary by species, with *P. falciparum* being the quickest to develop at about 10 days, *P. vivax* taking 16 days, and *P. malariae* taking 40 days or more.<sup>39</sup> Where a donor has been implicated, recent history in the United States implicates presumably semi-immune visitors from malaria-endemic areas. Over a 20-year period, only one US civilian without previous residence in malaria-endemic countries has been implicated in transfusion transmission, in contrast to 28 former residents of malaria-endemic countries.<sup>41</sup>

In the absence of an FDA-approved blood screening assay, prevention of transfusion-transmitted malaria in the United States has long relied on exclusion of presenting donors with elevated risk for malaria infection. The different categories, which follow guidelines of FDA<sup>50</sup> and AABB,<sup>51</sup> are as follows:

1. Donors who are permanent residents of countries where malaria is not endemic who travel to an area considered malaria-endemic by the Centers for Disease Control and Prevention (CDC) are not accepted as donors of whole blood and blood components until 1 year following departure from the malaria-endemic area, assuming they have remained free of malaria symptoms.
2. Prospective donors who have had malaria should be deferred for 3 years after symptoms have abated.
3. Immigrants, refugees, citizens, or residents of countries where malaria is endemic should not be accepted as donors of whole blood and blood components before 3 years after departure, assuming they have remained free of malaria symptoms.

These guidelines do not apply to plasma, or plasma components or derivatives lacking intact red cells. In 2000, the FDA released draft guidance<sup>52</sup> that contained the following modifications to the 1994 policy:

1. Clarified the term “resident” of a malaria-endemic country as applying to those who had resided in a malarious area for 5 years or longer.
2. Clarified that prospective donors who have had malaria must have received appropriate treatment before remaining asymptomatic for 3 years.
3. Stipulated that donors who might possess partial acquired immunity to malaria should not be accepted as donors of whole blood or blood components for a period of 3 years following their last visit to a malarious region.
4. Called for specific donor travel questions, including capture questions with follow-up of travel history.

This 2000 draft guidance remains pending, and may be superseded by different recommendations discussed at a March 15, 2001 Blood Products Advisory Committee meeting.<sup>53</sup>

Advances in diagnostics have created opportunities for non-malarious countries to implement strategies that lessen the impact of malaria deferrals while minimizing risk of transfusion transmission. In Europe, regulations<sup>54</sup> published by the Council of Europe in 2006—and updated since then—endorse the use of validated immunologic tests to shorten the deferral period of donors with potential malaria risk who test negative. Those donors who have lived for 6 months or more in a malaria-endemic area are acceptable as blood donors if they test antibody-negative at least 4 months after their last visit to such an area, as opposed to being permanently deferred. Likewise, donors who report a travel history <6 months duration to malaria-endemic area may be accepted as blood donors if they test antibody-negative at least 4 months after their last visit to such an area, in contrast to a 1-year (no malaria symptoms reported) or 3-year deferral (malaria-like symptoms within 6 months of return from malarious area).<sup>54</sup>

Since 2001, England has used an enzyme immunoassay (EIA) based on three recombinant *P. falciparum* antigens and one *P. vivax* antigen (all to erythrocytic merozoite stage) to shorten the deferral period for at-risk donors to 6 months for those testing negative.<sup>55</sup> Australia also seeks to reinstate deferred donors on the basis of this same test,<sup>56</sup> and several other countries have malaria donor screening tests under evaluation.<sup>43</sup> Although not all four *Plasmodia* species are screened for in the assay adopted by England, it accounts for the two species causing most cases of transfusion transmission and does appear to have some cross-reactivity with other species.<sup>57</sup> Immunofluorescent antibody tests for malaria antibody detection tend to be sensitive, but have the limitations of being time-consuming and subjective. Direct methods for detection of malaria infection are also available. Most widely used for malaria diagnosis worldwide is Giemsa- or Wright-stained blood films, although their use is not practical for mass screening in areas where malaria is not endemic, where labor costs are prohibitive, and the expertise is lacking. Assays detecting circulating parasite antigens such as histidine-rich protein 2 and lactate dehydrogenase offer sensitivity as low as 100 to 1000 parasites per microliter,<sup>43</sup> still insufficient to prevent transfusion transmission. A variety of nucleic acid amplification test (NAT) techniques allow for detection of one or more malaria species. Conventional<sup>58</sup> and semi-nested polymerase chain reaction (PCR)<sup>59</sup> screening of blood bank samples have detection thresholds on the order of  $10^{-3}$  parasites/ $\mu$ L. Evaluation of the costs of screening blood donors by PCR supports a strategy targeting only those donors with identified risk factors for malaria by questionnaire, not one based on universal screening.<sup>60</sup> Newer NAT techniques such as loop-mediated isothermal amplification assay offer sensitivity and specificity equivalent to real-time PCR, but with shorter turnaround time and lower costs.<sup>61</sup> With an infectious dose theoretically as low as one to 10 parasites per unit of blood, however, even the most sensitive NAT detection methods cannot reduce the risk to zero.

---

## Babesiosis

Awareness of the risk for transfusion-transmitted babesiosis is growing, though historically it has been underappreciated. Transmitted by ticks, over 100 species of these intra-erythrocytic protozoan parasites infect a large number of vertebrate species worldwide.<sup>62</sup> In the United States, most reported cases of human babesiosis are caused by *Babesia microti*, especially in the Northeast and Upper Midwest; in Europe, *B. divergens* is considered responsible for most human illness from babesial infection. Heightened scrutiny, together with growing phylogenetic analyses, is documenting the human risk in new areas, as well as demonstrating a greater diversity of infecting species than heretofore appreciated.

Clinical manifestation of *Babesia* infection covers a broad spectrum, ranging from chronic, silent infection to fulminant, malaria-like illness. Most *B. microti* infections appear to be sub-clinical, but mild flu-like symptoms including fever, headache,

and myalgias can occur 1 to 6 weeks following a tick bite.<sup>62</sup> Risk for severe disease is higher in the elderly, the immunocompromised, and the asplenic. Complications can include thrombocytopenia; hemolytic anemia; and renal, heart, or respiratory failure.<sup>62</sup> The case fatality rate can range from 5% to 10% for *B. microti*<sup>63</sup> to 29% for *B. divergens*.<sup>64</sup> All reported cases of *B. divergens* have occurred in asplenic hosts,<sup>64</sup> which almost certainly contributes to this disparity.

Since the first case of human babesiosis was recorded in the United States in 1968,<sup>65</sup> over 1500 cases have been reported in the country. The primary agent *B. microti* is transmitted by the black-legged deer tick (*Ixodes scapularis*, formerly known as *I. dammini*), the vector of Lyme disease. Most US cases are reported in the Northeast and the Upper Midwest, with the former region extending as far south as New Jersey. Sporadic cases of human babesiosis caused by other *Babesia* species have been reported from Washington state and northern California, Missouri, and Kentucky since the early 1990s.<sup>66-68</sup> In Europe, about 30 human cases of babesiosis have been reported since the first report in 1957, a fatal case in an asplenic Yugoslav farmer.<sup>69</sup> Most European cases are attributed to *B. divergens*, also a bovine pathogen, with cases reported from several countries in Western Europe, the former Yugoslavia, and the former USSR.<sup>64</sup> Risk for human infection correlates geographically with the presence of infected cattle populations and areas infested by the tick vector, *Ixodes ricinus*; little is understood about the role that spleen-intact human populations and silent carriage of *B. divergens* might play in terms of risk to the blood supply.<sup>64</sup>

Greater awareness and scrutiny, together with molecular and biologic characterization of patient isolates of *Babesia* parasites, have yielded a more complex picture than historically thought, one still being elucidated. The predominant cause of human babesiosis in the United States—*B. microti*—has been denominated a diverse species complex composed of three distinct clades with identical morphology, but partly distinct vertebrate hosts and potentially differing levels of pathogenicity for humans.<sup>70</sup> Also in the United States, some, but not all, of the isolates from the Pacific Northwest have been grouped as a new species, *Babesia duncani*, that has been found in humans, dogs, and wildlife in the Western United States.<sup>71</sup> *Babesia* isolates from human cases in Missouri and Kentucky<sup>67,68</sup> and also from rabbits on Nantucket Island<sup>72</sup> that were originally attributed to *B. divergens* are now considered to be distinct from the agent of most human babesiosis in Europe.<sup>73</sup> These isolates, along with another from an asplenic man whose parasitemia surpassed 40%, are considered “*divergens*-like” on the basis of morphologic, serologic, and phylogenetic analysis.<sup>74</sup> This means that at least three distinct species of *Babesia* protozoa are known to cause human illness in the United States. As underappreciated as the risk for *B. microti* might be, even less is known about the risk posed to human health and the blood supply by the newly described species and isolates.

In Europe a similar picture is emerging. Although most cases of human babesiosis are attributed to *B. divergens*, a new

variant—designated EU1—has been isolated from asplenic patients in Italy and Austria. A near-identical isolate (EU3) was found in an asplenic German patient. Both organisms are phylogenetically closest to *B. divergens* and *B. odocoilei* (a parasite of white-tailed deer).<sup>75,76</sup> Also, the mounting entomologic<sup>77</sup> and serologic<sup>78</sup> evidence for human cases of *B. microti* in Europe has been confirmed by the first documented autochthonous case of human babesiosis in Europe caused by this agent, likely through blood transfusion.<sup>79</sup>

Finally, in East Asia, the first case of autochthonous human babesiosis in Japan has recently been confirmed, a result of transfusion-acquired *B. microti*-like infection.<sup>80</sup> Asymptomatic, *B. microti*-like infection has been documented in Taiwan.<sup>81</sup> The first case of human babesiosis has been reported from Korea, with the isolated parasite designated KO1 and appearing to be related to *Babesia* species that infect sheep.<sup>82</sup>

The two most salient features of *B. microti* infection contributing to transfusion risk are the probability that most infections are clinically silent<sup>83</sup> and the ability of immunocompetent persons to carry infection for lengthy periods.<sup>84</sup> There is no certain measure of what proportion of infections are asymptomatic, but seropositivity rates of blood donors or the general population tend to be orders of magnitude higher than the rates of symptomatic cases reported to public health departments. For example, the highest reported incidence of babesiosis in any part of Connecticut in 2002 was 62.7 cases per 100,000 population (0.06 %) in the town of Waterford.<sup>85</sup> However, a survey of blood donors in the region of the state of highest endemicity (southeast corner) indicated a point prevalence more than 20 times higher, at 1.4%.<sup>86</sup> Of 19 seropositive donors, 10 were confirmed parasitemic by PCR. Early research confirmed the ability of the parasite to persist for several months in untreated individuals.<sup>84</sup> In in-vitro studies, the parasite survives storage at 4°C and remains infective for up to 21 days,<sup>87</sup> and one case of transfusion transmission occurred after the storage of blood for 35 days.<sup>88</sup> The implications of long-term carriage of *B. microti* are amply demonstrated in a case in Minnesota, where an asymptomatic donor infected recipients from each of four donations over a 6-month period.<sup>89</sup>

In the United States, an estimated 60 transfusion cases of *Babesia* infection have occurred since the first report in 1980, with an estimate that 10 cases occur annually, many unpublished.<sup>90</sup> Most cases of transfusion transmission have involved RBCs, although transmission through platelet concentrates has also been reported.<sup>91</sup> In transfusion cases, symptoms typically develop 2 to 8 weeks following transfusion, and include fever, hemolytic anemia, and thrombocytopenia.<sup>92</sup> Transfusion transmission of *B. microti* has been documented once each in Canada,<sup>93</sup> Germany,<sup>79</sup> and Japan,<sup>94</sup> the only countries besides the United States to report transfusion cases of *Babesia*. Only the cases in Germany and Japan reflect autochthonous transmission, however. In Canada the donor acquired infection while on holiday in the United States. In the Pacific Northwest, the variant designated WA-1, since named *B. duncani*, has also been implicated in two cases of transfusion transmission.<sup>95</sup>

Few studies have directly measured the risk for transfusion transmission of *Babesia* parasites. Given the absence of symptoms in healthy individuals, studying paired donor-recipient specimens is the most secure way of estimating the risk in areas of endemicity. One study estimated a risk of 1 in 617 units (0.17%) of RBCs might be at risk for transmitting *B. microti* in the state of Connecticut, with the risk from platelets estimated as zero.<sup>96</sup> In another Connecticut study, analysis of paired donor-recipient specimens involving chronically transfused patients indicated one possible *B. microti* seroconversion in nearly 2000 evaluable transfusions.<sup>97</sup> Infectivity of different blood components is not easy to determine given that the likelihood of transmitting infection to and detecting clinical infection in the recipient are both likely to depend on the dose of parasites, the length of storage, and the recipient's immune status. In the aforementioned case in Minnesota, one of three recipients of platelets became infected with *B. microti*, while all three surviving recipients of red cells became infected.<sup>89</sup> In another case, of six individuals transfused with RBCs from an asymptomatic donor, two neonates and one elderly adult became infected, while two other neonates and a child remained aparasitemic.<sup>98</sup> Look-back studies in Connecticut found that 26% of recipients of RBC units became infected, compared to only 11% of those receiving platelet products.<sup>99</sup>

Traditional diagnosis of *Babesia* infection relies on microscopic examination of Giemsa-stained blood films. This method, however, requires an experienced microscopist, and a high enough index of clinical suspicion to perform the examination. Immunofluorescent assay diagnosis is both sensitive and specific for measuring exposure, but is too time consuming for mass screening, and involves subjectivity on the reader's part. Inoculation of blood from suspected human cases into laboratory animals offers both high sensitivity and specificity, but its utility is limited to research investigation. Real-time PCR appears to be up to three times as sensitive as conventional nested PCR for donors with variable serologic status.<sup>100</sup>

Human babesiosis has historically been treated with clindamycin and quinine (CQ), but atovaquone with azithromycin has emerged as the first-line recommendation in the United States because of fewer collateral effects.<sup>101</sup> Treatment with CQ continues to be recommended for severe cases, although partial or whole blood exchange transfusion might be performed in such cases.<sup>101,102</sup>

In the absence of a licensed screening assay, prevention of transfusion-transmitted babesiosis relies exclusively on asking donors if they have ever had babesiosis. This strategy is insufficient because only donors whose *Babesia* infection was patent and properly diagnosed will self-report a risk. Because the majority of *B. microti* infections are silent or remain undiagnosed,<sup>103</sup> parasitemic donors can escape detection. Seasonal deferral in areas of endemicity would adversely impact the blood supply, and would not address the issues of nonresidents who travel to *Babesia*-endemic areas<sup>93</sup> nor the transfer of blood components from areas where the infection is endemic to areas where it is not.

The predictive value of self-reported exposure to ticks in relation to serologic status has proven low in Wisconsin and Connecticut donors.<sup>104</sup>

As with other protozoan infections, pathogen inactivation methods hold promise in reducing the risk from transfusion-transmitted babesiosis. A range of photochemical treatments currently under development indicate reductions by 4 to 5 logs in plasma<sup>105</sup> and platelets.<sup>106</sup> Electrophilic agents that disrupt nucleic acid replication have shown potency in inactivating *B. microti* by bio-assay (hamster inoculation) and by PCR.<sup>107</sup>

---

## Leishmaniasis

*Leishmania* species are a large group of protozoan parasites with broad distribution worldwide.<sup>108</sup> *Leishmania* parasites are transmitted in nature by the bite of a female phlebotomine sandfly, but can also be transmitted via blood components and, rarely, congenitally or sexually.<sup>109</sup> Clinical manifestations can vary widely, ranging from asymptomatic infection to severe illness with visceral, cutaneous, or mucosal involvement. The visceral form (kala-azar) is characterized by fever, wasting, hepatosplenomegaly, and pancytopenia; if untreated it is usually lethal.<sup>110</sup> Cutaneous forms involve progressive skin lesions that become ulcerative, sometimes with mucosal involvement. Although *Leishmania* species are endemic in about 88 countries, the public health burden is hardly uniform. More than 90% of visceral cases appear in Bangladesh, Brazil, India, Nepal, and Sudan, and about 90% of cutaneous leishmaniasis occurs in Afghanistan, Brazil, Peru, Iran, Saudi Arabia, and Syria.<sup>111</sup> The World Health Organization (WHO) estimates that 2 million new infections occur annually—about 1.5 million are cutaneous leishmaniasis (CL), and half a million are visceral leishmaniasis (VL); overall, as many as 12 million people worldwide are infected.<sup>111</sup> The distribution is expanding because of myriad factors that include ecological disturbances, growing urbanization in developing countries, and the growing numbers of people immunocompromised by human immunodeficiency virus (HIV) infection or other reasons.<sup>109</sup> The United States is home to both phlebotomine sandflies and *Leishmania* parasites, but autochthonous transmission is limited to infrequent and isolated outbreaks.<sup>112</sup>

The infective form of *Leishmania* parasites in the sandfly is the flagellated promastigote; in humans and other vertebrate hosts the parasite takes the form of an oval amastigote that is typically found in phagocytic vacuoles of macrophages and other mononuclear phagocytes.<sup>113</sup> Diagnostic methods include microscopic visualization of amastigotes in the tissue aspirates or biopsies from spleen, marrow, or lymph nodes, or in the peripheral blood buffy coat. The duration of parasite circulation in the blood can vary across the >20 *Leishmania* species, but in any case rarely lasts more than 1 year.<sup>114</sup> The immunologic response differs according to the clinical syndrome, with VL leading to a stronger and more enduring antibody production than CL.<sup>114</sup> The conventional treatment of leishmaniasis has been pentavalent antimony, but

new strategies include lipid formulations of amphotericin B, injectable paromomycin, and miltefosine.<sup>115</sup>

The risk for transfusion transmission of *Leishmania* may be underappreciated and its occurrence underreported, with 10 probable or confirmed cases having been reported in the literature<sup>116</sup> over the past 60 years. Half of these cases were in infants, and nine of 10 were in children 6 years of age or younger.<sup>108</sup> The average incubation period was over 7 months, with fever and hepatosplenomegaly being the most common symptoms.<sup>108</sup> Studies from areas of endemicity, as well as studies of US military personnel returning from operations in southwest Asia, highlight the risk. Viscerotropic *L. donovani* and *L. tropica* isolated from US armed service personnel have been shown to survive at least 25 days in Whole Blood or RBCs stored at 4°C, at least 5 days in platelet concentrates stored at 24°C, and at least 35 days in glycerolized RBCs frozen at -70°C. Further, *L. tropica*-spiked Whole Blood stored at 4°C for 30 days retained infectivity to healthy mice. Fresh frozen plasma did not support parasite survival.<sup>117</sup>

Because transfusion transmission would likely be mistaken for sandfly transmission in *Leishmania*-endemic areas, and because infection may remain subpatent in immunocompetent individuals, assessing the risk for transmission in blood is a challenge. The few studies involving blood donors indicate nonnegligible rates of detectable parasitemia. In one study in southern France, 76 of 565 blood donors were seropositive by Western blot, and direct detection via kinetoplast DNA amplification and/or direct culture from buffy coat samples were positive in 16 donors. The investigators concluded that *L. infantum* circulates intermittently and at low density, and that serologic screening of donors would be insufficiently specific to maintain blood availability.<sup>118</sup> Another study in the Balearic Islands of Spain found similar results. From 656 healthy blood donors, 2.4% to 7.6% were seropositive by different methods, and 22% of a subset of donors yielded positive cultures. Further, nine of 18 donors who were positive by nested PCR remained positive 12 months later.<sup>119</sup> Numbers of this magnitude suggest that the actual transfusion risk might be quite a bit higher than indicated by published reports, which represent cases detected in largely immunosuppressed individuals.

The options available to blood banks to prevent distribution of *Leishmania*-contaminated blood are limited. Targeted donor exclusion is practiced selectively in the United States, specifically relating to the risk of armed services personnel and other travelers to theaters of war harboring *Leishmania* species upon return. To prevent this, AABB established a 12-month deferral during Operation Desert Storm in Iraq in the early 1990s, and again more recently.<sup>116</sup> Given the broad distribution of *Leishmania* across 88 countries, travel-based deferrals might prejudice blood availability if strictly applied, while further lengthening and complicating the donor health history questionnaire. Because serologic status correlates poorly with asymptomatic infection,<sup>120,121</sup> antibody tests hold little promise for donor screening. Photochemical inactivation of different *Leishmania* species has shown 4-log reduction of amastigote and promastigote forms

in apheresis platelets,<sup>122</sup> and another study demonstrated 5- to 6-log reductions in both platelets and plasma.<sup>123</sup> Early results of another method using phototreatment alone shows promise in red cells.<sup>124</sup> Further, filtration of leukocytes at both the point of collection and the bedside has been shown to dramatically lower free and intracellular *Leishmania* parasites.<sup>125</sup>

## Toxoplasmosis

*Toxoplasma gondii* is an obligate, intracellular protozoan that can grow in any mammalian or avian organs or tissues.<sup>113</sup> Felines (the definitive host) become infected in nature by consuming intermediate rodent hosts with infective *Toxoplasma* cysts in the brain or skeletal muscle. The parasite is ubiquitous in nature and can infect a wide variety of animals, including sheep, cattle, and pigs, developing into cysts that remain infective for years. Human infection can occur through many modes of transmission. Most commonly, they include consumption of raw or undercooked meat containing *Toxoplasma* cysts, and accidental ingestion of *T. gondii* oocysts from soil or cat litter contaminated with excreted oocysts. Water is increasingly implicated as a vehicle for transmission.<sup>126</sup> There are rare reports of infection acquired via solid-organ transplantation and blood transfusion.<sup>113</sup> Finally, congenital transmission can occur when the mother acquires primary infection during pregnancy, but the probability of transmission to the fetus (and clinical outcome) depends on the timing of infection.<sup>127</sup>

Up to one-third of the world's population is estimated to be infected with *T. gondii*. About 90% of primary infections are subclinical, and appear to be lifelong. Illness in those with patent infections is usually non-specific and self-limiting, typically involving fever and isolated swollen lymph nodes. More rarely, infection might lead to myocarditis, pneumonitis, hepatitis, or encephalitis.<sup>128</sup> Toxoplasmosis is more frequently severe in immunocompromised hosts, and it has emerged as a common opportunistic infection of persons with AIDS.<sup>129</sup> Estimates of seroprevalence across countries vary from less than 10% to greater than 90%, and the acquisition of infection depends on an array of local and household factors that include hygiene and sanitation, source and preparation of food, exposure to felines, and climatic factors influencing the survivability of oocysts in nature.<sup>128</sup> In the United States, the National Health and Nutrition Examination Survey (NHANES) from 1988 to 1994 indicated an age-adjusted seroprevalence of 22.5% for those above 12 years of age.<sup>129</sup> The subsequent NHANES (1999-2004), also drawn from a nationally representative sample, demonstrated a decline in seroprevalence greater than one-third for US-born residents between 12 and 49 years of age. Notably, foreign-born residents living in the United States were three times as likely as US-born residents to be antibody-positive, 24.8% vs 8.2%, respectively.<sup>130</sup>

Transfusion transmission of toxoplasmosis was reported nearly 40 years ago, in a case where patients with acute leukemia were transfused with leukocytes from donors with chronic

myelogenous leukemia.<sup>131</sup> Although few reports of transfusion transmission are recorded in the literature, the risk has been well documented in recipients of cardiac transplant,<sup>128</sup> bone marrow transplant,<sup>132</sup> and more recently, small-bowel and other solid-organ transplantation.<sup>133</sup> Limited seroprevalence studies have been conducted in healthy blood donors, indicating a broad range of antibody prevalence: 7.4% in Durango, Mexico<sup>134</sup>; 9.6% in northeast Thailand<sup>135</sup>; 20% in Turkey<sup>136</sup> and southern India<sup>137</sup>; and 75% in northeastern Brazil.<sup>138</sup> Antibody presence is long-lived and does not necessarily denote infectivity. Little information is available on the long-term kinetics of antibody development and patent parasitemia. Advances in diagnostic methods include nested PCR<sup>139</sup> and rapid, real-time PCR,<sup>140</sup> but these assays are used principally for diagnosis of congenital and ocular toxoplasmosis and with immunocompromised patients.<sup>128</sup> Parasite isolation or detection by PCR is rarely useful in immunocompetent patients,<sup>141</sup> indicating low probability of detectable parasitemia. One study in Brazil performed real-time PCR on buffy coat samples from individuals classified by serology as chronically infected, and found 3.6% (4 of 110) were positive.<sup>140</sup> The mechanisms regulating the persistence of *T. gondii* infection and the conversion from quiescent to active infection are still being elucidated.<sup>142</sup> Although PCR has been established as effective at diagnosing ocular toxoplasmosis in immunocompetent patients,<sup>128</sup> the presence of low-grade or intermittent parasitemia in healthy individuals remains little studied. However, the ability of the parasite to survive 50 days at 4°C,<sup>131</sup> and the isolated reports of transfusion transmission in the literature, both establish an element of risk.

Prevention of transfusion-transmitted toxoplasmosis is not feasible with either donor exclusion or serologic screening. In most places, discarding units from seropositive donors would heavily prejudice blood availability, with unclear indications that positive antibody status of the donor implies risk for parasitemia. In high-prevalence countries, many blood recipients are likely to have been previously exposed. In an immunocompetent recipient, transfusion transmission is likely to go undetected. Given the parasite's ability to readily invade and replicate in leukocytes,<sup>143,144</sup> leukocyte filtration might diminish the risk in similar fashion as with cytomegalovirus. Whether inactivation treatments being evaluated for other protozoa might be of use for *Toxoplasma* remains unexplored.

## Microfilariasis

Filarial worms are arthropod-borne macroparasites that can be caused by a number of different organisms. *Wuchereria bancrofti* and *Brugia spp.* cause lymphatic filariasis; *Loa loa*, *Onchocerca volvulus*, and *Mansonella streptocerca* cause nonlymphatic, subcutaneous filariasis; and *M. ozzardi* and *M. perstans* cause nonlymphatic infections of different body cavities and are typically asymptomatic or mild.<sup>113</sup> The filariases occur in more than 80 countries, and the health and socioeconomic burden from

lymphatic filariasis and *O. volvulus* are particularly severe, with an estimated prevalence of 120 million and 37 million infections, respectively.<sup>145</sup> These organisms share similar life cycles and are all transmitted by hematophagous arthropods. In each, adult female worms produce larvae called microfilaria, which for most species circulate in the bloodstream, sometimes with periodicity timed to their primary insect vector's feeding habits.<sup>113</sup> The microfilaria are the infective form for insects, but when transmitted by transfusion are incapable of propagating further.<sup>146</sup>

The lymphatic forms of filariasis, which cause elephantiasis, have been targeted by WHO as potentially eradicable, primarily by eliminating the human reservoir of microfilaria that infect the mosquito vectors through repeated mass administration of curative drugs.<sup>147,148</sup> Results from low- to moderate-prevalence areas in Egypt<sup>149</sup> and from moderate- to high-prevalence parts of Papua New Guinea<sup>150</sup> indicate dramatic success in lowering human infections and even, surprisingly, reversing the pathology associated with infection.

There is little published information on the risk for transfusion transmission of filariasis. In most filariasis-endemic areas, the risk for vector-acquired infection would be orders of magnitude greater than that from transfusion for the average individual, given the relative degree of exposure to infective insect vectors and the limited rate of blood transfusion. However, limited studies from Nigeria have shown prevalence of microfilaria of 3.5% with *Loa loa*<sup>151</sup>; 15.6% with *M. perstans* and 1.3% with *L. loa*<sup>152</sup>; and 1.3% with unspecified microfilaria.<sup>153</sup> There has been at least one report of an American blood donor being found with microfilaria.<sup>146</sup> Isolated case reports of transfusion transmission exist from Italy<sup>154</sup> and India,<sup>155</sup> in both cases indicating that the outcome in blood recipients might often be no more severe than mild allergic reaction in response to microfilarial antigens.

The microfilaria of both *W. bancrofti*<sup>156</sup> and *L. loa*<sup>157</sup> survive routine storage conditions for blood. Those from *M. ozzardi*<sup>158</sup> and from *B. malayi* and *W. bancrofti*<sup>159</sup> have been successfully recovered following cryopreservation in research laboratories. One article from Spain reports an evaluation of alternative strategies for screening for *L. loa* microfilaria in donors from Central and West Africa.<sup>160</sup> This example is the exception, however, as most countries appear to consider the risk to blood recipients too small to merit donor or component screening.

## Conclusion

The risk for transfusion transmission of parasites in the United States is not high, but might well be greater than the prevailing estimated risks of one per million units. Until the recent licensure of a screening assay, it appears likely that hundreds of individuals have donated annually while infected with *T. cruzi*, the result of demographic changes in the United States and its donor population. Even assuming low-end estimates of infectivity, that implies dozens of cases of transfusion-transmission annually. The clinical impact of such events might be

uncertain, but at least in immunocompromised blood recipients the risk is serious.

Perceived risk for *Babesia* species in blood might not be widespread, but the combination of asymptomatic infection in healthy donors, the lack of a licensed screening assay, and the mobility of both people and blood components implies risks that are higher and geographically less circumscribed than appreciated.

Silent infection in semi-immune donors contributes to risk for malaria transmission in blood components, but recent years have seen an average of one case per year. Serologic or direct detection assays can both contribute to enhanced safety against these and other parasitic agents. Broadly effective methods such as pathogen removal or inactivation also appear promising.

Bacterial contamination of blood components is a persistent but often overlooked problem in transfusion medicine. Before recent developments in skin preparation, diversion, and testing for bacterial contamination, the incidence of platelet bacterial contamination was approximately 1 in 1000.<sup>1</sup> Although recent public attention has focused on transfusion-transmitted viral infection, improved methods of screening through donor questioning and testing have greatly reduced the transmission of hepatitis viruses and retroviruses. Given the reduction of viral transmission via allogeneic blood, the risk of bacterial contamination has emerged as the greatest residual threat of transfusion-transmitted disease.

This chapter provides a quick overview of risks associated with blood components. The main focus is on approaches to minimize or eliminate the risk of bacterial contamination.

---

**Transfusion-Transmitted Bacterial Infection of Red Blood Cells**

Sepsis associated with the transfusion of bacterially contaminated Red Blood Cell (RBC) components is generally regarded as a very rare event. From 1995 to 2004, 25 fatalities thought to be secondary to contamination of Whole Blood or RBC units were reported to the US Food and Drug Administration (FDA) (Fig 49-1).<sup>2</sup> The risk of death from a bacterially contaminated RBC transfusion in the United States has been estimated to be 0.13 per million.<sup>3</sup> Reports from New Zealand have indicated a *Yersinia enterocolitica* transfusion-transmitted incidence rate of 1 in 65,000, with a fatality rate of 1 in 104,000 RBC units transfused.<sup>4</sup> Unrecognized cases, underreporting, and regional variation may account for observed differences in the incidence.

Passive reporting studies from the United States,<sup>3</sup> France,<sup>5</sup> and United Kingdom (UK)<sup>6</sup> of bacterially contaminated RBCs that caused symptoms of infection show a relative paucity of

*Yersinia* cases (Table 49-1). Of the reported deaths, one was caused by a coagulase-negative *Staphylococcus* strain and seven were caused by a variety of gram-negative organisms. These organisms are all capable of growth at 1 to 6°C. Sepsis associated with the transfusion of gram-negative bacterially contaminated RBCs is typically severe and rapid in onset. Patients frequently develop high fevers (temperatures as high as 109°F have been observed) and chills during or immediately following transfusion. From 1987 to 1996, 20 cases of *Yersinia*-infected RBC units in 14 states were reported to the Centers for Disease Control and Prevention (CDC).<sup>8</sup> Twelve of the 20 recipients died in 37 days or less following transfusion. The median time from transfusion to death was 25 hours. Of the seven who developed disseminated intravascular coagulation, six died.

**Allogeneic RBC Units**

Asymptomatic donors with transient *Yersinia* bacteremia are presumed to be the source of contamination. Implicated donors are typically found to have infection elevated antibody titers [immunoglobulin M (IgM) or IgG] to *Y. enterocolitica*, implying a recent infection.<sup>8-10</sup> The possibility of contamination of RBC components is directly related to their storage time; most cases of *Yersinia* contamination of RBC units occur after storage for 25 days.<sup>11</sup>

*Serratia marcescens* was linked to an outbreak caused by contamination of RBCs in Denmark and Sweden.<sup>12,13</sup> The contamination was thought to involve the manufacturing process, because the sterile bag sets were autoclaved and put in a clean but not sterile outer plastic package. It was thought that *S. marcescens* present in the dust in the factory contaminated the outside of the containers, and in the presence of moisture and a nutrient (the plasticizer diethylhexylphthalate), the bacteria proliferated and somehow gained entry into the bag.<sup>14</sup>

Prospective bacterial cultures of Whole Blood or RBC units, however, have shown a much higher incidence of bacterial contamination (2 to 4 per 1000 units). The organisms commonly cultured are *Staphylococcus* or *Propionibacterium* spp., which generally proliferate poorly during storage at 1 to 6°C.

**Figure 49-1.** Transfusion fatalities by organism in RBC units or whole blood, as reported to the United States Food and Drug Administration from 1995-2004 10 yrs, 25 cases (data from Niu et al<sup>2</sup>).

**Table 49-1.** Summary of Organisms from RBC Transfusions Identified in the BACON, SHOT, and BACTHEM Studies\*

| Organism                                | United States<br>BACON | United Kingdom<br>SHOT | France BACTHEM<br>(29 isolates, 25<br>implicated units) | Total         |

Autologous RBC Units

Although autologous blood is generally considered a “safer” blood component, there have been at least six reported cases of bacterial contamination of autologous RBC units, five

from *Y. enterocolitica*<sup>15-18</sup> (and personal communication, Susan Cookson, CDC, September 23, 1996) and one from *Serratia liquefaciens*.<sup>19</sup> Fortunately, all recipients survived, possibly because of preformed immunity. Upon retrospective

**Figure 49-2.** Transfusion fatalities by organism in platelets, as reported to the United States Food and Drug Administration from 1995-2004 10 yrs, 60 cases (data from Niu et al<sup>2</sup>).

questioning, all patients infected by *Yersinia* recalled gastrointestinal symptoms in the days before donation. In the case of *Serratia* contamination, the patient's infected toe ulcer was presumed to be the source.

### Transfusion-Transmitted Bacterial Infection of Plasma, Cryoprecipitate, and Derivatives

Cell-free products, such as plasma and cryoprecipitate, are stored in the frozen state and thus are rarely associated with significant contamination. However, *Pseudomonas cepacia* and *P. aeruginosa* have been cultured from cryoprecipitate and plasma thawed in contaminated waterbaths.<sup>20,21</sup>

Human serum albumin is a good culture medium and preserves viability of contaminants. The heating step (60°C for 10 hours) in the manufacturing of albumin is performed to inactivate certain viruses, not to ensure bacterial sterility.<sup>22,23</sup> This would require autoclaving (superheated under pressure), which would cause albumin to denature. On occasion, specific lots of albumin product have been found to be contaminated with bacteria, typically *Pseudomonas* spp.<sup>24</sup> These lots have produced endotoxic shock, transient bacteremias, and febrile reactions in recipients. Two patients in different hospitals developed *Enterobacter cloacae* septicemia after receiving albumin.<sup>24,25</sup> Cultures of unopened product grew *Stenotrophomonas multophilus* and *Enterococcus gallinarum* in addition to *E. cloacae*. This resulted in a worldwide recall of certain lots of 5%, and 25% albumin. It is suspected that cracks in the glass bottles were responsible for the contamination. Manufacturing problems, therefore, are a source of bacterial risk from these derivatives.

### Transfusion-Transmitted Bacterial Infection of Platelets

#### Source of Contamination

Skin commensal organisms such as *Staphylococcus epidermidis* and *Bacillus cereus* are the organisms most often implicated in platelet bacterial contamination.<sup>26,27</sup> These organisms typically do not grow at 0 to 6°C, but survive and multiply readily at 20 to 24°C, the storage temperature of platelets. Fatalities caused by platelet contamination tend to be predominantly gram-negative organisms (Fig 49-2). Potential sources of these organisms include 1) donor-related transient bacteremia; 2) incomplete disinfection or skin core removal by the collection needle; and 3) contamination of the collection bag, tubing, or anticoagulant. In some cases, retrograde flow from vacuum tubes used in collection or even the recipient have been implicated as a source of contamination.<sup>28,29</sup>

#### Clinical Presentation

The clinical sequelae resulting from transfusion of bacterially contaminated platelets range from asymptomatic to mild fever (which may be indistinguishable from a nonhemolytic transfusion reaction) to acute sepsis, hypotension, and death. The clinical picture is much more varied and often less severe than that of patients infected by transfusion of bacterially contaminated RBCs.<sup>30</sup> Sepsis caused by transfusion of contaminated platelets is vastly underrecognized and underreported. Those patients who receive the greatest number of platelets (patients being treated with chemotherapy who are both thrombocytopenic and immunosuppressed) are those most at risk of sepsis (Table 49-2). In such patients fever can be readily

attributed to other infectious causes. Broad-spectrum antibiotics should be considered for any patient who develops fever within 6 hours of platelet transfusion.<sup>31,32</sup>

Incidence

Sepsis resulting from transfusion of bacterially contaminated platelets is the most common transfusion-transmitted disease. Platelets are stored at room temperature, 20 to 24°C, making them an excellent growth medium. Multiple aerobic-culture surveillance studies have demonstrated that 1 in 1000 to 3000 platelet units are bacterially contaminated (Table 49-3). Based on the fact that approximately 10 million platelet units are transfused every year in the United States,<sup>39</sup> it has been estimated that 2000 to 4000 bacterially contaminated platelets units are transfused every year. Despite the estimates of contamination, the actual septic transfusion reaction rates were much lower at approximately 1 in 25,000 platelet units (range 1 in 13,000 to 100,000).<sup>3,5,40</sup> Observations from hospitals actively pursuing platelet-related sepsis support these estimates. Johns Hopkins found a fatality rate of 1 in 17,000 for pooled platelet-rich plasma, whole-blood-derived (PRP-WBD) platelets

Table 49-2. Factors Affecting Outcome of Transfusion of Bacterially Contaminated Blood Components

- Virulence of the organism
- Immune status and general condition of the recipient
- Concentration and bolus dose of bacteria transfused
- Timely recognition and therapeutic intervention
- Intensity of patient monitoring—ie, inpatient vs outpatient
- Medicines the patient is receiving—ie, antibiotics

and 1 in 61,000 for apheresis units.<sup>40</sup> The University Hospitals of Cleveland reported a fatality rate of 1 in 48,000 per PRP-WBD platelets.<sup>41</sup> However, it is widely suspected that platelet bacterial sepsis is frequently unrecognized and, thus, is underreported. From October 1, 1995 to September 30, 2004, there were 60 transfusion-transmitted fatalities caused by contamination of platelets reported to the FDA (2) (Tables 49-4 and 49-5).

## Prevention

Both the College of American Pathologists (CAP) and AABB have instituted steps to require the detection of bacteria in platelet products. In December 2002, the CAP added a phase I item to the Laboratory Accreditation Checklist regarding the detection of bacteria.<sup>42</sup> The checklist item, TRM.44955, asked “Does the laboratory have a system to detect the presence of bacteria in platelet components?” The question was revised in December 2004 to ask “Does the laboratory have a validated system to detect the presence of bacteria in platelet components?” With this revision, the CAP ceased allowing swirling to be an acceptable method of detection, but still allows the use of surrogate testing methods such as pH or glucose measurements.

In March 2004, AABB instituted a new standard that requires blood banks or transfusion services to have steps in place to limit and detect bacterial contamination in all platelet products.<sup>43</sup> Since that time, blood centers and transfusion services have been implementing a variety of interventions to accomplish this goal.

The American Red Cross (ARC) began routine aerobic cultures using the BacT/ALERT (bioMérieux, Durham, NC) at that time and in their first 10 months of testing, 226 of 350,658 platelet collections initially tested positive.<sup>44</sup> Sixty-eight of these were confirmed positives for a rate of bacterial contamination of 1 in 5157. In the first two years of testing by the ARC, the confirmed positive rate was 1 in 5399 apheresis platelet units.<sup>45</sup> Despite universal testing of all platelet products, in the 2-year period from March 2004 through May 2006, the ARC reported 20 septic transfusion reactions caused by transfusion of

bacterially screened units. Of the 20 septic reactions, three were fatal and involved a *Staphylococcus* species. All of the units involved with septic fatalities and 13 of the units implicated in septic reactions were associated with platelets transfused on the fifth day after collection. If the units implicated in the septic transfusion reactions (which were culture negative) were considered to have tested as false-negative, the false-negative rate would be 1 in 74,807.<sup>46</sup>

The effects of the AABB standard are difficult to quantify. On the basis of 2006 platelet utilization data, in the United States in one year, approximately 2.8 million platelet units were transfused (1.5 million apheresis platelets and 1.3 million WBD platelets).<sup>39</sup> Using different fatality projections, anywhere from eight fatalities per year, based on the BaCon study,<sup>3</sup> up to 40 fatalities per year, based on a 1% fatality rate<sup>46</sup> would be expected. From 1995 to 2004, 60 deaths caused by bacterially contaminated platelets were reported to the FDA, averaging six deaths per year before the initiation of the standard.<sup>2</sup> Using the ARC data for 2004 through 2006 with additional data from Blood Systems, Inc. (1 probable septic transfusion reaction in 209,654 collections tested) and the New York Blood Center (no septic transfusion reactions in 150,241 collections tested), the passively reported septic reaction rate with platelets since testing is approximately 1 in 230,000.<sup>47</sup> This is compared to an approximate rate of 1 in 40,000 reported by ARC for a 10-month period in 2003.<sup>44</sup> This shows a decrease in the risk of septic reactions from platelets since the institution of the AABB standard, but these data are limited by virtue of being passively reported.<sup>47</sup>

Strategies to Reduce the Risk of Posttransfusion Sepsis

Several approaches to the reduction of risk of posttransfusion sepsis can be grouped into four major categories: bacterial avoidance, growth inhibition, detection, and elimination.

Bacterial Avoidance

Donor Screening

Histories of recent dental procedures, gastrointestinal or genitourinary procedure, and breast feeding (which can be associated with skin cracks) may all be associated with bacteremia and are cause to defer a potential donor. Unfortunately, asking donors about symptoms suggestive of infections are problematic. For example, 13% of donors have had gastrointestinal symptoms in the 30 days before donation.<sup>48</sup> In addition, retrospective questioning of donors implicated in *Yersinia* red cell sepsis showed that only half had any gastrointestinal symptoms in the preceding 30 days.<sup>8-10</sup> Therefore, donor questioning about gastrointestinal symptoms does not appear to be a specific predictor of *Yersinia* bacteremia.

Skin Preparation

Despite excellent technique, one cannot ensure a sterile venipuncture, because organisms harbored in sebaceous glands and hair follicles cannot be completely removed or killed, and skin fragments drawn up into the collection bag during the initial phase of donation can provide a source of infectious organisms.<sup>49,50</sup> Scarring or dimpling of the venipuncture site from prior donation has also been recognized as a risk factor for bacterial contamination, because these areas frequently are difficult to disinfect.<sup>51</sup> In one case, phlebotomy at a dimpled venipuncture site of an apheresis donor resulted in three episodes of platelet contamination with gram-positive organisms; sepsis occurred in four recipients of those platelets.

Iodine solutions have been shown to be the most effective in reducing the donor skin bacterial burden (Table 49-6). Skin of donors who are allergic to iodine is often cleansed with a chlorhexidine solution or double isopropyl alcohol skin

disinfection. In general, tincture of iodine, povidone iodine, or chlorhexidine are used for skin preparation. Table 49-7 summarizes the effectiveness of the most commonly used disinfection methods.<sup>53</sup>

Diversion

Diversion of the first few milliliters of whole blood from the primary container has been shown to reduce the amount of bacterial contamination from the skin. A study performed on 22,000 blood donations by the Red Cross in the Netherlands, in which the first 10 mL of donor blood were diverted from the primary bag, showed that 16 of the first 5-mL aliquots were bacterially contaminated, while only two of the second 5-mL aliquots were positive after culture.<sup>54</sup> A second study from the Netherlands compared the bacterial contamination rates of whole blood collections with and without the removal of the first 10 mL. The diversion of the first 10 mL showed a significant decrease in bacterial contamination (18,263 collections with 0.39% contamination without diversion compared with 7,115 collections with 0.21% contamination with diversion,  $p < 0.05$ ).<sup>55</sup>

It must be remembered that diversion is most effective at decreasing contamination with skin flora.<sup>56,57</sup> A majority of bacteria-related fatalities involve gram-negative organisms, which are not interdicted by diversion. Using the ARC data for collections between 2004 and 2006, it is possible to compare the true-positive rates with and without diversion. The authors report on the contamination rate of one-arm collections and two-arm collections.

Table 49-7. Percentage and Mean Count of Donors with Bacteria after Skin Disinfection

| CFU/Plate  | Povidone Iodine × 2 | IPA and Iodine | IPA × 2 Sponge | IPA × 2 Swab |
|------------|---------------------|----------------|----------------|--------------|
| 0          | 39%                 | 79%            | 0%             | 29%          |
| ≤ 10       | 57%                 | 93%            | 69%            | 50%          |
| ≤ 100      | 75%                 | 100%           | 86%            | 68%          |
| ≤ 1000     | 96%                 | 100%           | 97%            | 89%          |
| Mean count | 175                 | 3              | 161            | 237          |

The two-arm collection set-ups involved a diversion pouch that was located on the venous return line, not the inlet line. The one-arm collections utilized a correctly placed diversion pouch. Table 49-8 shows the decrease in the contamination rate of skin flora with the use of a correctly placed diversion pouch.<sup>45</sup>

### Apheresis Platelet vs Whole-Blood-Derived Platelet Concentrates

Therapeutic doses of platelets can be obtained from a single donor through an apheresis procedure or from whole blood donation. Four to six platelets concentrates from whole blood donations must be pooled to make a therapeutic dose; therefore, it would be expected that pooled platelets obtained from multiple donors would be at higher risk of bacterial contamination. From 1986 to 1998, Johns Hopkins Hospital increased the use of apheresis platelets from 51.7% to 99.4% and saw a threefold reduction in septic transfusion reaction involving platelets, from 1 in 4818 transfusions to 1 in 15,098 transfusions.<sup>58</sup>

A survey of AABB-accredited blood centers, hospital blood banks, and transfusion services (in total, 900 institutions) in late 2004 examined platelet usage, supply, and testing methods.<sup>59</sup> Between 2003 and 2004 there was an 11.3% reduction in the use of WBD platelets and 77.2% of platelets transfused by the institutions surveyed were apheresis platelets. Not only do apheresis platelets decrease the risk of exposing a recipient to a contaminated unit, the type of platelet used appears to affect the type of testing performed to detect bacteria in the United States. Over 90% of apheresis units were tested with culture, whereas most WBD platelets were tested using a variety of methods including staining with microscopic examination and the use of markers of increased metabolism such as pH and glucose. In practice, many institutions have felt that culturing of individual WBD platelets to be impractical.

A new system, Acrodose PL (Pall, Covina, CA) is now available for prestorage pooling of WBD platelets. The Acrodose system allows institutions to pool WBD platelets and then store them for the life of the individual platelets. By using prestorage pooling, the volume of the product is acceptable for culturing with either the BacT/ALERT or enhanced bacterial detection

system (eBDS, Pall, East Hills, NY). Platelets collected in CPD or CP2D collections bags, both leukocyte-reduced and non-leukocyte-reduced, can be pooled with the Acrodose system. This would allow users of PRP-WBPC to transition from surrogate testing to the more sensitive method of culturing.

Prepooled whole-blood-derived platelets prepared by the buffy coat method have been available in Europe since the early 1990s. Recently, Canada has been in the process of transitioning from the platelet-rich plasma method to the buffy coat method. The experience in Europe is that the confirmed positive culture rate of prepooled buffy coat platelets is equivalent to apheresis platelets.<sup>60</sup> This may be a result of the overnight incubation in the presence of white cells.

### Growth Inhibition

#### Optimizing Storage Time

In 1991, the Blood Products Advisory Committee (BPAC) of the FDA reviewed all cases of *Yersinia* sepsis from RBC units reported to either the FDA or the CDC during the late 1980s. At that time all reported cases of RBC-associated *Yersinia* sepsis in the United States had occurred in units older than 25 days. As a result of timing necessary for the bacteria to attain a lethal concentration, the BPAC proposed reducing the storage time of RBCs from 42 to 25 days. This recommendation was subsequently rejected for several reasons.

1. A questionnaire distributed at the time revealed that 20% of RBC units in stock at over 1500 blood banks and transfusion services were more than 28 days old.<sup>61,62</sup> Discarding such units would have severely compromised the nation's blood supply.
2. A shorter outdate would require recruitment of new donors. It was estimated that the addition of a quarter of million donations per year would be required to replace the loss resulting from shorter outdates. This would involve additional risk, because first-time donors are more likely to carry disease because their blood has not been repeatedly tested, as has the blood of repeat donors.
3. Units less than 25 days old can also cause sepsis, so that decreasing the allowable storage time would lessen the problem but not eliminate it.<sup>11,63,64</sup>
4. Older units are less likely to transmit viruses such as human immunodeficiency virus (HIV) and human T-cell lymphotropic virus types I and II.<sup>65,66</sup>

Longer platelet storage time has also been associated with increased probability of contamination. In 1983, in the United States platelet storage for WBD platelets was transiently approved for 7 days. This 7-day storage was based on acceptable in-vitro function, in-vivo recovery, and survival data. However, because of anecdotal reports of bacterial proliferation over the extended storage time, the shelf life was returned in 1986 to 5 days. Unfortunately, merely decreasing the shelf life did not eliminate the problem of bacterial contamination. It has been shown that even a moderate inoculate [10 to 50 colony-forming units (CFU/mL)] of certain bacteria such as *B. cereus* and *P. aeruginosa* in platelets has a minimal lag phase with a doubling time of 1 to 2 hours.<sup>67</sup> This can lead to a bacterial load of  $10^8$  in just 1 to

**Table 49-8.** Comparison of One- and Two-Arm Apheresis Platelet Collections

|                                               | Two-arm procedures                | One-arm procedures*              | OR (95% CI)   |
|-----------------------------------------------|-----------------------------------|----------------------------------|---------------|
| Rate of skin contaminants per $10^5$ cultures | 17.2 (106 of 617,595 collections) | 7.8 (30 of 386,611 collections)  | 2.2 (1.5-3.3) |
| Rate of nonskin organisms per $10^5$ cultures | 5.5 (10 of 617,595 collections)   | 4.1 (16 of 386,611 collections)  | 1.3 (0.7-2.4) |
| Rate of true positives per $10^5$ cultures    | 22.7 (140 of 617,595 collections) | 11.9 (46 of 386,611 collections) | 1.9 (1.4-2.7) |

\*The diversion pouch was in the correct place on the one-arm procedures only.<sup>45</sup>

2 days. The lowest safest limit of bacteria and the time to clinical symptoms are unknown. In one well-documented outbreak of *Salmonella choleraesuis* in seven patients linked to one common repeat donor with an occult chronic osteomyelitis, the time to the onset of illness ranged from 5 to 12 days (mean 8.6 days). In all cases, the platelet units were stored for less than 1 day.<sup>68</sup> In a similar situation, the CDC reported in 2006 a multistate outbreak of *Pseudomonas fluorescens* bloodstream infections. All cases could be traced to contaminated heparin flushes.<sup>69</sup> A total of 28 patients had delayed onset of *P. fluorescens* infections, ranging from 84 to 421 days after their last potential exposure.

Only by severely reducing the storage time of platelets to 1 to 2 days would one significantly impact the risk of bacterial overgrowth. However, operational changes affect the storage age of available platelets. With increased complexity of disease-marker testing, the availability of 1-day-old platelets has decreased. For example, in the United States in 1982 the mean age of distributed platelets was 1.6 days, in 1983 (after extension of the dating period to 5 days) it was 2.0 days, and in 1992 (after addition of increased laboratory testing) it was 2.5 days. In 1983, only 5% of issued platelets were greater than 3 days old. In 1992, just 10% were older than 3 days. But with the introduction of centralized testing by the ARC, the mean age of issued platelets increased 2.7 days with 20% older than 3 days.<sup>70</sup> With the addition of nucleic acid testing for HIV and hepatitis C virus (HCV), additional delays occurred. Not only can this decrease available shelf life of an already precariously limited supply of platelets, it can also decrease the availability of fresh platelets, which are the most hemostatic and the least likely to be bacterially contaminated.

### Optimizing Storage Temperature

Bacterial proliferation in red cells or whole blood is generally limited to a few gram-negative organisms capable of proliferation at 1 to 6°C (so-called psychrophilic organisms, most notably *Y. enterocolitica*, *Serratia* spp., and *Pseudomonas fluorescens*). Freezing red cells with glycerol would prevent the proliferation of bacteria but would be associated with significant decreased availability and increased cost.

Platelets are typically stored at 20 to 24°C, principally because of a potential concern of bacterial contamination and progressive decline in platelet function (storage lesion) if stored for longer periods at these temperatures. Recently, with the addition of an early culture, the use of 7 day platelets has resumed in many parts of the world (see the discussion of international practice and specifically the United States Post Approval Surveillance Study of Platelet Outcomes, Release Tested (PASSPORT) later in the chapter). Although storage of platelets at 4°C results in a significantly lower rate of bacterial growth, it also causes a temperature-induced activation of platelets and rapid decline in functional ability and in-vitro viability. Studies of cold-storage platelets with the addition of specific second-messenger stimulators have reported that platelets stored at 4°C were bacteriostatic and retained partial functional ability and viability compared with control platelets.<sup>71,72</sup> If a practical method for storing platelets at 4°C or in a frozen state were perfected, it would have the potential to reduce the risk of bacterial contamination of this blood component.

### Addition of Antibiotics

The addition of antibiotics to blood components has been considered but has not been adopted because of the added risk of an adverse drug reactions (trading one infrequent reaction for another) and the potential for the development of antibiotic resistance if small amounts of antibiotics were infused with every transfusion.<sup>73</sup>

### Bacteria Detection

A simple low-cost method to detect bacterial overgrowth would be a valuable tool for screening units before release from the blood bank. Several methods for bacterial detection are available and more are in development (Fig 49-3). Unlike viral contamination of blood components, which is detected from a sample obtained at the time of donation, bacterial contamination of blood components frequently requires time for the organisms to proliferate before being detectable. Therefore, knowledge of growth characteristics of bacteria in blood components must be considered for successful implementation of a detection strategy (Figs 49-4 and 49-5).

**Figure 49-3.** Methods of detection of bacterial contamination of blood components. Areas of light gray shading represent concentrations (CFU/mL) at which some, but not all, bacteria are detected by each method. Dark gray shaded areas represent ranges over which each method is reliable. The approximate time from beginning to end of the assay is reported.

### Timing of Detection

Using an automated detection system (Bactec, Becton Dickinson, Cockeysville, MD) Blajchman et al cultured WBD platelets concentrates on Days 1 (16,290 platelet concentrates) and 3 (10,065 platelet concentrates) following preparation.<sup>38</sup> Of the 16,290 platelet concentrates cultured on the day of collection, 4 units were found to be positive; however, an additional 3 units that were culture negative on the day of collection were culture positive after 2 additional days of storage. On the basis of these results the authors concluded that cultures from the day of collection may be inadequate to detect all contaminated platelet concentrates.

Bacterial growth characteristics were reported for 165 platelet units, each inoculated on the day of collection with one of the following organisms: *B. cereus*, *P. aeruginosa*, *Klebsiella pneumoniae*, *S. marcescens*, *S. aureus*, and *S. epidermidis*.<sup>72</sup> All examples of *B. cereus*, *P. aeruginosa*, *K. pneumoniae*, *S. marcescens*, and *S. aureus* had concentrations  $\geq 10^2$  CFU/mL by Day 3 following inoculation. By Day 4, all units with these organisms contained  $\geq 10^5$  CFU/mL. Units contaminated with *S. epidermidis*

showed slower and more varied growth.<sup>75</sup> This study concluded that an assay capable of detecting  $10^2$  CFU/mL on Day 3 of storage would detect a vast majority of bacterially contaminated platelet units.

In the case of red cell contamination, inoculation experiments of whole blood with *Y. enterocolitica* have demonstrated an initial rapid decline in the number of viable organisms followed by a resumption of growth after a lag phase of approximately 3 to 14 days.<sup>11,76-80</sup> During this lag phase, *Yersinia* typically cannot be recovered from samples obtained from the bag.

### Visual Inspection of Red Blood Cells to Detect Color Change

It is known that in bacterially contaminated RBC units, the attached tubing segments almost invariably remain sterile even when the organism is cultured from the blood bag.<sup>9,10</sup> An observation first noted by Kim et al and subsequently confirmed by multiple authors is a darkening of the color of unit as compared to the attached segments in additive solution RBC units.<sup>80-83</sup> Compared with sterile units, the contaminated units became noticeably darker in color 1.5 to 2 weeks after the organism was

**Figure 49-4.** Growth curves of 4 units of AS-3 RBCs inoculated with *Serratia liquefaciens* (2 units inoculated to 4.2 CFU/mL) and *Yersinia enterocolitica* (2 units inoculated to 11.6 CFU/mL). Bacteria was not detectable by culture until Days 3 to 6. Isolates were from strains actually implicated in posttransfusion sepsis (the isolates were kindly provided by M. Arduino, Centers for Disease Control and Prevention, Atlanta, GA). Used with permission from Brecher et al.<sup>74</sup>

**Figure 49-5.** Growth curves of six bacteria species (*Serratia marcescens*, n = 7; *Klebsiella pneumoniae*, n = 21; *Staphylococcus epidermidis*, n = 21; *Pseudomonas sp.*, n = 15; *Bacillus cereus*, n = 9; and *Staphylococcus aureus*, n = 22) in 95 platelet units. All bacteria were inoculated on Day 0 at 10 to 50 CFU/mL. Used with permission from Brecher and Hay.<sup>7</sup>

detected in culture. This color change was very apparent when the contaminated units were compared to the attached segments of tubing, which did not darken. The sensitivity of visual identification of bacterial contamination in this manner is approximately  $10^8$  CFU/mL. One study found bacterial concentrations in the range of  $1.8 \times 10^4$  to  $1.6 \times 10^9$  CFU/mL at the time the whole blood units were first identified by visual inspection as potentially contaminated.<sup>83</sup>

#### Microscopic Examination with Gram's Stain and Acridine Orange

Microscopic examination has been used to detect bacterial contamination in both red cell components and platelets. Several authors have reported the use of the Gram's stain for microscopic examination of blood components.<sup>84,85</sup> One institution implemented a surveillance program that included pretransfusion Gram's stains of platelet pools and apheresis units.<sup>80</sup> In platelets aged 1 to 5 days, the sensitivity and specificity of this method were 80% and 96% to 99%, respectively. In 4- to 5-day-old platelets, the sensitivity increased to 100%, with a specificity of 99.3%. The true-positive results were associated with bacterial concentrations  $>10^6$  CFU/mL. Based on their analysis, these authors concluded that the use of the pretransfusion Gram's stain, combined with culture of 4- to 5-day-old units, was more cost-effective than discarding WBD platelets stored for 5 days. However, Barrett et al<sup>84</sup> reported a higher rate of false positives. In their study, eight of 5334 platelet units yielded positive Gram's stain results, six of which were negative by culture.<sup>84</sup> Other investigators have reported on the use of acridine orange as a stain for bacteria.<sup>76,86</sup>

#### Surrogate Markers

Brecher et al<sup>87</sup> described a decrease in  $PO_2$  and an increase in  $PCO_2$  (with an associated decrease in pH) in platelets that supported the growth of *S. epidermidis*. The units, which had initial  $PO_2$  levels of 79 to 137 mmHg, often showed  $PO_2$  levels below 20 mmHg by the time the organisms reached a plateau concentration of  $10^7$  to  $10^8$  CFU/mL. Other groups have explored this method.<sup>88-91</sup> Although this technique has the added advantage of being potentially noninvasive, it detects contamination only at high levels. Because platelets (and white cells) also produce carbon dioxide, this complicates attempts to detect bacterial contamination by measurements of this analyte.

Because proliferating bacteria consume glucose and generate acid, several investigators have explored the use of dipsticks to indicate metabolic changes consistent with bacterial proliferation.<sup>92,93</sup> Prospective surveillance of 3000 platelet concentrates at the M.D. Anderson Cancer Center in using reagent strips found 12 platelet concentrates with a glucose concentration or pH outside the reference range.<sup>94</sup> Two of 12 platelet concentrates were found to be culture positive for *B. cereus*. The remaining 10 platelet concentrates did not demonstrate bacterial proliferation upon culture.

Many users of WBD platelets employ the surrogate markers because culture would require a large proportion of the unit's

volume. Unfortunately, the rate of detection of the surrogate markers is much less than bacterial culture. The 2004 survey of AABB institutions showed the true-positive rate for institutions using culture was 1 in 4028 compared to a true-positive rate of 1 in 18,535 for institutions using a nonculture method.<sup>59</sup> This represents a 4.6-fold difference in the true-positive rate between culture and nonculture methods.

#### Endotoxin Assay

Investigators have used the *Limulus* amebocyte lysate assay for detection of endotoxin in blood components.<sup>11,77</sup> This method is limited to detection of endotoxin-producing organisms such as *Y. enterocolitica*.

#### DNA/RNA Techniques

Several amplification methods have been described for the detection of bacterial contamination. Schmidt et al<sup>95</sup> reported on the use of RNA polymerase chain reaction (PCR) to detect *S. aureus*, *E. coli*, *B. cereus*, and *K. pneumoniae* in pooled platelet concentrates. At an inoculum of 10 CFU/mL, the PCR testing detected all four bacteria at 12, 16, 20, and 24 hours after spiking. With a lower inoculum of 10 CFU/bag, the PCR testing detected 60% of *E. coli*, 80% of *B. cereus*, 90% of *K. pneumoniae*, and 100% of *S. aureus* 12 hours after spiking. Another study compared DNA PCR with the automated culture system BacT/ALERT.<sup>96</sup> A total of 2146 platelet concentrates were tested with both methods. When comparing to the culture method, the PCR had a sensitivity and specificity of 100%. To date, because of the complexities associated with such tests, nucleotide-based amplification has not been routinely applied to bacterial screening of platelets. One group described the use of a nonamplified chemiluminescence-linked universal bacterial rRNA probe.<sup>67,87</sup> This method uses an acridinium ester-labeled single-stranded DNA probe complementary to highly conserved bacterial rRNA regions. Although a multicenter trial confirmed the effectiveness of this technique in detecting platelet samples contaminated with one of four bacterial species, the company developing this assay chose to not pursue further assay development.

#### Rapid Immunoassay

In September 2007, the FDA approved a new rapid immunoassay for the detection of aerobic and anaerobic bacteria in leukocyte-reduced apheresis platelets as an adjunct quality control device. The Platelet PGD Test (Verax Biomedical, Worcester, MA) is a qualitative immunoassay that differentiates between gram-positive and gram-negative bacteria. As approved, it is intended to be an adjunct test after the use of an FDA-cleared bacterial culture method. The Platelet PGD Test can detect *B. cereus*, *C. perfringens*, *E. aerogenes*, *E. coli*, *K. pneumoniae*, *P. aeruginosa*, *S. aureus*, *S. epidermidis*, and *S. agalactiae* at a level  $\leq 10^5$  CFU/mL and *S. marcescens* at a level of  $8.6 \times 10^5$  CFU/mL. The test takes approximately 25 minutes to perform and is optimally performed after at least 72 hours of platelet storage. The system is approved only for leukocyte-reduced apheresis platelets and has not been validated in WBD platelets.

### Bacterial Culture

There are currently two FDA-approved culture systems for bacteria detection in platelets in the United States. One uses an automated liquid culture system that includes broth bottles containing colorimetric sensors that change color as a consequence of increasing CO<sub>2</sub> produced by bacterial proliferation. The system (BacT/ALERT) monitors both the rate of change of the colorimetric sensor and the absolute color change of the sensor. The bottles are inoculated with a needle, rendering the system not completely closed. This creates the possibility of introducing bacteria into the bottle. The method reliably detects contamination of platelets inoculated to 10 CFU/mL and in many cases  $\leq 5$  CFU/mL (eg, *B. cereus*, *S. marcescens*, *C. perfringens*, *S. epidermidis*, *S. pyogenes*, *E. coli*, *K. pneumoniae*, *S. aureus*, and viridans streptococci) in 12 to 26 hours.

The ARC experience for 2004 through 2006 with the BacT/ALERT testing of 1,004,206 apheresis platelets showed a true-positive rate of 30.3% of all initially positive cultures.<sup>45</sup> A true-positive is defined as concordance between the initial culture and an additional confirmatory sample, a second 4 to 5 mL taken from the unit or its co-component. The false-positive rate was 57%, 32.4% caused by sampling contamination and 24.5%

caused by instrument signal error. The remainder of the initially positive cultures (12.7%) was called indeterminate, defined as the component not being available for confirmatory testing. In total, 612 donations had an initial positive culture result. Ninety-seven platelet units had been transfused at the time of the positive results; and only one of the 97 was confirmed positive, for coagulase-negative *Staphylococcus*. This unit was transfused on Day 2 and the patient did not have signs of sepsis. No septic reactions were noted with the units associated with an indeterminate or the false-positive culture.

Blood Systems, another large collection system in the United States, also reported their first 2 years of experience with culturing apheresis platelets and WBD platelets.<sup>97</sup> With the apheresis platelets, 198 of 122,971 collections initially tested positive and 21 were confirmed positive to give a confirmed positive rate of 1 in 5568. No confirmed positives were transfused. A total of 50 false-positive results were seen, caused by either machine reading error or contamination, and 26 cases were indeterminate. For WBD platelets, a total of 13,579 were cultured with 12 initial positives, one true positive, and 11 false positives. Data from ARC and Blood Systems are summarized in Table 49-9 and Fig 49-6.

**Table 49-9.** Summary of Experience with Bacterial Culture at ARC and Blood Systems\*

|                                     | True Positive (%)      | False Positive (%) | Indeterminate (%) |
|-------------------------------------|------------------------|--------------------|-------------------|
| <b>Gram positive</b>                | 77 (86.5)              | 200 (98.5)         | 59 (92.2)         |
| <i>Staphylococcus</i> sp.           | 43 (48.3)              | 53 (26.1)          | 15 (23.4)         |
| <i>Bacillus</i> sp.                 | 7 (7.9)                | 117 (57.6)         | 28 (43.8)         |
| <i>Streptococcus</i> sp.            | 21 (23.6)              | 5 (2.5)            | 3 (4.7)           |
| <i>Diphtheroids/Corynebacterium</i> | 1 (1.1)                | 10 (4.9)           | 8 (12.5)          |
| Other                               | 5 (5.6)                | 15 (7.4)           | 5 (7.8)           |
| <b>Gram negative</b>                | 12 <sup>†</sup> (13.4) | 2 (1.0)            | 2 (3.1)           |
| Fungal                              | 0 (0)                  | 1 (0.5)            | 3 (4.7)           |
| <b>Total</b>                        | 89 (100)               | 203 (100)          | 64 (100)          |

\*Used with permission from Pietersz et al.<sup>98</sup>

<sup>†</sup>True-positive gram negatives included *Serratia marcescens* (n = 4), *Klebsiella* sp. (n = 3), *Escherichia coli* (n = 3), *Citrobacter diversus* (n = 1) and unspecified gram-negative rod (n = 1).

**Figure 49-6.** True-positive (confirmed) organisms, isolated from 1,237,177 apheresis cultures (tested with 4 mL in an aerobic BacT/ALERT bottle). Examples of organisms isolated only once or twice were grouped in the "other" category. These included example(s) of *Micrococcus* sp., *Diphtheroids/Corynebacterium*, *Enterococcus avium* (n = 2), *Granulicatella adiacens*, *Citrobacter* sp., *Lactobacillus* sp., and *Enterobacter aerogenes*. Used with permission from Pietersz et al.<sup>98</sup>

The second culture system is the enhanced Pall Bacterial Detection System (eBDS). The eBDS system measures the oxygen in the headspace gas of the sample pouch. Because the system measures oxygen consumption, it will not detect obligate anaerobes. One study reported on the use of the eBDS system with 118,067 apheresis and WBD units from 23 US blood centers.<sup>98,99</sup> Investigators found 118 initially reactive (1 in 992) and 23 confirmed positive (1 in 5133) units. All true-positive units contained *Staphylococcus* spp. and *Streptococcus* spp. Ninety-five false-positive units were identified (1 in 1243). Of the false positives, 18 were caused contamination and 56 had no bacteria present. There was one report of a missed detection with *S. epidermidis*. In a study by Fourneir-Wirth et al, 5 to 50 CFU/mL bacteria was inoculated into apheresis platelet units and tested in the eBDS.<sup>100</sup> No false-positive results were seen. After 18 hours of incubation, 61 of 63 units tested positive and after 24 hours, all 63 tested positive. In the earlier incubation, two cases of *B. cereus* were missed.

### Sampling and Bottle Types for Culture

The BacT/ALERT system can be used either with one aerobic bottle or with one aerobic and one anaerobic bottle. In 2004, approximately half of hospital blood banks used only the aerobic bottle, which is inoculated with 4 mL of the platelet product.<sup>59</sup> Although most bacteria involved in septic transfusion reactions are aerobic, certain aerobic bacteria grow faster in the anaerobic bottle, most likely because of the difference in the nutrient broth.<sup>101-107</sup> One study used a strain of *Staphylococcus lugdunensis* to perform a variety of spiking experiments to investigate the growth characteristics in the two types of bottles.<sup>108</sup> The strain of *S. lugdunensis* was implicated in a fatal septic reaction to a platelet unit. Using a 4-mL inoculum, the anaerobic bottle became positive at a mean time of 18.73 hours as compared to the aerobic bottle at 21.07 ( $p < 0.001$ ). As the number of organisms inoculated into each bottle was increased, the difference in time to reactivity decreased (Fig 49-7). Because most centers use 4 mL per bottle, the use of an anaerobic bottle could reduce the time to detection and possibly prevent the transfusion of contaminated units.

In 2005, the FDA approved the Post Approval Surveillance Study of Platelet Outcomes, Release Tested (PASSPORT) for use

with apheresis platelets collected with caridianBCT (Lakewood, CO) and Baxter (Deerfield, IL) equipment. This study allows centers to extend the expiration of these apheresis platelets to 7 days if the units are cultured with both an aerobic and an anaerobic bottle. The University of North Carolina recently reported its experiences with regard to inventory impact as a result of the extended shelf life.<sup>109</sup> In total from March through August 2006, of the 1688 platelets transfused, 139 were older than 5 days. Since the implementation of 7-day platelets, the mean day of issue was 4.02 as compared to 3.44 before the extended shelf life. Additionally, the percent of outdating decreased from 2.8% to 1.3% with the extended shelf life. In the study period, 6 units were removed from inventory for an initial positive culture, none of which was confirmed. Only one allergic reaction was noted to a 7-day platelet, but no other adverse events were reported. Due to the higher than expected culture positive rate with outdated platelets, the passport study has been suspended.

### Causes of False-Negative Results

Even though great strides have been made in the prevention of platelet septic transfusion reactions, there are still missed cases. Missampling, micropunctures, leakage, postsampling handling, and contaminated tubes or container surfaces are all possible causes of contamination.<sup>110</sup> WBD platelets have presented a problem because of the difficulty with culture, but with the introduction of the Acrodose prestorage pooling system, more contaminated WBD platelets can be interdicted before transfusion. With the recent FDA clearance of the Verax system, contaminated units that are culture negative might be interdicted immediately before transfusion (although this would be an off-label use if used with WBD platelets). Reduced morbidity and mortality of platelet transfusion is also achieved with the optimal and correct use of blood components.<sup>47</sup>

### Bacterial Elimination

#### Filtration

Leukocyte reduction of blood components is widely used in North American, Europe, Asia, and Australia. Several countries,

**Figure 49-7.** Time to reactivity of the aerobic (BPA) and the anaerobic (BPN) bottles inoculated at 1.5 CFU/mL with increasing volume. At lower inocula, the reactive BPN bottles are faster than the BPA bottles; at higher inocula, the time to reactivity were equivalent. Used with permission from Brecher and Hay.<sup>108</sup>

including Canada, England, Portugal, France, Ireland, and Norway, have switched to a completely leukocyte-reduced blood supply (so-called “universal leukocyte reduction”).<sup>111,112</sup>

Because of concern regarding the accumulation of cytokines, leukocyte and platelet breakdown products, and possibly immunogenic white cell fragments in stored blood, emphasis has been placed on prestorage rather than poststorage leukocyte reduction.<sup>113-115</sup> A theoretic risk of prestorage filtration is that early removal of the phagocytic leukocytes, which would normally remove low levels of bacteria present in these products, might lead to an increase in bacterial contamination of blood components and septic complications. In the case of *Y. enterocolitica* (the organism that has been most extensively studied), prestorage leukocyte reduction by filtration actually is associated with a decrease in bacterial growth in inoculated RBCs.<sup>4,76,77,116-118</sup> (Table 49-10).

The mechanism by which leukocyte reduction removes bacteria is multifactorial. Bacteria that have been phagocytosed but not killed are removed with the white cells. Alternatively, organisms may be adsorbed to leukocytes or activated by complement, to then be bound indirectly to the charged filter fibers, or the bacteria may directly adhere to the filter fibers. AuBuchon and Pickard showed with a panel of bacterial organisms, differences in the affinity for bacteria by direct adherence of red cell leukocyte reduction filters and platelet leukocyte reduction filters.<sup>119</sup> In general, red cell reduction filters are most efficient, removing 88% to 100% of organisms, while platelet filters remove only 67% to 97% of organisms. Unlike the decrease in *Y. enterocolitica* growth seen with filtered, prestorage leukocyte-reduced red cells, leukocyte reduction by filtration failed to decrease bacterial growth in platelets spiked with bacteria.<sup>120-121</sup>

### Prolonged Room Temperature Hold of Red Blood Cells

When whole blood is placed immediately at 4°C, bacterial growth occurs more rapidly than if held at 10°C for 24 hours before 4°C storage.<sup>123</sup> Bacterial growth of most pathogens is inhibited by cold temperatures, but host mechanisms present in fresh whole

blood are also inhibited at 4°C. With plasmid-encoded complement resistance, *Yersinia* can be complement sensitive when blood is transiently stored at 20°C.<sup>73</sup> Because phagocytosis and complement activation are impaired at 4°C, it may be advantageous to allow red cells to remain in contact with plasma for several hours before separation and storage of components.

### Pathogen Inactivation

Several techniques to inactivate pathogens in blood components using chemicals are under active investigation or are implemented in select countries (see Chapter 51).

### International Comparison

There is wide variation in the way different countries approach the problem of bacterial contamination of platelets. A recent survey of 12 different countries reveals the many approaches to preventing septic transfusion reactions.<sup>98</sup> The responses are summarized in Table 49-11.

## Transfusion-Transmitted Syphilis

*Treponema pallidum* is a thin-walled, motile, spiral gram-negative rod or spirochete that cannot be visualized with Gram's stain and does not grow on bacteriologic media or cell culture. Although it is a bacterium, it is often treated as a distinct entity, different from other transfusion-transmitted bacterial organisms and thus is addressed separately. Only 25% of patients with primary syphilis have a reactive serologic test for syphilis and the test does not become routinely positive until the fourth week after the onset of symptoms; therefore, donors infected with *T. pallidum* may be asymptomatic with negative serology during periods of spirochetemia.<sup>124,125</sup> Although the organism does not survive prolonged storage at 4°C, it may live for 1 to 5 days at these cold temperatures.<sup>126,127</sup> Therefore, a rare infection may be associated with transfusion of a fresh RBC unit from a donor who was in the seronegative phase at the time of

**Table 49-10.** Selected Studies of *Yersinia enterocolitica* Growth and Prestorage Leukocyte Reduction by Filtration

| United Kingdom | In England, only for QC or tested in order to extend the shelf life over holidays; in Scotland, Wales, and in Northern Ireland all PCs are routinely tested  | If used to extend shelf life: sampled on Day 3 into a Bact/ALERT aerobic bottle and quarantined for 48 hours<br><br>If used in retrospective national monitoring study: Bact/ALERT aerobic and anaerobic bottles are inoculated and incubated for 7 days | Extending the shelf life has assisted with supply over extended holidays                                                                      |
| United States  | No governmental mandate but required by AABB and CAP                                                                                                         | Two systems FDA approved and available for testing: Bact/ALERT, eBDS, all units sampled after 24-36 hour hold; whole blood derived platelets tested with surrogate markers such as glucose or pH                                                         | No or modest impact on availability as well as no increase in outdating                                                                       |

\* Pathogen inactivation is being used on Reunion Island because of the risk of chikungunya transmission; being studied in other French locations and will be implemented gradually.

donation. Platelets stored at 20 to 24°C, provide a more hospitable temperature for *T. pallidum*; however, this organism does not thrive with the high oxygen tension in modern platelet storage bags. Since 1969, only three cases of transfusion-transmitted syphilis have been reported in the literature.<sup>128-130</sup> The extremely low rate of transfusion-transmitted syphilis infection likely results from 1) donor questioning targeting high-risk behavior; 2) the cardiolipin-based assay, although an insensitive test in the acute postinfectious setting, does pick up a number of infected donors; 3) refrigerator storage, which results in the death of spirochetes; 4) antibiotics given to many patients at the time of platelet transfusion, which would be bactericidal for any viable organisms; and 5) donors excluded for a positive test for HIV, HCV, or hepatitis B because of the high correlation between infection with *T. pallidum* and viruses such as these, even though the donors may have been in the seronegative phase of syphilis at the time of donation.<sup>131-136</sup> Because syphilis testing plays only a minor role in protecting the blood supply and is associated with a high degree of false-positive reactions, elimination of syphilis testing has been advocated. The counter argument is that such testing provides a surrogate marker for individuals at risk of other sexually transmitted diseases and, therefore, should be retained.

## Transfusion-Transmitted Lyme Disease

Lyme disease, a tick-borne illness, caused by the spirochete *Borrelia burgdorferi* is theoretically transmittable through blood, although no reported human transfusion-transmitted cases have been identified.<sup>137</sup> The tick that carries *B. burgdorferi*, *Ixodes scapularis*, also carries *Babesia microti* and *Anaplasma phagocytophilum*, both of which are transmissible by transfusion. In a murine model of Lyme disease, approximately 50% of mice transfused blood from a spirochetemic donor mouse became infected.<sup>138</sup> Although there have been cases of blood donors being diagnosed with Lyme disease shortly after their donation, no spirochetes could be identified in the recipient of the units.<sup>139</sup> This might be unrecognized because of vague symptoms of Lyme disease as well as the lack of characteristic erythema migrans at the site of tick bite.<sup>137,140</sup> Additionally, spirochetes are rarely identified even in patients with active disease, which may in turn limit the transmission through transfusion.<sup>139</sup>

## Conclusion

Bacterial contamination of blood components is the most common cause of transfusion-transmitted infectious disease. Most cases of posttransfusion sepsis involve platelets that must be stored at room temperature. With the introduction of diversion techniques and bacteria detection of platelets, the rate of clinically significant septic reaction has substantially decreased and the availability of platelets to patients has been enhanced.

Prion diseases, or transmissible spongiform encephalopathies (TSEs), comprise a spectrum of diseases in animals and humans. In animals, these diseases include scrapie in sheep and goats, chronic wasting disease in deer and elk, and transmissible mink encephalopathy. Bovine spongiform encephalopathy (BSE) was first described in cattle in the United Kingdom (UK) in the early 1980s and developed into an epidemic of more than 180,000 bovine cases, spreading also to a range of other animals including domestic and exotic cats and exotic ungulates.

Sporadic or classical Creutzfeldt-Jakob disease (CJD), first described in the early 1920s,<sup>1</sup> occurs at an incidence of around 1 in 1 million per year. It presents at a mean age of 68 years with a rapidly progressive dementia, leading to death after about 6 months. Kuru, described in the Fore people of Papua New Guinea,<sup>2</sup> comprised an endemic disease presenting with cerebellar ataxia and a more prolonged clinical course. The disease is thought to have been spread through cannibalistic funeral rites. Although these cultural practices died out toward the end of the 1950s, there are still occasional people who develop new clinical disease, pointing to the potentially very prolonged incubation periods of these diseases. Iatrogenic transmission of sporadic CJD has occurred via neurosurgical instrumentation and electroencephalogram (EEG) electrodes, corneal and dura mater grafts, and cadaveric pituitary-derived growth and follicular-stimulating hormones.<sup>3</sup> Those patients infected through direct central nervous system inoculation tend to manifest an incubation period of around 2 years and a rapidly progressive dementia reminiscent of sporadic CJD. Those infected through peripheral inoculation demonstrate a more prolonged and variable incubation period (mean 13–15 years) and a clinical syndrome similar to that of Kuru, suggesting that the route of infection has a significant impact on the incubation period and clinical manifestation of disease.

Finally, there are a group of rare inherited human prion diseases—including familial CJD, Gerstmann-Sträusler-Scheinker (GSS) disease, and fatal familial insomnia—related to polymorphisms within the gene for prion protein.<sup>4</sup> The pathology of these disorders is characterized by the accumulation of abnormal prion protein (PrP<sup>TSE</sup>) within the central nervous system associated with neuronal degeneration and reactive gliosis, giving rise to the characteristic spongiform appearance from which these diseases took their original name.<sup>5</sup> There is patchy evidence of peripheral accumulation of PrP<sup>TSE</sup> in patients with sporadic and familial forms of CJD, but little substantive evidence of infectivity in peripheral blood and tissues or of transmission by blood components, plasma derivatives, or cellular, tissue, or organ transplants.<sup>6</sup>

Variant CJD was first described in 1996.<sup>7</sup> The disease is characterized by a relatively early onset compared to sporadic disease (median 28 years, range 12–74 years), a clinical presentation consisting of behavioral disturbance,<sup>8</sup> dysesthesia and ataxia followed by progressive neurologic deterioration,<sup>9</sup> and a prolonged clinical phase (median 14 months, range 6 to 48 months).<sup>10</sup> The pathologic features are also characteristic, with the presence of PrP<sup>TSE</sup> not only within the central nervous system, but also in the follicular dendritic cells of peripheral lymphoid tissues including tonsils, spleen, lymph nodes, and gut-associated lymphoid tissue. PrP<sup>TSE</sup> has been demonstrated in two appendix samples removed 8 months and 2 years before the onset of clinical disease.<sup>11</sup> The epidemiologic, pathologic, and experimental data are consistent with variant CJD having arisen from the oral transmission of BSE from infected cattle.

To date, 167 cases have been described in the UK, 23 in France, four in Ireland, three each in the US and Spain, two each in the Netherlands and Portugal, and one each in Canada, Japan, Saudi Arabia, and Italy.<sup>12</sup> Two of the Irish patients, two of those in the US, and those in Canada and Japan are thought to have been infected during travel in the UK. The overall incidence of clinical cases appears to be diminishing, with current mathematical models projecting a maximum likelihood of 70 [95% confidence interval (CI), 10–190] further clinical

cases in the UK.<sup>13</sup> However, the possibility of a cohort of subclinically infected individuals<sup>14</sup> and four cases of transmission of variant CJD prions by blood components described in 2004 and 2006<sup>15-17</sup> raise concern that secondary and higher order transmissions by blood components, plasma derivatives, and cellular, tissue, or organ transplantation could extend the outbreak, particularly if compounded by other potential routes of transmission such as surgery and interventional medical procedures. Although blood service organizations have taken several precautionary measures,<sup>18,19</sup> the persisting uncertainties surrounding the nature, level, and distribution of infectivity; the prevalence of subclinical disease; and the overall transmissibility of the disease undermine any ability to accurately judge the magnitude of this risk and evaluate the impact of current and proposed risk management strategies.

## The Molecular Basis of Prion Diseases

Prion diseases are associated with a change in the secondary and tertiary conformation of a widely expressed glycoprotein termed prion protein (PrP<sup>C</sup>). PrP<sup>C</sup> is a 30- to 35-kD protein with two N-linked glycosylation sites and a glycosylphosphatidylinositol anchor. The secondary structure consists of around 40% alpha-helix and 3% to 4% beta-pleated sheet. Prion infection is associated with a conformational transformation, resulting in an increase in the proportion of beta-pleated sheet. This, in turn, engenders a change in the physicochemical and biological properties of the molecule (PrP<sup>TSE</sup>), including an increased resistance to degradation of biological and physical agents (PrP<sup>RES</sup>).<sup>20</sup> The precise etiology of the conformational change remains unclear, with some authorities favoring a process of homodimerization and others preferring one of nuclear polymerization. The prion hypothesis<sup>21,22</sup> proposes that PrP<sup>TSE</sup> is the direct cause of infectivity, although it is acknowledged that the relationship between PrP<sup>TSE</sup>, PrP<sup>RES</sup>, infectivity, and tissue damage is not straightforward. Some authorities suggest that a small nucleic acid-based agent may be the causative agent.<sup>23,24</sup>

## The Nature, Concentration, and Distribution of Infectivity

The current understanding of the pathogenesis of CJD is largely predicated on animal studies. Biochemical and biological assays point to the accumulation of high concentrations of PrP<sup>TSE</sup> and infectivity in the central nervous system in all forms of CJD. Animal models of peripherally transmitted prion diseases,<sup>25,26</sup> point to follicular dendritic cells (FDCs)<sup>27,28</sup> in the germinal centers of lymphoid tissue as the key cell in the establishment of infection and not B lymphocytes as previously suggested.<sup>29,30</sup> The presence of abnormal prion accumulation in the FDCs in tonsil, spleen, and lymph nodes of all patients with variant CJD thus far examined postmortem suggests a similar pathophysiology

for CJD in humans following primary (eg, cattle BSE to humans) or secondary and higher order (human to human) transmission.<sup>31</sup>

The exact nature of infectivity in peripheral blood and tissues is uncertain. Recent work suggests that in brain homogenates, the maximum specific infectivity is associated with proteinase-resistant particles of 300 to 600 kD (ie, oligomers of 14 to 28 PrP molecules).<sup>32</sup> There are also data suggesting that proteinase sensitive forms of PrP<sup>TSE</sup> could be infectious. Further work in this area, particularly relating to the physicochemical characteristics of the infectious prion in plasma is a priority.

The World Health Organization (WHO) has reviewed the data on the distribution of infectivity and PrP<sup>TSE</sup> in peripheral tissues and organs in human prion diseases and in naturally and experimentally infected animal prion diseases.<sup>6</sup> Although the highest levels of infectivity are confined to neurologic tissues, lower levels of infectivity and/or PrP<sup>TSE</sup> have been demonstrated in a wide range of other tissues.

Two sets of rodent studies are informative with regard to the likely concentration and distribution of infectivity in peripheral blood. The first studies were carried out in mice infected with the Fukuoka-1 strain of GSS disease<sup>33,34</sup> and provided the data on which the original risk assessments were based.<sup>35</sup> The second set of studies was carried out in hamsters infected with the 263K strain of scrapie and has led to a review of blood infectivity assumptions.<sup>36,37</sup> Overall, the current working assumption is that the level of infectivity in the peripheral blood during the incubation period of a peripherally transmitted prion disease such as variant CJD is likely to be in the order of magnitude of 10 infectious doses/mL. In humans the data on peripheral blood infectivity in sporadic and familial CJD is open to interpretation<sup>38</sup> and it has not yet proven possible to detect infectivity in the peripheral blood of patients with variant CJD, despite the fact that the disease is clearly clinically transmissible. Moreover, it is known that the distribution of PrP<sup>C</sup> varies significantly between rodents and humans.<sup>39-41</sup> There are, therefore, important caveats regarding the extrapolation of these estimates to humans and it is probably safer to consider a plausible range of infectivity in the peripheral blood of humans for the purposes of risk assessment.

The spatial distribution of infectivity also varies between models. Brown et al<sup>33,34</sup> mimicked to a certain extent clinical blood separation processes and demonstrated a four- to five-fold higher concentration of infectivity in the buffy coat (per unit volume) compared to plasma. Gregori et al studied purified blood components and concluded that red cells and platelets have very little infectivity, and that approximately 40% of infectivity is associated with leukocytes, with most of the remainder residing within the plasma.<sup>36,42</sup>

The temporal development of infectivity in peripheral tissues during the incubation period is similarly uncertain. In rodent models, a variety of patterns of change in infectivity and PrP<sup>TSE</sup> concentration have been observed.<sup>43,44</sup> In humans, the pattern of development of infectivity in peripheral blood and tissues during CJD infection is unknown, although, as noted previously,

abnormal PrP has been detected in an appendix sample removed 2 years before development of clinical variant CJD.

### Transmissibility of CJD by Blood and Tissues

In general, one would expect that transmission of infection within a species would be more efficient than that between different species.<sup>45</sup> The transmission of infection by blood drawn from a donor during both the incubation period and clinical phase of disease has been demonstrated in sheep naturally infected with scrapie and experimentally infected with BSE with an efficiency of approximately 50%, suggesting that the level of infectivity might be lower than that seen in the rodent models.<sup>46-48</sup>

Although there are a handful of reports of patients who have developed sporadic CJD following exposure to blood components,<sup>49</sup> plasma derivatives,<sup>50-53</sup> or organ transplantation,<sup>50</sup> these reports have not established a convincing link with sporadic CJD in the donors. To the contrary, a large number of epidemiologic case control,<sup>54-64</sup> look-back,<sup>65,66</sup> and surveillance<sup>67-70</sup> studies over the past 25 years have demonstrated no clear evidence of transmission of sporadic CJD by blood transfusion or plasma derivatives. It should be borne in mind, however, that CJD is a rare disease and occasional cases of transmission by blood components could have been missed.

The Transfusion Medicine Epidemiology Review was established in the UK in 1996 in order to monitor potential linkage between CJD in donors and recipients.<sup>71,72</sup> Individuals who develop variant CJD are reported to the UK Blood Services by the National CJD Surveillance Unit (NCJD-SU) to establish whether they have previously been blood donors. If they have been donors, the recipients are traced and notified. In the reverse arm, NCJD-SU determines whether individuals who have developed variant CJD have themselves received blood. If they have been transfusion recipients, the UK Blood Services trace and notify the donors. Individuals identified in this way are considered to be “at risk for public health purposes.”<sup>73</sup> There are clear ethical and social tensions in adopting a notification strategy when the level of risk is uncertain, psychologic and social detriment may ensue, and no practical benefit accrues to the notified individuals.<sup>74,75</sup> No linkage has been identified between donors and recipients with sporadic or familial CJD in this study. However, 18 UK blood donors have gone on to develop variant CJD and of their 66 traceable recipients (26 of whom are informative in the sense of having survived more than 5 years after transfusion), three have developed variant CJD and one showed evidence of subclinical infection at postmortem examination (having died of an unrelated condition).<sup>15-17</sup> In France, three blood donors have developed variant CJD, although of their 18 traceable recipients, none have developed variant CJD at the time of this writing.

Eleven of the above-noted UK blood donors also contributed 25 plasma donations to pools from which a total of 178 plasma batches were manufactured before the UK began importing plasma in 1999. No recipients of implicated products have thus

far developed clinical variant CJD—although again, following risk assessment, many of these people are now regarded as “potentially at risk for public health purposes.”<sup>73,76</sup>

Cells, tissues, and organs are much less frequently transplanted and many are derived from brain-stem dead or non-heart-beating donors. In the absence of routine cadaveric testing it is, therefore, not possible to know whether such individuals may have been incubating CJD at the time of their deaths.<sup>77</sup> There are no clearly substantiated reports of individuals having developed CJD as a result of cellular, tissue, or organ transplantation. However, both prion diseases and these transplant procedures are relatively uncommon events and given that a significant tissue mass is transplanted, the concentration of infectivity that would be required to transmit infection is well below the level of sensitivity of current assay methods. Therefore, a precautionary assumption is that these tissues may be capable of transmitting disease should the donor be infected.

### The Prevalence and Distribution of Subclinical Disease

It is the prevalence and epidemiologic distribution of pre- or subclinical disease that drives the risk of secondary transmission, rather than the incidence of clinical disease. Although the incidence of sporadic CJD is known, the incubation period is uncertain and the prevalence of pre- or subclinical disease is unknown. Iatrogenic and familial forms of CJD are fortunately rare; however, it appears likely that preclinical cases will occur in these forms of disease. Those individuals in at-risk groups can often be identified by family or medical history and excluded as donors.

The prevalence and distribution of subclinical variant CJD is also unknown; however, the available data provide some important hints.

First, the median age of onset of disease has not altered over the past decade in the way one would expect where a cohort of individuals has been exposed to the risk of infection over a discrete period.<sup>7,12,78</sup> These data suggest the existence of age-related susceptibility and/or exposure between the ages of 10 and 20 years,<sup>13,79,80</sup> a cohort who would now be between 20 and 40 years old. The patients who have developed variant CJD in France have an older age profile (median age 37 years) than in those in the UK: the reason for this difference is unknown.

The data generated by retrospective study of tonsil and appendix samples has also been revealing.<sup>14,81,82</sup> Three out of 12,674 samples were found to be positive for abnormal prion protein on Western blot,<sup>83</sup> where the specificity is thought to be high,<sup>84</sup> but the sensitivity uncertain.<sup>85</sup> Mathematical modeling suggests a maximum likelihood of 3000 infected people (95% CI, 520-6810) in the UK, mainly in the 10- to 30-year age group.<sup>13</sup> This is at variance with the number of individuals projected to develop clinical disease and suggests a probability of subclinical infection of 0.93 (95% CI, 0.70-0.97).<sup>13,86</sup> The potential existence of a cohort of individuals in the population with long-term

subclinical infection<sup>87,88</sup> is consistent with experimental animal data<sup>89,90</sup> suggesting that methionine/valine heterozygosity or valine homozygosity at codon 129 of the *PRNP* gene predisposes to a prolonged period of subclinical disease. Although all clinical cases of variant CJD thus far have been methionine homozygous at codon 129,<sup>91</sup> the second reported case of transfusion-transmitted variant CJD prions was shown to be methionine/valine heterozygous at codon 129.<sup>16</sup> Two of the three patients who tested positive in the retrospective study of tonsils and appendices have also recently been shown to be valine homozygous at this locus,<sup>92</sup> suggesting that codon 129 genotype (among other things) may influence the propensity of an infected individual to develop clinical disease. Long-term studies on patients who developed Kuru or iatrogenic CJD support this possibility. Individuals who were homozygous for methionine at codon 129 developed clinical disease sooner than those of other codon 129 genotypes, who have developed disease more sporadically and with longer incubation periods (in some cases, over 40 years from their likely infection).<sup>93</sup>

Taken together, these data suggest that the underlying prevalence of subclinical disease in the UK could be around 1 in 10,000 (range 1 in 1000 to 1 in 20,000) and that there could be further waves of clinical disease in individuals with other codon 129 genotypes. There are no specific data on which to estimate the prevalence in other countries. However, from the relative incidence of clinical disease, one might expect prevalence in Ireland to be approximately 20% of that in the UK, that in France to be approximately 10%, and that in the Netherlands to be around 5%.

## Approaches to Risk Management

In the face of the uncertainties and extrapolated estimates, a precautionary set of assumptions is that it is likely that there exists a proportion of healthy people with subclinical variant CJD in the UK and other Western European countries, that infectivity is present in the peripheral blood of these individuals, and that transmission of disease is possible through blood and tissue products, but the exact magnitude of these risks is unclear. The best risk management approaches are those that are likely to have some beneficial impact over the widest range of plausible scenarios. However, the effectiveness of such precautionary strategies may be partial or unknown and the potential for risk substitution and ethical dilemma needs to be considered.

### Donor Selection

Residence in the UK (and, to a lesser extent, Ireland and France) is clearly a risk factor for variant CJD and many countries exclude prospective donors who have lived in such countries.<sup>94</sup> The stipulated period of residence varies widely, depending on the negative impact on the blood donor base and the perceived differential risk.<sup>95</sup>

It has proved more difficult to delineate subpopulations who may be considered to be at higher risk of subclinical vCJD than the general population. Individuals considered to be “presumed

infected” or “at risk for public health purposes” are deferred from blood transfusion and tissue transplantation.<sup>73</sup> Although blood transfusion by itself is thought unlikely to give rise to a self-sustaining outbreak, it is possible that transfusion in combination with other potential routes of transmission such as surgical or invasive medical procedures could result in such an event. Confirmation of clinical transmission of variant CJD via blood transfusion led to the introduction of deferral of donors in the UK who themselves have definitely or probably received blood components in order to reduce the risk of tertiary and higher order transmissions, at the cost of a 5% to 10% loss in blood donations. However, surveys have documented considerable inconsistency in donor recall of blood transfusion, undermining confidence in the effectiveness of such measures. Donor exclusion criteria are blunt risk management tools that have the potential for significant negative impact on individual donors and on the blood and tissue supply.

### Donor Screening Assays

The development of peripheral blood assays aimed at the detection of subclinical CJD in donor populations is hampered by the absence of an antibody response or of detectable DNA associated with transmission of the infectious agent.

Surrogate assays providing nonspecific evidence of neurologic damage<sup>96,97</sup> or alteration in peripheral tissue physiology<sup>98,99</sup> have thus far proved insufficiently sensitive and specific for subclinical CJD.

PrP<sup>TSE</sup> detection remains the most promising route to development of a preclinical screening assay,<sup>100-101</sup> despite caveats about the precise relationship with infectivity. Achieving the required levels of sensitivity and specificity has, however, proved to be a major challenge. It has been estimated that the threshold of detection may need to be as low as 10<sup>6</sup> molecules of PrP<sup>TSE</sup>/mL in peripheral blood.<sup>102</sup> Immunoblotting with proteinase K digestion and gel electrophoresis has been enhanced using phosphotungstic acid precipitation and chemiluminescence,<sup>103</sup> but is probably still insufficiently sensitive to detect PrP<sup>TSE</sup> in blood. Capillary immunoelectrophoresis following proteinase K digestion and competitive antibody binding was the first method to describe detection of PrP<sup>TSE</sup> in blood,<sup>104</sup> but has proved complex and difficult to reproduce in other laboratories.<sup>105</sup> A number of attempts have now been made to move away from the use of proteinase K resistance as the defining principle.<sup>106</sup>

Several assays use denaturation of PrP<sup>TSE</sup> aggregates, the best characterized of which is the conformation dependent immunoassay.<sup>107</sup> Several PrP<sup>TSE</sup>-specific monoclonal antibodies have now been described, of which 15B3 is the best characterized.<sup>108</sup> Several groups have developed assays predicated on differential binding of other ligands including polyanionic compounds,<sup>109</sup> synthetic polypeptides,<sup>6</sup> streptomycin/calix-6-arene,<sup>6</sup> and palindromic peptides.<sup>110</sup> Some of these approaches are now showing sufficient sensitivity to detect infectivity in the peripheral blood of TSE-infected animals. Finally, two approaches appear to amplify PrP<sup>TSE</sup> and/or infectivity. Protein folding cyclic amplification

**Figure 50-1.** The impact of sensitivity and specificity of an assay for variant CJD on test results from a donor population.

uses repeated cycles of incubation and sonication to amplify PrP<sup>TSE</sup> up to 10<sup>7</sup>-fold,<sup>44</sup> whereas in-vitro cell culture has also proved capable of amplifying murine scrapie.<sup>111</sup> Such amplification might prove a valuable adjunct to other detection methods.

There are three key concerns relating to the introduction of donor screening assays.

1. The specificity of an assay is dependent not only on its technical properties, but also on the population in which it is deployed. An assay with a satisfactory positive predictive value in the context of patients with suspect disease may have a very poor positive predictive value in the context of general population screening. The potential impact of an assay with a low specificity on the false-positive rate of a healthy donor population is illustrated in Fig 50-1. Overall, there is a clear need for assays employing different analytical principles, one or more of which can be used for primary screening and others as supplementary or confirmatory assays to help control the false-positive rate.

2. The validation of such assays is problematic.<sup>112-114</sup> The standard approach to validation of microbiological screening assays uses large numbers of samples from patients known to have the disease in question. Patients with variant CJD in particular are fortunately rare and it will be problematic to obtain large volumes of blood for ethical and practical reasons. It is likely, therefore, that it will be necessary to carry out the development and validation of peripheral blood screening assays on spiked brain homogenates and endogenously infected animal models, raising concerns about the relevance of these models to the human setting.

3. Consideration will need to be given to the impact of introduction of a screening assay on donors. There are likely to be difficulties in the discrimination of false from true positives and, indeed, in understanding the “meaning” of a true-positive result in terms of the implications for the donor. Donors will have to be informed that they will be screened and notified of any positive result. The psychological and social impact on the individual is likely to be high and the negative impact on the blood supply could be profound. Further, detailed consideration needs to be given to the practical and ethical implications of introducing an assay and the provision of adequate supporting resources.<sup>115-117</sup>

### Blood Component Processing

Whole blood is now rarely transfused, the majority of components being collected via apheresis or derived from whole blood

donation and processed into red cell concentrate (in additive solution), platelet concentrate, and fresh frozen plasma. In addition, in the UK, Ireland, France, and some other countries, all clinical blood components are subject to universal leukocyte reduction, which removes 3-4 log<sub>10</sub> leukocytes.<sup>118-120</sup> The rodent studies of Brown et al<sup>33,34</sup> and Gregori et al<sup>36</sup> suggest that it is likely that component processing brings about some reduction in overall infectivity because of reduction in the amount of residual leukocytes and plasma, but it is unlikely that this will significantly affect transmissibility.

Several companies are working on the development of prion reduction filters for red cell components that offer the possibility of a further reduction in infectivity.<sup>121,122</sup> Current risk management models suggest that a 3 log<sub>10</sub> reduction in infectivity with use of the device would be needed in association with leukocyte reduction in order to effect a reduction in the risk of transmission. Potential detrimental effects include additional blood loss in the dead volume of the filter and the possibility of alterations to red cell antigenicity or membrane properties. There are concerns about the evaluation of the efficacy of these technologies given that they have developed using spiked brain homogenates and endogenous infectivity animal models. The UK and Irish Blood Services have developed a series of quality, efficacy, and operational specifications and are commissioning independent evaluation and clinical safety studies.

### Plasma Derivative Manufacture

It is unlikely that the virus inactivation steps used in the manufacture of plasma derivatives will have a significant impact on prion infectivity.<sup>123</sup> However, work based on consideration of the likely physicochemical characteristics of the prion agent and the partitioning effects of plasma fractionation suggests that a significant reduction in infectivity may occur during the fractionation process, resulting in a relatively low risk of transmission by plasma derivatives.<sup>124</sup> Studies of spiked brain homogenates support this prediction, but are unlikely to accurately reflect the physicochemical nature of the infectious agent in plasma.<sup>125-128</sup> A smaller number of endogenous infectivity studies have been carried out in animal models that again support the general premise, but are unable to demonstrate more than a 1- to 2-log reduction because of low concentrations of infectivity in the starting material.<sup>34</sup> Several manufacturers are using nanofiltration as a second

virus reduction step, and these filters have, at least experimentally, demonstrated prion removal, mainly using brain homogenate spikes. Prion-binding affinity chromatography systems are under development but are probably still some way from routine application. There has been no documented case of transmission of sporadic CJD by plasma derivatives. Surveillance of patients exposed to large volumes of plasma products have also not shown any evidence of transmission. Some of these products are known to have been manufactured from pools that contained plasma from a donor who subsequently developed variant CJD. Most such individuals are considered to be “potentially at risk for public health purposes.”<sup>129</sup>

### Cellular, Tissue, and Organ Transplantation

Many types of cells, tissues, and organs are transplanted.<sup>130</sup> As noted previously, the concentration of infectivity in such tissues is uncertain, although broadly speaking, a very low concentration would suffice to cause transmission of disease if the donor were infected. Deferral of transfused donors has proved to be complex because of the nature of the donor population(s), the shortage of some tissues, and the lifesaving nature of the procedure—particularly of organ transplantation. A feasibility study has been initiated to look at the possibility of testing tonsil from cadaveric donors for PrP<sup>TSE</sup> accumulation. Broadly speaking, any processing that reduces the amount of cellular material and also avoids pooling is likely to be of benefit. There are ongoing studies of the applicability of, for example, washing method for bone processing. Agents that proved effective in the decontamination of surgical instrumentation are largely inapplicable to cells or organs although some might be applicable to acellular tissues such as heart valves, bone, or tendons. Finally, it is possible that some of the compounds found to mitigate TSE infectivity in vitro and/or in vivo could be applicable to these products.<sup>131,132</sup> Substantial further research and development work will need to be carried out before results of these investigations can be translated to the clinical setting.

### Ethical, Legal, and Societal Considerations

Many of the issues raised above pose not only scientific and medical challenges, but also wider ethical, legal, and societal questions. Early uncertainty over the possibility of secondary transmission of CJD by blood transfusion or plasma derivatives led to the implementation of risk management strategies based on the precautionary principle, perhaps best articulated by the Krever Commission in Canada<sup>133,134</sup>:

“Preventive action should be taken when there is evidence that a potentially disease-causing agent is or may be blood borne, even when there is no evidence that recipients have been affected. If harm can occur, it should be assumed that it will occur. If there are no measures that will entirely prevent the harm, measures that may only partially prevent transmission should be taken.”

The accumulating evidence of the existence of a cohort of individuals subclinically infected with variant CJD prions in the UK, along with recent reports of clinical transmission by blood transfusion, speak to the prudence of these measures. However, important uncertainties persist and the effectiveness of current risk reduction measures including donor selection procedures, component processing, and plasma fractionation remains unclear. New technologies such as prion reduction filters and prion screening assays are under development and the precautionary principle would speak to the need to implement these where possible. However, such measures are not without potential countervailing risks and ethical problems.<sup>135</sup> Donor deferral criteria can be considered discriminatory, and the introduction of a donor screening assay could have a serious impact on the psychological health of individuals who test positive, leading to difficulties in balancing non-malevolence with regard to the patient against non-maleficence with regard to the donor. Donor deferral and screening measures could have a serious negative impact on the sufficiency of blood and tissue supply, leading to a failure of beneficence.<sup>136</sup> Component processing technologies such as universal leukocyte reduction<sup>137</sup> and prion reduction filters<sup>138</sup> offer the opportunity to circumvent these problems, but at significant financial cost, raising issues of equity of access to health-care resources. Finally, compulsory notification of people at potentially increased risk of exposure to CJD infection through blood components or plasma derivatives raises the issue of respect for autonomy.<sup>139</sup>

In this context, continued efforts should be made to improve the evidence base regarding clinical blood transfusion and tissue transplantation<sup>140</sup>; to promote a conservative approach to the use of human blood and tissue products<sup>141</sup>; to ensure that patients are appropriately informed<sup>142,143</sup>; and to facilitate public understanding of, and engagement with, the uncertainties and ethical dilemmas inherent in managing this risk.<sup>144</sup>

Transfusion-transmitted infections (TTIs) involving the infectious agents described in Chapters 46–50 have been significantly reduced in industrialized countries during the last two decades by careful donor selection and extensive laboratory testing. However, blood transfusions represent an ideal portal of entry for infectious agents and often contain trace amounts of endogenous bacteria (mostly from the gut or from presymptomatic infections) and/or exogenous bacteria (from the skin). With the volumes generally collected during a donation, trace contaminations are a problem. This is particularly true for platelet products (stored at 22°C) and in the transfusion of immunocompromised patients. Important interventions to reduce the risk for trace contaminations are careful donor selection, enhanced cleansing of the venipuncture site, use of diversion pouches for the first 15 to 20 mL of a blood collection,<sup>1</sup> and the testing of platelet preparations for the presence of bacteria. Risks for TTIs are escalated by emerging infections combined with increased international air travel.<sup>2</sup> This has been demonstrated by the mosquito-spread viruses, West Nile virus in the United States and the chikungunya virus in the Indian Ocean region. For the former a nucleic acid amplification test (NAT) has been developed, while this is not the case for chikungunya virus, which spread to Italy in 2007 and posed a risk in the Mediterranean area. On the Île de Réunion in the Indian Ocean in 2006, more than 25% of the inhabitants were infected. As a temporary measure in order to ensure a safe blood supply, components were supplied from France [except platelets, which were prepared locally by apheresis and subjected to pathogen inactivation (PI)].<sup>3</sup>

Programs for careful donor selection and extensive laboratory testing pose both organizational and economic challenges in most developing countries. In addition, the epidemiology is less favorable than in most developed countries, the use of whole blood is still dominating, and safe fractionated plasma proteins

are mostly unavailable. Therefore, TTIs are a serious problem, causing thousands of infections a year particularly with hepatitis B virus (HBV), hepatitis C virus (HCV), human immunodeficiency virus (HIV), and malaria. Robust and affordable PI technologies for whole blood and blood components would be of great value in these countries. In developed countries, the risk for bacterial and protozoan infections and emerging infectious agents are the main drive for PI.

Several approaches have been explored for PI. Except for solvent/detergent (SD) treatment, all are based on PI of single plasma units from recovered or apheresis plasma. Whether applied under good manufacturing practice (GMP) conditions in blood centers or on a larger scale outside blood centers, in-process control of single plasma units is not performed. Thus, exceptionally high loads of a pathogen could slip through; NAT should be performed in spite of PI.<sup>2</sup>

Pathogen inactivation of pooled fractionated plasma proteins has virtually eliminated the risk of TTIs, without compromising the quality of the products significantly. After addition of stabilizers, some proteins such as albumin have been pasteurized with excellent pathogen safety records. However, it took almost 60 years before attention was drawn to the fact that the addition of caprylic acid and N-acetyl-DL-tryptophan as stabilizers during pasteurization impairs drug binding of pharmaceutical grade albumin.<sup>4</sup>

In this chapter the much more challenging PI of blood components are discussed. Solvent/detergent treatment, which is successfully applied for biopharmaceutical plasma products, dissolves cell membranes; hence, it is highly effective also against intracellular pathogens but not applicable for cellular blood components. PI methods that target nucleic acids have been the prime choice for PI of cellular components, but their efficiency against intracellular microorganisms depends on the ability to penetrate cell membranes.

PI of blood components should inactivate or remove all types of infectious agents, without inducing neoantigens or reducing the function or life span of a blood component. PI should not result in residual toxic substances or involve a risk greater than any TTI associated with the original blood component.<sup>5</sup> Because

toxicity may first be revealed after large-scale clinical use, Phase IV postmarketing studies and hemovigilance programs are important.

Plasma Pathogen Inactivation

Solvent/Detergent Treatment

SD treatment is the most extensively used and best validated PI technology: 50 to 60 million doses of SD-treated pooled fractionated plasma proteins have been given without the reported transmission of enveloped viruses. However, the method does not inactivate nonenveloped viruses, and nanofiltration or heat treatment has been introduced as a second PI step for many fractionated plasma proteins. SD treatment removes infectivity by disrupting the membranes of enveloped viruses; bacteria, protozoa, and cells are also affected, but so far this has not been extensively validated.<sup>2</sup> The most frequently used technique is the combination of 1% tri-(N-butyl)-phosphate (TNBP) and 1% polyoxyethylene-p-t-octylphenol (Triton X-100) for 4 hours at 30 to 31°C.<sup>6</sup> TNBP acts as an organic solvent and removes lipids

from the membranes; it is used alone in some protocols for PI. Triton X-100 is a non-ionic detergent that disrupts lipid bilayers for easier extraction of lipids; it also stabilizes TNBP.<sup>6</sup> SD treatment was first licensed for clotting factors in 1985 and has been in use for the treatment of plasma since 1991.<sup>7,8</sup> The inactivation rate of enveloped viruses is fast and the safety of the method very high (Table 51-1).<sup>7,8</sup> Inactivation is below virus detection levels (>6log) within 15 minutes,<sup>9</sup> except for vaccinia virus, which shows a relative resistance, but is inactivated with TNBP and Triton X-100 according to the protocol mentioned above.<sup>10</sup> So far, all tested enveloped viruses, including the recently emerging ones, are inactivated. For plasma no second PI step is available, but immune antibodies in a plasma pool can protect against disease with hepatitis A virus (HAV) and parvovirus B19.<sup>11,12</sup> In addition, NAT screening for HAV and parvovirus B19 ensures the safety of SD-treated plasma, as an essential regulatory requirement.

A major advantage of SD treatment is that the inactivation reagents in general do not affect proteins and protein activity in plasma. One important exception is reduction of the α<sub>2</sub>-antiplasmin activity by 70% to 80% during SD treatment. This seems to

Table 51-1. Inactivation Agents, Susceptible Pathogens, and Modified Targets

be caused by Triton X-100 because a reduction of only about 10% is observed with Triton X-45, which in preliminary virus inactivation validation is as effective as Triton X-100.<sup>13</sup> Triton X-45 and X-100 differ in molecular mass, the former having only five ethylene oxide groups, the latter nine or 10 groups. This difference in molecular mass suggests a differential impact of the two non-ionic detergents on the conformation (and activity) of  $\alpha_2$ -antiplasmin.<sup>13</sup> After removal with oil extraction and hydrophobic interaction chromatography, TNBP and Triton X-100 are either undetectable or present as trace contaminations far below toxicity levels.<sup>6</sup>

SD treatment is the only current technology for PI of pooled plasma. This allows for the production of a standardized biopharmaceutical product with extensive in-process control and without the significant normal variation in plasma protein concentrations observed in single plasma units. Pooling also dilutes and in some instances neutralizes antibodies and allergens, and allows the production of ABO-independent universal plasma (see later). There is a risk that emerging TTIs would be increased by pooling. However, SD plasma pools (60–380 L) are 10 to 100 times smaller than those used in the production of PI fractionated plasma proteins. Recently, a very gentle method for SD treatment of single plasma units and cryoprecipitate at blood centers was published.<sup>14,15</sup>

SD-treated pooled Fresh Frozen Plasma (SDPP) was introduced in Europe in 1991, with Octaplas (Octapharma AG, Lachen, Switzerland) as the leading product. Octaplas is a licensed biopharmaceutical product in 29 countries worldwide (including Canada and Mexico in North America). A total of over 6 million units of SDPP have been transfused so far. In the United States, SDPP (PLAS+SD, Vitex, Watertown, MA) was licensed in the second half of the 1990s but later withdrawn from the market.<sup>2</sup> After SD treatment, these SDPP products are normally frozen in 200-mL plastic bags; however, the South African Bioplasma FDP is lyophilized.

Nine studies covering all indications for plasma (including six European prospective randomized trials with SDPP) have investigated the clinical efficacy and tolerance, with Octaplas as the best-documented product.<sup>16,17</sup> Although the SD treatment process has been the same for all SDPP products, there have been some differences in the quality of plasma and manufacturing processes.<sup>16,17</sup> Apheresis plasma is preferred, followed by recovered plasma optimally frozen within few hours after collection. Plasma from whole blood stored for 15 hours before separation and freezing has a reduced content of coagulation factors and inhibitors.<sup>18</sup> The usage pattern of such plasma and some differences in production processes could account for the thromboembolism and compositional differences observed with PLAS+SD but not with Octaplas.<sup>19–21</sup> All SDPP products have low levels of  $\alpha_2$ -antiplasmin. Except for protein S in the lower normal range and the reduction of  $\alpha_2$ -antiplasmin, Octaplas has a concentration of coagulation factors and inhibitors and clinical effect similar to apheresis FFP (frozen within 24 hours after collection).<sup>17,22</sup> SD treatment of single plasma units (1% TNBP + 1% Triton X-45 or only 2% TNBP) has been reported to have minimal effect on coagulation factors

and inhibitors, including protein S and  $\alpha_2$ -antiplasmin.<sup>15</sup> This promising method, however, needs further validation.

$\alpha_2$ -antiplasmin is an acute-phase serine protease inhibitor of plasmin that is synthesized in the liver.<sup>23</sup> This explains why most clinical observations show that low  $\alpha_2$ -antiplasmin levels in SDPP are insignificant except in patients with liver deficiency or fibrinolysis.<sup>17</sup> In these patients, antifibrinolytic treatment or administration of the serine protease inhibitor aprotinin has to be considered.<sup>2,24</sup> In an enhanced version of Octaplas  $\alpha_2$ -antiplasmin levels are now reduced by only 30% to 40% (T-E Svae, Octapharma, personal communication). Low levels of protein S have been associated with thromboembolism observed in liver transplantation with PLAS+SD,<sup>17</sup> and a retrospective study in Europe indicated possible thromboembolism after repeated plasma exchanges with Octaplas in patients with thrombotic thrombocytopenic purpura (TTP).<sup>25</sup> However, in a large study, the same authors subsequently observed no problems with venous thromboembolism and concluded that there was no difference in the number of exchanges needed when cryosupernatant and Octaplas were compared. In addition, they reported that allergic/urticarial and citrate reactions were more common with cryosupernatant.<sup>26</sup>

Adverse events are less common with SDPP than with ordinary FFP. Particularly important is that there have been no reports of transfusion-related acute lung injury (TRALI) after transfusion of over 5 million units of SDPP in Europe.<sup>27,28</sup> Hemovigilance data indicate that febrile, allergic, or anaphylactic reactions are reduced by 70% to 80% with SDPP.<sup>21</sup> These observations are best explained by dilution/neutralization that results from pooling and removal of all cellular components during the SD treatment process.

An improved version of SDPP is ABO-universal plasma that eliminates the need for ABO group-specific plasma.<sup>2</sup> It is based on the principle that anti-A and anti-B can be neutralized by soluble A and B antigens in plasma. This was first exploited during World War II, when the Allied Forces used randomly pooled plasma. Such a lyophilized product was licensed for emergency needs in several European countries until the 1970s, but represented a high risk of transfusion-transmitted hepatitis.<sup>2</sup> Since 1996, a lyophilized ABO-universal SDPP, Bioplasma FDP (National Bioproducts Institute, Pinetown, South Africa), has been prepared from low-titered plasma pools in South Africa.<sup>29</sup> More than 370,000 units have been transfused so far, with an excellent record of safety and efficacy.<sup>2</sup> In Europe an ABO-independent universal SDPP has been developed by Octapharma by proportionally pooling A, B, and AB plasma. The product (tentatively named Uniplas) is not yet licensed, but has been used successfully in clinical trials in cardiac surgery and liver resection in Europe.<sup>30–32</sup>

## Photosensitizers

### Methylene Blue Light Treatment

Methylene blue (MB) is a positively charged phenothiazine dye with high affinity for negatively charged compounds, such as guanine, proteins, and some lipids. The virus inactivating activity of illuminated phenothiazines has been recognized since the

early 1930s.<sup>33</sup> Evidence suggests that MB interacts with nucleic acids through intercalative binding and produces singlet oxygen-mediated damage, primarily to nucleic acid guanosine residues, upon illumination with visible light.<sup>34</sup> MB light treatment is effective against enveloped and some nonenveloped viruses (Table 51-1). MB does not effectively permeate plasma membranes; thus intracellular pathogens and leukocytes may not be fully inactivated. Therefore, the original protocol developed by Institute Springe introduced a freeze-thaw step to destroy residual leukocytes. Grifols (Barcelona, Spain) employs leukocyte filtration of blood, which also removes platelets and to some degree cellular fragments and microparticles, and brings residual leukocyte counts in plasma well below  $1 \times 10^6$ .<sup>35</sup> However, only plasma membrane filters remove all cellular components, and reduce intracellular HIV infectivity to detection limits after MB light treatment of plasma. Binding of MB to membrane proteins may affect red cell viability, while binding to plasma proteins reduces coagulation factor activity in plasma, cryoprecipitate, and cryosupernatant.<sup>37</sup> Toxicity of MB is low. Intravenous doses of 1 to 5 mg/kg have been administered in clinical situations without the report of serious adverse effects; a unit of MB-treated plasma would represent 0.0012 mg/kg for an adult, and could be reduced to 0.00012 mg/kg with absorption devices.<sup>2</sup> No neoantigenicity caused by various intercalated proteins remaining after MB treatment have been reported. However, on theoretical basis, long-term side effects cannot be ruled out completely because of the binding of MB to proteins.<sup>21</sup>

MB-treated plasma is the second most frequently used pathogen-inactivated FFP, and more than 4 million units have been used clinically in European countries, including Germany, Belgium, France, Greece, Italy, Spain, Switzerland, and the UK. The method is applied on single plasma units. The original Springe protocol was factory based, and in use for more than a decade in Germany and Switzerland.<sup>38</sup> Grifols has introduced a similar factory-based method, but with leukocyte filtration instead of a freeze-thaw step. This method is still in use in Spain. Macopharma (Tourcoing, France) has modified MB treatment of plasma for use in blood centers, and improved the method. The firm has introduced the Theraflex MB-Plasma system, with a 0.65-micron plasma filter and a removal device for MB that eliminates more than 90% MB and its photoproducts, without any significant additional loss of coagulation factors.<sup>2</sup> The system is granted Conformité Européenne (CE) mark and used to prepare PI plasma in house at a number of blood centers in Europe. In Germany the Paul Ehrlich Institute (Frankfurt, Germany) has granted authorization for manufacture and sale of plasma treated with the Theraflex MB-Plasma system.

In spite of extensive use, there have been no full reports of large randomized trials with MB-treated plasma using relevant endpoints such as blood loss or exposure to other blood components.<sup>39</sup> In one small study, cardiac surgery patients were transfused with either MB-treated plasma or SDPP. The former gave better replacement of protein S and  $\alpha_2$ -antiplasmin, but no difference in blood loss.<sup>40</sup> A 5-year observational study in Greece

with the Theraflex MB-Plasma system reported good safety and a reduced number of adverse events.<sup>41</sup>

As with all other PI methods, MB treatment reduces the potency of some active elements of plasma. Fibrinogen, Factor V, and Factor VIII activity are decreased by approximately 30%; the effect on other coagulation factors and inhibitors is smaller.<sup>2,41</sup> Significant prolongation of fibrin polymerization time has been reported; the prolongation is, however, eliminated after admixture of 60% Octaplas.<sup>42</sup> Thrombin generation capacity is impaired in MB-treated plasma.<sup>43</sup> Overall, satisfactory clinical results and efficacy have been reported with MB-treated plasma. However, it seems to be less effective than FFP as replacement fluid in plasma exchange for TTP, in spite of normal levels of von Willebrand factor cleaving enzyme (ADAMTS13) in MB-treated plasma.<sup>2,44</sup>

### Psoralen Ultraviolet Light Treatment

Furocoumarins, which include psoralens, are active compounds isolated from plants; they have been known as photosensitizers since ancient times. Amotosalen hydrochloric acid (also known as S-59) is a synthetic psoralen (Fig 51-1) specially selected by Cerus (Concord, CA) for PI of blood components because it crosses plasma membranes efficiently and demonstrates excellent protection against pathogens.<sup>6</sup> S-59 is activated by ultraviolet A (UVA) light. Because hemoglobin absorbs UVA light, S-59 is not applicable for PI of red cells.

**Figure 51-1.** Structures and general formula for some pathogen inactivating agents. The formula for Thiazole orange is used with permission from Skripchenko et al.<sup>45</sup>

S-59 targets the helical region of single- or double-stranded DNA or RNA, and intercalates almost instantly. Upon exposure to UVA light, S-59 binds covalently to pyrimidine, and with continued UVA light exposure a second bond is generated cross-linking double-stranded structures, while single-stranded structures are cross-linked in loops. S-59 photodegrades into well-characterized molecules that are rapidly excreted.<sup>6</sup> In addition to targeting nucleic acids, S-59 also binds to lipids and proteins. Thus, about 15% of the initially added S-59 remains bound to plasma and platelets even after removal of S-59 and its photoproducts with a compound absorbing device (CAD). Most S-59 is associated with lipids, but 1% to 2% is associated with proteins.<sup>2</sup> Psoralen UVA light treatment with S-59 inactivates a broad spectrum of enveloped viruses, bacteria, protozoa, and residual leukocytes, but its effect on nonenveloped viruses is more variable (Table 51-1).<sup>6,46</sup>

The INTERCEPT Blood System device developed by Cerus uses S-59, UVA illumination, and a CAD for the removal of residual S-59 and metabolites. In Europe the system was granted CE mark for PI of plasma in 2006, and is supposed to be implemented under GMP conditions in blood centers. In the United States it is approved only for clinical trials by the FDA. Preclinical studies have demonstrated high levels of safety.<sup>47,48</sup> Fibrinogen, Factor V, Factor VII, Factor VIII, and Factor X are reduced by 17% to 30%, while coagulation factor inhibitor activity is less affected.<sup>46</sup> Four randomized studies indicate adequate clinical effect, including support of plasma exchange for TTP<sup>48-51</sup>; however, more than 60% of the patients with congenital coagulation deficiencies experienced urticaria.<sup>49</sup> Although no neoantigenicity or toxicologically relevant effects have been observed with INTERCEPT-treated plasma, Phase IV postmarketing studies could still reveal such effects resulting from some binding of S-59 to lipids and proteins.

### Riboflavin Light Treatment

In spite of phototoxic targeting of nucleic acids, vitamin B2 (riboflavin) is generally recognized as safe by the US FDA. This safety is supported by extensive experience with phototherapy treatment of neonatal jaundice (see Chapter 27). Riboflavin and its photoproducts are present in a wide range of foods and natural products in common use. In addition, riboflavin, its photoproducts, and its catabolites are detectable in normal blood, which suggests that their presence may be ubiquitous.<sup>52</sup> However, further research is required because the level of photoproducts is considerable higher in riboflavin-treated blood components. Both oxygen-dependent (formation of free radicals) and oxygen-independent (electron transfer) processes are involved in the phototoxic PI effect of riboflavin, which damages guanine and may form adducts of thymine and adenine.<sup>53</sup> Riboflavin light treatment has proven effective against a range of pathogens, including bacteria, enveloped viruses, protozoa, leukocytes, and some nonenveloped viruses (Table 51-1).<sup>52</sup>

Navigant Biotechnologies (Lakewood, CO) has developed the Mirasol system for riboflavin treatment of blood components.

Because riboflavin can be photoactivated by visible as well as UV light, the Mirasol system is being adapted for PI for all blood components, including red cells and whole blood. The system is similar to INTERCEPT, except that removal of reagents may not be necessary, and is not currently performed. Mirasol has been adapted for PI of platelets and plasma, while treatment of red cells and whole blood still is under development. Extensive PI of selected viruses (including parvovirus), bacteria, and protozoa in addition to leukocyte inactivation has been reported in platelet concentrates.<sup>52</sup> Similar results have been obtained with Mirasol treatment of FFP (RP Goodrich, Navigant Biotechnologies, personal communication).

Compared with the INTERCEPT system, the Mirasol system for PI of plasma reduces the time plasma is stored in liquid state, and early studies indicate that plasma protein activity is only marginally affected.<sup>52</sup> Preclinical studies with Mirasol-treated plasma are promising, and no neoantigenicity has been observed. Pending the successful completion of remaining field verification and clinical studies in Europe, the Mirasol system for PI of plasma is expected to receive a CE mark (RP Goodrich, Navigant Biotechnologies, personal communication).

---

## Platelet Pathogen Inactivation

### Psoralen UV Light Treatment

The INTERCEPT Blood Systems device for PI of platelets is similar to the one for plasma, and was granted CE mark in Europe in 2002; the FDA so far has approved it only for clinical trials. During the rather complex operation of PI with INTERCEPT, platelets come in contact with many surfaces that may induce surface changes and loss of granule contents. Studies have demonstrated inactivation of a broad spectrum of viruses, bacteria, protozoa, and leukocytes, including clinically relevant nonenveloped viruses such as parvovirus B19 (Table 51-1).<sup>6</sup> Typical experiments have been reported by Lin et al.<sup>54</sup> INTERCEPT treatment also inactivates mitochondrial DNA and inhibits cytokine synthesis, while platelet metabolic functions seem retained.<sup>55</sup> In-vitro INTERCEPT-treated platelets demonstrate increased CD61 microparticle formation, higher metabolic rate, accelerated metabolic changes, and reduced agonist-induced aggregation responses. Spontaneous platelet activation measured by fluorescent-activated cell sorter showed increased expression of CD62P and CD42b after INTERCEPT treatment; in addition, phosphatidyl-serine (PS) on the platelet surface (a hallmark of apoptosis) is significantly increased.<sup>56-58</sup> These changes are accelerated when the storage time is increased to 7 days. To what degree the formation of apoptotic cells, as measured by PS exposure, is of clinical significance remains to be established. In-vitro data show cytokine accumulation also in INTERCEPT-treated platelet concentrates.<sup>56</sup>

A European study including 166 thrombocytopenic patients transfused with INTERCEPT-treated buffy-coat platelets showed comparable platelet count increments and adverse reactions to untreated platelets.<sup>59</sup> However, in a larger US study (n = 645)

assessing apheresis platelets, the 1-hour posttransfusion corrected count increment and average number of days to next platelet transfusion were slightly reduced, while the number of platelet transfusions was increased compared to untreated platelets.<sup>60</sup> In these studies storage time was limited to 5 days. Many facilities have increased storage time to 7 days without additional clinical trials in spite of the in-vitro study results. After CE marking in 2002 the system has been used for the production of more than 50,000 doses of PI platelets for routine clinical use in 14 European countries, and is reported to have replaced bacterial testing, gamma irradiation, and the use of cytomegalovirus-negative platelets. In addition there has been a report of a reduction in allergic nonhemolytic transfusion reactions with INTERCEPT-treated platelets.<sup>2</sup> Although no neoantigenicity or toxicologically relevant effects have so far been observed after clinical use of INTERCEPT-treated platelets, Phase IV postmarketing studies could reveal such effects resulting from some binding of S-59 to platelet lipids and proteins.

### Riboflavin-Treated Platelets

The Mirasol system for PI of platelets is similar to the one for plasma. It is less complex than the INTERCEPT system in that removal of reagents is not performed; thus it may be more gentle to the platelets. Nevertheless, this PI process also leads to some platelet activation as expressed by increased metabolic activity and P-selectin expression.<sup>53</sup> However, both in-vitro activity and mitochondria function seem not to be affected.<sup>61,62</sup> Extensive PI of selected viruses (including parvovirus B19), bacteria, and protozoa and inactivation of leukocytes has been reported.<sup>53</sup> Preclinical studies have demonstrated that in-vitro and in-vivo capabilities of Mirasol-treated platelets are similar to INTERCEPT-treated platelets.<sup>53,61,63</sup> After a Phase III study was completed in Europe in 2007, the Mirasol system for platelet PI was granted CE marking for application under GMP conditions in blood centers.

### Thionine Light Treatment

The phenothiazine dye thionine and UV light combined with strong agitation is effective in the PI of platelets, and development of a protocol is being pursued by Blood Centers of the German Red Cross and MacoPharma (H Mohr, Institute Springe, Germany, personal communication). However, strong agitation could pose problems with irreversible activation of platelets.

---

## Red Cell Pathogen Inactivation

PI systems for red cells and whole blood have been explored with some negative results but also some promising developments.

### Alkylating Agents

#### FRALE Compounds

Frangible anchor linker effector (FRALE) compounds are alkylating agents that specifically inactivate DNA/RNA via

covalent adducts to the nucleic acid. The compounds consist of a nucleic acid-binding ligand that serves as an anchor and promotes nucleic acid specificity, an alkylating agent that functions as an effector, and a chain that joins the two moieties.<sup>6,64</sup> Cerus has developed the Helinx system for PI of red cells with S-303 (Fig 51-1), which is a compound with an acridine-based anchor. S-303 is designed so that the alkyl chain is cleaved upon contact with blood at a rate slower than the rate of binding and alkylation to nucleic acids. This does not inhibit PI, but promotes the breakdown of residual unreacted compound into S-300, which does not further interact with nucleic acids.<sup>6,64</sup> Acridine nitrogen mustards have been shown to alkylate proteins in addition to nucleic acids.<sup>65</sup> Helinx treatment is performed at room temperature for 12 hours followed by incubation with a CAD in the final storage container for 8 hours in order to remove residual S-303 and S-300.<sup>6</sup> Helinx PI has been shown to inactivate viruses, bacteria, protozoa, and leukocytes efficiently (Table 51-1), and extensive toxicology studies indicated that the process was safe.<sup>66</sup> However, the literature with regard to the technology is sparse and mostly based on abstracts.<sup>6</sup>

PI with FRALE compounds has been applied to red cells, and the only available protocol is Helinx with S-303. After satisfactory results with in-vitro studies and genotoxicity tests, successful Phase I and II trials were performed, followed by Phase III trials in cardiac surgery and sickle cell/thalassemia patients. S-303 PI and conventional red cells were equivalent with regard to supporting the transfusion needs of cardiac surgery patients.<sup>67</sup> Nevertheless, the Phase III trial was put on hold because some patients in each group developed antibodies reactive with S-303-treated red cells, but no hemolysis.<sup>67</sup> Neoantigen formation may have been caused by alkylation of proteins by acridine nitrogen mustards.<sup>65</sup> Some patients even demonstrated antibodies before transfusion with S-303-treated red cells. These antibodies could have been induced by S-303-like agents such as the local anesthetic quinacrine, which also can alkylate proteins. Experiments to modify the Helinx system by adding quenchers has so far eliminated immunoreactivity of S-303 PI red cells,<sup>68</sup> but has not totally eliminated the formation of modified groups when red cells are tested with sensitive assays after treatment with S-303.<sup>2</sup>

### Aziridine Compounds

Aziridine compounds, such as ethylenimine, have been used to inactivate vaccines for the past 30 years. The method inactivates both enveloped and nonenveloped viruses, including members of the *Parvoviridae* family, which is often difficult to accomplish.<sup>69</sup> By forming oligomers of ethylenimine the selectivity of aziridines for nucleic acids is improved. Inactines are small molecules with a cationic tail, conferring DNA binding and an effector group based on ethylenimine or aziridine. PEN110 is a small, highly water-soluble cation with an ethylenimine oligomer (Fig 51-1), and selective affinity for nucleic acids,<sup>6</sup> but can also alkylate proteins.<sup>70</sup> It diffuses readily through cell membranes and, when forming ionic bounds with nucleic acids, the molecule is activated. The active form can then alkylate guanine. This

induces a break and results in a stop message. Vitex has developed the INACTINE system with PEN110 for PI of red cells. The treatment is performed at room temperature for 6 to 24 hours, followed by washing with unbuffered saline to levels below the limit of detection of PEN110.<sup>71</sup> Extensive studies with selected enveloped and nonenveloped viruses, bacteria, protozoa, and leukocytes (Table 51-1) demonstrate the high PI efficiency of PEN110.<sup>6</sup> Toxicology studies indicated that even if an individual human received multiple PI red cell components at once or over time, the dose would be far less than that required to have reproductive effects or induce genotoxicity.<sup>71</sup> After preclinical tests, successful Phase I and II trials were performed, but Phase III trials were stopped because of antibody responses to PEN110-treated red cells. In spite of protocol modifications the problem was not solved, and in June 2005 Vitex discontinued further investment in the development of PI with INACTINE.

### Photosensitizers

PI of red cells with photosensitizers poses problems because of light absorption by hemoglobin and the high number of red cells, which requires complex technical adjustments to secure uniform distribution of light for the treatment of Red Blood Cell (RBC) units (see Chapter 4).

Several studies have been conducted with porphyrin and phenothiazine dyes, which are rigid planar aromatic compounds activated by visible light, while psoralens are not applicable because hemoglobin absorbs UV light. However, because of hemolysis following PI of red cells with these aromatic dyes, the methods have been abandoned. Some of the hemolysis upon illumination arises from dye bound to the red cell membrane, while other damage is caused by singlet oxygen produced by illumination of dye residing in the cytoplasm or supernatant, and reacting with membrane lipids or proteins.<sup>72</sup> A new approach was opened by the discovery of flexible dyes that can act as photosensitizers when rigidly bound to substrate but cannot generate reactive oxygen species when in solution because the energy from absorbed light is dissipated as heat. Wagner and associates have pioneered the work with PI of red cells with two flexible dyes.<sup>45,72</sup>

Thiopyrylium (TP) is a flexible photosensitizer that intercalates with nucleic acids but also binds to red cells. Dipyrromethane (DP) (vasodilator, antioxidant, red cell band 3 ligand) acts as a competitive inhibitor of TP binding to red cells, and a protocol for PI of red cells was therefore designed with TP and DP. This method inactivated model viruses including intracellular HIV >6log, and six bacterial species >5log. Hemolysis increased within acceptable levels and most, but not all, red cell properties were retained after 42 days of storage.<sup>72</sup>

Thiazole orange (TO) (Fig 51-1) is another flexible nucleic acid intercalating dye, which shows less binding to red cells. Without addition of quenchers or competitive inhibitors, five tested viruses (including intracellular HIV) were inactivated >5.4log, and eight tested bacteria were inactivated from 2.3 to >7log. The PI red cells exhibited only slightly increased hemolysis, moderately elevated potassium efflux, and similar

levels of adenosine triphosphate compared to controls.<sup>45</sup> However, much work remains to understand and improve the technique, perform toxicology studies, characterize in-vitro and in-vivo properties of TO PI red cells, and eventually scale up the technique to treat entire RBC units in order to perform clinical trials. Because of some binding of TO to red cells, this dye has an inherent risk of neoantigen formation with subsequent immunization after transfusion.

### Riboflavin Light Treatment

Preliminary studies show promising results with PI of red cells using the Mirasol system adapted for red cells. Pathogen activation of microorganisms and leukocytes is similar to Mirasol treatment of platelets and plasma, while hemolysis and in-vitro red cell properties are within acceptable limits (RP Goodrich, Navigant Biotechnologies, personal communication).

The Mirasol system has now also been adapted for PI of whole blood, which afterwards can be separated into red cells, platelets, and plasma. Studies with this modified protocol include a full panel of in-vitro evaluations with the three separated blood components during storage, and radiolabeled red cell recovery and survival in healthy volunteers after 42 days of storage (RP Goodrich, Navigant Biotechnologies, personal communication). Because the chemistry employed by the Mirasol system does not involve covalent linking or alkylation and riboflavin is a natural constituent in human bodies, the risk that altered proteins in plasma or on platelet and red cell surfaces will induce antibody formation against neoantigens is small. Further studies with Mirasol PI of whole blood are, therefore, of great interest.

### Emerging Technologies

CryoFacets (Raleigh, NC) has under development an integrated system for PI, reduction of noninfectious complications, "fractionation of plasma," and effective, gentle cell processing. PI of this integrated system is based on the following:

- Vacuum ultrasound removal of oxygen in plasma or suspending solutions in order to eliminate oxidative damage of plasma proteins or cell membranes
- UVC illumination
- Ozone treatment

Plasma is first vacuum treated, then exposed to UVC light, and finally mixed with ozone. Following PI, plasma is separated into three fractions according to molecular weight: "above albumin," "albumin," and "below albumin."

Platelets are highly purified by separation with a specially developed counterflow centrifugal elutriation system; plasma, cell fragments, and bacteria are washed away. After isolation, platelets are mixed with an ozone solution in order to inactivate remaining bacteria. After a brief exposure to ozone the platelets are suspended in the "below albumin" fraction for storage. When platelets are needed the product is washed with degassed saline, which removes metabolic byproducts and cell fragments, and prepares the platelets for UVC exposure in order to inactivate viruses and possibly leukocytes. Because UVC-induced damage

to the platelets is first observed after several days, this treatment is undertaken shortly before transfusion.

Red cell treatment follows essentially the same process as that used for platelets.

PI with the CryoFacets protocols is reported to be very efficient and, because of innovative technologies, processing time is low. However, considerable in-vitro and in-vivo characterization of the PI products will be required before applicability assessments in hospitals and clinical trials can be planned.

---

## Prion Elimination

None of the above-mentioned PI technologies eliminate prions. However, a significant reduction in infectivity occurs during plasma fractionation, resulting in relatively low risk for prion transmission with fractionated plasma proteins (see Chapter 50).<sup>73</sup> For SDPP (Octaplas) a reduction of 2.5 log has been reported.<sup>73</sup> Phenothiazines may react with prions,<sup>74</sup> but there are no reports on a possible effect of MB treatment of plasma. Several companies are developing prion reduction filters for red cell components and interesting studies are in progress with ligand chromatography, which may reduce prion infectivity of plasma significantly (see Chapter 50). After introduction of such ligand chromatography in the production process of Octaplas an additional reduction of at least 3 log is achieved (T-E Svae, Octapharma, personal communication).

---

## Summary

SDPP is the most extensively used and documented PI plasma. An ABO-universal variant, introduced in 1996 in South Africa, eliminates the need for ABO group-specific plasma. Photochemical PI of plasma with MB light treatment has gained extensive use in Europe in spite of sparse published documentation; one protocol has gained CE mark. The protocol for psoralen light treatment of FFP gained CE mark in 2006, while the protocol for riboflavin light treatment of FFP is in advanced preclinical and clinical development. Photochemical PI of platelets with psoralen light treatment gained CE mark in 2002, and so far >50,000 platelet units have been transfused in Europe. The protocol for riboflavin light treatment of platelets gained CE mark in 2007, and is introduced in clinical settings in Europe. Two PI methods for red cells employing alkylating agents reached Phase III clinical trials; however, formation of antibodies against neoantigens on red cells has halted further progress. Riboflavin light treatment of red cells has now been adapted for PI of whole blood, which subsequently could be separated into plasma, platelets, and red cells. It is the only protocol for whole blood; therefore, further development will be followed with particular interest.

Clinical experience has shown reduced frequency (40%-80%) of allergic/immunologic (febrile nonhemolytic) adverse events with SDPP, MB-treated FFP (PI with the CE marked system), and psoralen light-treated platelets. This may be explained by the elimination of cellular components in the plasma and additional

dilution/neutralization in SDPP. Leukocyte activation and cytokine production are blocked in the platelets. In addition, no cases of TRALI have been documented after extensive use of SDPP; this may be the result of dilution and possible neutralization of leukocyte-reactive antibodies by pooling of FFP. For biopharmaceutical SDPP, the reduction of 2.5 log in prion infectivity is enhanced by ligand chromatography.

Cost-effectiveness of PI is rather low in most developed countries when compared to other strategies to reduce noninfectious risks of transfusion,<sup>75</sup> but comparable to NAT of blood components. When only the effect of virus inactivation is considered, the cost of a quality-adjusted life year has been calculated to approach US\$10 million for SDPP, and is assumed to be similar for PI of plasma by other methods.<sup>2</sup> The high cost is due to very low residual risk for recognized viral infections. During outbreaks of emerging infections and in developing countries with high residual infection risk the cost-effectiveness is much better. When TRALI is taken into consideration, the cost for SDPP is reduced to US\$40,000-170,000 per life year saved depending on patient age.<sup>2</sup> Further reduction is obtained when the reduction in allergic/anaphylactic adverse events and the benefits of ABO-universal SDPP are also considered.<sup>21</sup> For PI of platelets, no cost-effectiveness data have been published, but it has been suggested that the cost per life year saved in immunocompromised patients may be in the same range as for SD treated plasma, assuming that TRALI and allergic/anaphylactic adverse events are taken into account.<sup>16</sup> A possible introduction of riboflavin light treatment of whole blood may be expected to have considerable cost implications for all countries.

A consensus conference<sup>76</sup> recently concluded that cost-effectiveness studies should be carried out by public agencies before general introduction of a PI method and that an additional cost consequence analysis<sup>77</sup> should be included. The conference also pointed out that: "Large adequately powered randomized clinical trials should be performed to evaluate and/or confirm the effectiveness of any new PI. Postlicensure Phase VI studies should be integrated with hemovigilance systems to enhance the ability to detect adverse events."<sup>76</sup>

52 Hemolytic Transfusion Reactions

Robertson D. Davenport

Associate Professor, Department of Pathology, The University of Michigan Medical School, Ann Arbor, Michigan, USA

A hemolytic transfusion reaction (HTR) is the accelerated clearance or lysis of transfused red cells because of immunologic incompatibility. It is distinguished from autoimmune hemolysis or nonimmune causes of shortened survival of transfused red cells. HTR may occur when antigen-positive red cells are transfused to a patient with a preexisting alloantibody, or when a recently transfused patient makes a new alloantibody.

The great majority of HTRs are a result of Red Blood Cell (RBC) transfusion. However, HTRs may also result from transfusion of plasma-containing blood components, such as Fresh Frozen Plasma or Platelets, which contain red cell antibodies but very few, if any, red cells.<sup>1,2</sup> Occasionally, HTRs may be caused by incompatibility between red cells from one donor and antibody-containing plasma from a different donor transfused to the same recipient.<sup>3</sup>

Incidence

The actual incidence of HTR is difficult to determine. Much of the data are derived from retrospective studies and are likely to suffer from underreporting. A prospective study of bedside transfusion errors over a 15-month period found that major errors occurred in 1.24% of transfused patients.<sup>4</sup> Although only one of these errors resulted in a clinical reaction, none were reported—indicating that most errors in transfusion practice are not recognized at the time. In some cases, underlying medical conditions such as liver disease, sickle cell anemia, or bleeding may make a definite diagnosis difficult, particularly in delayed HTR (DHTR).

The reported incidence of HTR depends to some degree on the recipient patient population, and is likely to be higher in academic medical centers with heavily transfused patient populations. Reports from blood centers have largely relied on surveys of transfusion services, which may result in underestimation. Improvement in antibody identification techniques over time,

as well as increased knowledge of immunohematology, have undoubtedly resulted in a progressive decrease in HTRs.

Estimates of the incidence of HTR derived from both blood centers and transfusion services are summarized in Table 52-1. Some reports do not differentiate between acute and delayed reactions, or between intravascular and extravascular hemolysis. HTRs have not necessarily been differentiated from serologic reactions without hemolysis. Overall, there has been an apparent increase in the incidence of DHTR and a decreased in acute HTR (AHTR) with time. Factors contributing to a higher rate of delayed reactions include improved serologic detection, longer survival of transfusion patients, and increasing total number of red cell transfusions. Because most patients receive more than one RBC unit, estimates of the incidence of HTR per transfused patient range from 1:854 to 1:524, which is higher than the incidence per unit transfused.<sup>11,15</sup> The population incidence rate of DHTR has been estimated at 1.69 events per 100,000 population per year.<sup>15</sup>

Table 52-1. Estimated Incidence of Hemolytic Transfusion Reactions (HTRs)

| Setting                                                             | Period    | HTR Risk Estimate per Unit Transfused |
|---------------------------------------------------------------------|-----------|---------------------------------------|
| <b>Overall HTR (acute and delayed reactions not differentiated)</b> |           |                                       |
| Blood center <sup>5</sup>                                           | 1981-1987 | 1:15,605                              |

Rossi's Principles of Transfusion Medicine, 4th Edition, Edited by Toby L. Simon, E. L. Snyder, B. G. Solheim, Christopher, P. Stowell, Ronald, G. Strauss and Marian Petrides © 2009 Blackwell Publishing Ltd. ISBN: 978-1-405-17588-3

**Figure 52-1.** Time course of hemolytic and coagulation parameters in intravascular HTR. Adapted with permission from Duvall et al.<sup>18</sup>

Since 1996, the Serious Hazards of Transfusion (SHOT) program in the United Kingdom has reported and tracked HTRs. In 2004, HTRs caused by ABO-incompatible RBC transfusions were reported in 19 of 2,607,410 units issued, for a rate of 1:137,000.<sup>16</sup> The number of patients transfused or units transfused was not reported. However, the wastage rate was estimated to be less than 5%. The number of ABO-incompatible transfusions reported annually to SHOT officials since the program's inception has varied from 13 to 36. The number of units issued was not reported for years prior to 2004.

Data on HTRs from the Quebec Hemovigilance System covering 2000 to 2004 have been reported.<sup>17</sup> Over a 5-year period, 47 ABO-incompatible transfusions, 55 AHTRs, and 91 DHTRs out of 7059 total transfusion reactions occurred. The incidence per RBC unit issued was 1:27,318 for ABO incompatibility, 1:14,901 for AHTR, and 1:9313 for DHTR. The most common cause of AHTR was ABO incompatibility, accounting for 30% of reactions.

HTRs are classified as acute or delayed reactions, based on whether they occur within 24 hours or after 24 hours of the implicated transfusion. A more important distinction is between intravascular and extravascular hemolytic reactions. Intravascular hemolysis is characterized by hemoglobinemia and hemoglobinuria. In contrast, extravascular hemolysis lacks these dramatic signs, but is characterized by shortened survival of transfused red cells along with the accumulation of hemoglobin breakdown products. Generally, intravascular hemolysis is seen with AHTR, while extravascular hemolysis is usually seen in DHTR. This distinction is not absolute, however. Occasional acute reactions

result in extravascular hemolysis, and some intravascular hemolytic reactions are delayed.

Accelerated clearance of incompatible red cells is an essential feature of HTRs. Transfusion may also stimulate the production of alloantibody without hemolysis. This phenomenon has been termed delayed serologic transfusion reaction (DSTR), and needs to be differentiated from delayed HTR.<sup>11,13</sup> DSTR is clinically benign, but predisposes to later HTR. Earlier reports of hemolytic reactions have not necessarily differentiated clearly between serologic and true hemolytic reactions.

## Signs and Symptoms

There is a broad range of initial clinical presentations of HTR. The typical progression of intravascular and extravascular hemolysis is shown in Fig 52-1 and Fig 52-2. In all cases, there is an unexpected degree of anemia from the loss of transfused red blood cells. In some cases, particularly with extravascular hemolysis, this is the only clue to HTR. Some reactions, both immediate and delayed, are asymptomatic. In intravascular hemolysis, however, most symptomatic patients experience fever and/or chills. Nausea or vomiting, pain, dyspnea, and hypotension or tachycardia are also common initial symptoms. The reported pain may localize to the infusion site, back, flanks, chest, groin, or head. The cause of pain in HTR is unclear, but is most likely the result of direct stimulation of nociceptive nerves in perivascular

**Figure 52-2.** Time course of hemolytic parameters in extravascular hemolysis. Adapted from Cummins et al.<sup>19</sup>

tissue by bradykinin generated from activation of the complement system.<sup>20</sup>

In extravascular hemolysis, fever and/or chills are the most commonly reported initial symptoms. Jaundice also may be an initial sign because elevation of serum bilirubin occurs with both intravascular and extravascular hemolysis. The degree of hyperbilirubinemia depends upon the patient's liver function and rate of red cell destruction. Conjugated and unconjugated bilirubin fractions tend to follow a parallel course, peaking at the same time.<sup>19</sup> Delta bilirubin, a minor albumin-bound fraction, persists past the peak of total bilirubin, and is a useful clue to previous hemolysis.

Although HTR typically presents during or shortly after the offending transfusion, the time from transfusion to clinical presentation of DHTR is quite variable. Most delayed reactions present within 2 weeks after transfusion, but the initial presentation may be up to 6 weeks later, because of the time required for antibody production.

## Complications

Autoantibody is found in about 28% of patients concomitantly with alloantibody, although the reported range is 15% to 53%.<sup>21</sup> A positive direct antiglobulin test (DAT) caused by IgG may persist for many months, and there may be evidence of complement deposition on autologous red cells, with a positive DAT caused by C3 persisting for up to 100 days.<sup>22</sup> In most cases, there is no evidence of loss of autologous red cells; however, so-called "bystander hemolysis" can occur. It is not possible to distinguish between autoimmune hemolytic anemia (AIHA) and bystander hemolysis by serologic testing alone.

Patients with sickle cell anemia can present a particular challenge. HTR can precipitate sickle crisis. Factors that contribute to the occurrence of sickle crisis include increased oxygen consumption resulting from fever, the relative loss of circulating hemoglobin A compared to hemoglobin S, and the release of vasoactive mediators causing reduction of local blood flow. HTRs may be particularly

severe in patients with sickle cell disease. In such reactions the degree of anemia may actually be greater than before transfusion, probably because of bystander hemolysis of autologous red cells. This phenomenon has been termed the sickle cell HTR syndrome.<sup>23</sup> In addition to hemolysis, there is often suppression of erythropoiesis as indicated by a marked drop in the reticulocyte count. Demonstration of an increase in corrected reticulocyte count, increase in the absolute number of hemoglobin-S-containing red cells, or decrease in the ratio of red cell hemoglobin to reticulocyte hemoglobin can indicate the occurrence of hyperhemolysis.<sup>23-25</sup> Pain crisis in a sickle cell patient following transfusion should suggest the occurrence of sickle cell HTR syndrome. Further transfusion in this setting may exacerbate the anemia and even result in fatality. Serologic studies often do not provide an explanation for HTR in these patients, because the causative antibody can be at an undetectable level in the serum during the reaction. In addition, the presence of multiple alloantibodies may make the serologic diagnosis difficult.

Hypotension occurs in some cases of intravascular HTR but is rare in extravascular reactions. Complement activation is likely to be the most important determining factor. The anaphylatoxins C3a, C4a, C5a, and C5a-des-arg are released during immune hemolysis. Additionally, consumption of C1-esterase inhibitor contributes to activation of the kinin pathway, leading to generation of bradykinin.<sup>26</sup> The proinflammatory cytokines tumor necrosis factor (TNF) and interleukin (IL)-1 produced by phagocytes during HTR also may contribute to hypotension and shock.

Impairment of renal function is seen in both intravascular and extravascular HTR, although it is more common in the former. The degree of renal function abnormality varies from an asymptomatic elevation of serum blood urea nitrogen (BUN) and creatinine to complete anuria. Both hypotension and intravascular coagulation contribute to renal impairment. Thrombus formation in renal arterioles caused by disseminated intravascular coagulation (DIC) may cause cortical infarcts. Free hemoglobin contributes to renal injury, causing so-called pigment nephropathy. Experimental evidence indicates that hemoglobin is toxic to renal tubular epithelium cells.<sup>27</sup>

Intravascular hemolysis modulates blood pressure and local blood flow through alterations in the metabolism of the potent physiologic vasodilator nitric oxide (NO). NO can combine with heme and thiol groups of hemoglobin.<sup>28</sup> In oxyhemoglobin, NO causes reduction of ferrous iron ( $\text{Fe}^{2+}$ ) to form ferric methemoglobin [ $\text{Hb}(\text{Fe}^{3+})$ ]. NO combines with deoxyhemoglobin to form  $\text{Hb}(\text{Fe}^{2+})\text{NO}$ , but does not cause reduction. Scavenging of NO by free hemoglobin through these pathways results in vasoconstriction and hypertension. NO can also combine with cysteine on the beta globin chain to form S-nitrosohemoglobin (SNO-Hb). This process is reversible, so SNO-Hb can act as a NO donor with resultant vasodilation. Free hemoglobin reacts with NO much more rapidly than does intraerythrocytic hemoglobin.<sup>29</sup> The effects of intravascular hemolysis may be very similar to the infusion of stroma-free hemoglobin. Indeed, prominent hypertensive effects limited early trials of hemoglobin solutions as a blood substitute.<sup>30</sup>

Disseminated intravascular coagulation occurs in intravascular HTR, but is relatively rare. Rarer still is the occurrence of DIC in extravascular HTR. The production of proinflammatory cytokines is likely to be a major factor in DIC. It can be difficult to distinguish DIC from other causes of coagulopathy, particularly in massive transfusion or liver disease. Uncontrolled bleeding caused by DIC may be the initial manifestation of an acute HTR, particularly in the intraoperative setting. Unfortunately, if HTR is not recognized early in this situation, more incompatible blood may be transfused in an attempt to keep up with blood loss. In one report, nine of 35 patients experiencing HTR while under anesthesia received 4 to 6 additional units because of excessive bleeding.<sup>31</sup>

Fatality from HTR is usually associated with intravascular hemolysis, but severe extravascular reactions may also cause death.<sup>7,32</sup> It is difficult to estimate the actual rate of mortality, but the best available data are derived from reports to regulatory agencies. A review of transfusion-associated deaths reported to the Food and Drug Administration (FDA) between 1976 and 1985 attributed 158 fatalities to acute hemolysis and 26 to delayed hemolysis.<sup>33</sup> Assuming that 100 million RBC units were transfused in this time, the mortality rate for AHTR would be 1:630,000 and that for DHTR would be 1:3,850,000 per unit transfused. Similarly, assuming that 30 million patients were transfused in this time, the per patient mortality rate for AHTR would be 1:190,000, and for DHTR would be 1:1,150,000. An earlier review of transfusion fatalities reported to the FDA covering 1976 to 1978 estimated the death rate from HTR to be 1:587,000 per unit transfused.<sup>34</sup> A recent update has extended the analysis of FDA fatality reports through 1995.<sup>35</sup> Since 1990 the number of deaths reported to the FDA annually has increased, probably because of increased vigilance in reporting. The total number of deaths (151) from acute and delayed hemolysis reported between 1986 and 1995 was essentially unchanged from the prior 10 years. However, acute hemolysis accounted for a higher proportion of deaths (62%) during the first decade, than during the second decade (50%). This difference was caused by a higher incidence

of deaths from other causes including bacterial contamination and acute lung injury in the later report. The total number and proportion of deaths from delayed HTR was unchanged between the two reporting periods (26 or 10% vs 29 or 10%).

An analysis of blood transfusion errors reported to the New York State Health Department, from January 1990 to October 1991, reported a death rate of 1:600,000 per unit transfused.<sup>36</sup> When these data were extended to the period 1990 to 1999, the fatality rate from erroneous administration of RBC units was 1:1,800,000.<sup>9</sup> It is not surprising that different studies result in discrepant estimates of mortality rate, because these figures are based on small numbers of events.

The cumulative SHOT data from 1996 to 2004 includes 245 ABO-incompatible transfusions. Among these, death related to transfusion occurred in 7% of cases, major morbidity in 22%, and no ill effect in 63%.<sup>16,37</sup>

Mortality is dependent on the amount of incompatible red cells transfused. A review of 41 HTRs causing acute renal failure indicated that no deaths occurred among patients receiving less than 500 mL of incompatible blood; there was 25% mortality in the group receiving 500 to 1000 mL and 44% mortality among those receiving greater than 1000 mL of incompatible blood.<sup>31</sup> However, transfusion of even small amounts of incompatible blood is not necessarily safe. At least 12 deaths have been reported to the FDA involving transfusion of less than 1 unit of blood.<sup>33</sup>

## Causes of Hemolytic Transfusion Reactions

Hemolytic transfusion reactions usually result from inadvertent administration of incompatible blood components, or the failure to detect a potential incompatibility. Rarely, incompatible blood components are deliberately transfused before ABO-incompatible marrow infusion or when compatible blood cannot be obtained, with an expectation of possible HTR. Among transfusion-related fatalities from acute hemolysis reported to the FDA during 1976 to 1985, 86% were the result of process errors.<sup>33</sup> Among these errors, 10% occurred in phlebotomy and ordering departments, 33% occurred within the blood bank, and 57% occurred during transfusion administration.

These frequencies are similar to reported transfusion errors in New York State, where 22% occurred in phlebotomy and ordering departments, 32% occurred within the blood bank, and 46% occurred during transfusion administration.<sup>36</sup> More recent figures indicate that non-blood-bank errors account for 56%, blood bank errors account for 29%, and compound errors account for the remaining 15% of transfusion errors.<sup>9</sup> In part, differences between the FDA and New York figures are accounted for by the inclusion of nonfatal errors in the latter. Serendipitously, a transfusion error may result in administration of compatible blood components, as occurred in a third of the reported New York State events.

Misidentification of a pretransfusion sample has been termed “wrong blood in tube” (WBIT). A study covering 62 institutions

in 10 countries performed by the Biomedical Excellence for Safer Transfusion Working Party of the International Society for Blood Transfusion has assessed the frequency of WBIT.<sup>38</sup> On the basis of results from over 690,000 samples, it was determined mislabeling occurred in 1 in every 165 samples. Two countries with national patient identification systems, Sweden and Finland, had miscollection rates too low to quantify. Outside these nations, miscollected samples demonstrating WBIT occurred at a median rate of 1 in every 1986 samples. The apparent discrepancy between mislabeling and WBIT is because not all mislabeled tubes are miscollected.

Data on the failure of pretransfusion tests to detect potential incompatibility are scant. This is more likely to be a factor in DHTR than in AHTR. A Mayo Clinic study suggested that at least five of 37 cases (14%) of delayed HTR could have been prevented by improving the sensitivity of red cell antibody screening procedures.<sup>8</sup>

The deliberate, physician-guided administration of incompatible blood components may occur in platelet transfusion, urgent transfusion required in patients with multiple alloantibodies or antibodies to high-incidence antigens, or in marrow transplantation. ABO-incompatible red cells have been successfully administered to patients before major ABO-incompatible marrow transplants in an effort to reduce the titer of isoagglutinins.<sup>39</sup> These patients have predictable, but manageable, reactions. In a retrospective study of 35 patients receiving major ABO-incompatible peripheral blood hematopoietic progenitor cell transplants who were transfused with 1 ABO-incompatible RBC unit, 23 had no clinical reaction, and four had severe reactions necessitating discontinuation of the transfusion.<sup>40</sup> Some patients who have received incompatible transfusions involving non-ABO antibodies were treated with high-dose intravenous immunoglobulin (IVIG) before transfusion and have not experienced HTR.<sup>41</sup>

High levels of anti-A or anti-B in platelet concentrates, particularly apheresis products, can cause acute hemolysis.<sup>42-45</sup> There is considerable variability in the strength of the implicated antibody, but a high-titer isoagglutinin is usually present in donor plasma when hemolysis occurs. A study of apheresis group O platelets found that 26% had anti-A or anti-A,B titer of 64 or greater, a level that has been associated with HTR.<sup>46</sup> A study of pooled whole-blood-derived platelets found 60% of group O pools had anti-A titer at least 64.<sup>47</sup> Repeated platelet transfusions within a brief period can result in sufficient accumulation of anti-A to cause severe acute hemolysis.<sup>48</sup> However, there is no clear consensus as to what constitutes a critical titer of ABO antibodies. At variance with reports of acute hemolysis, apheresis platelet concentrates are often transfused across ABO groups without adverse consequences. In one study 16 patients who received both ABO-compatible and -incompatible platelet concentrates were evaluated for evidence of hemolysis.<sup>49</sup> There was no difference between pre- and posttransfusion hemoglobin levels in 24 paired transfusion episodes.

## Diagnosis

Diagnosis of HTR requires clinical suspicion, especially when the transfusion occurred days to weeks previously. The initial laboratory evaluation includes confirmation of the ABO group, a test for free hemoglobin, and a DAT performed on a postreaction blood specimen (Table 52-2). Visual inspection of the postreaction plasma can detect hemoglobin in the range of 20 to 50 mg/dL, equivalent to the lysis of approximately 10 mL of red cells in an adult.<sup>50</sup> It should be remembered that free serum hemoglobin also may be present in nonimmune hemolysis, red cell fragility syndromes, hemoglobinopathies, severe burns, polyagglutination, or infusion of hemoglobin-based oxygen-carrying solutions. A common cause of a false-positive test result for free hemoglobin is drawing a sample through an indwelling catheter using inappropriate technique. Percutaneous intravascular thromboectomy can cause marked hemoglobinemia.<sup>51</sup> A false-negative test result for free hemoglobin may occur if too much time has been allowed to elapse before obtaining the postreaction specimen.

**Table 52-2.** Laboratory Investigation of Hemolytic Transfusion Reactions

### First-tier investigation

- Posttransfusion serum hemoglobin (qualitative)
- Posttransfusion direct antiglobulin test
- Confirmation of posttransfusion ABO/Rh

### Second-tier investigation

- Repeat pretransfusion ABO/Rh
- Pre- and posttransfusion antibody screen
- Repeat special antigen typing
- Crossmatch with pre- and postreaction specimens

### Third-tier investigation

- Antibody identification panels on pre- and postreaction samples
- Enhanced antibody screening method: PEG, extended incubation, gel, enzymes
- Red cell eluate on pre- and postreaction samples
- Investigation of transfusion technique and blood storage conditions
- Check of the blood bag, tubing, and segments for hemolysis
- Enhanced crossmatches: PEG, enzymes
- Minor crossmatches of implicated units
- Antibody detection tests on donor units
- Tests for polyagglutination
- Hemoglobin electrophoresis
- Quantitative serum hemoglobin
- Serum haptoglobin
- Serum bilirubin (conjugated and unconjugated)
- Urine hemoglobin and hemosiderin
- Bacterial culture and Gram's stain of blood bags
- Serum BUN and creatinine
- Peripheral blood smear
- Serial hemoglobin, hematocrit, and platelet count
- Blood coagulation studies (PT, aPTT, fibrinogen, FDP)
- DAT on donor units

PEG = polyethylene glycol; BUN = blood urea nitrogen; PT = prothrombin time; aPTT = activated partial thromboplastin time; FDP = fibrin degradation product; DAT = direct antiglobulin test.

A low level of free hemoglobin may be difficult to detect in an icteric specimen.

The DAT may be positive because of the effects of drugs, autoimmune disease, or autoantibodies. If the postreaction DAT is positive, then a test should be performed on a stored pre-reaction sample. If the pre-reaction sample is also a positive, then the test is not valid for the purpose of detecting, or excluding, the presence of alloantibody-coated transfused cells and further testing is required. The DAT will be negative if transfused antigen-positive cells have been cleared from circulation. In addition, when small numbers of antibody-coated allogeneic red cells are present, a DAT performed by routine methods may not be sufficiently sensitive. In a study that compared the relative sensitivity of DAT performed with monospecific IgG antiglobulin technique, flow cytometry, and antibody elution, the DAT could detect 10% antibody-coated cells.<sup>52</sup> Antibody could be detected in the eluate of the samples with as little as 1% antibody-coated red cells present, although in some cases it was not nearly as sensitive. Flow cytometry, however, was consistently the most sensitive method with a detection limit of approximately 1%.

The hemoglobin and antiglobulin tests are useful for screening purposes. However, if either of these is positive, or if there is a strong clinical suspicion, then further testing must be performed. At this point, the implicated blood bags with their attached administration sets should be returned to the blood bank, and all units dispensed to the patient should be returned and quarantined. Units that were transfused within the past 24 hours should also be identified. The ABO grouping and Rh typing of both pre- and postreaction blood specimens should be repeated. Care should be taken to look for mixed-field agglutination. The antibody screen should be repeated on both specimens, and any special antigen typing of donor units should be repeated.

Blood from saved segments or recovered bags and tubing of units transfused within 24 hours should be crossmatched against both the pre- and postreaction specimens. This testing should include a 37°C reading and an indirect antiglobulin test. If a large number of units have been transfused in the last 24 hours, the blood bank medical director may elect to substitute reconfirmation of ABO grouping of donor units. Negative results in these investigations usually rule out HTR, except in unusual circumstances.

Other causes of hemolysis or shortened red cell survival that should be considered in the differential diagnosis of HTR are listed in Table 52-3. Nonimmune hemolysis can have a similar clinical presentation to HTR. Lysis of red cells can be caused by overheating in a blood warmer, or by freezing. Hemolysis can also be caused by inadequate removal of glycerol from frozen red cells or by attempting to force blood through a filter or small-bore needle. The transfusion of outdated blood has been reported to cause hemoglobinuria and transient hemodynamic, pulmonary, and renal changes.<sup>53</sup> Transfusion administered with hypotonic solutions or some drugs may also cause hemolysis.<sup>54</sup> Intravenous dimethylsulfoxide infusion has been reported to mimic HTR.<sup>55</sup> In general, patients tolerate the infusion of

hemolyzed blood remarkable well. Often the only sign of an adverse event is hemoglobinuria. However, deaths caused by the transfusion of hemolyzed blood have been reported.<sup>33</sup>

Some hematologic abnormalities, particularly autoimmune hemolytic anemia, can have presentations similar to HTR. Patients with congenital hemolytic anemias, such as glucose-6-phosphate dehydrogenase deficiency, may manifest hemolysis after blood transfusion.<sup>56</sup> Conversely, blood donated by individuals with glucose-6-phosphate dehydrogenase deficiency can cause hemoglobinemia and hyperbilirubinemia in transfusion recipients.<sup>57</sup>

Establishing the diagnosis of HTR may be particularly difficult in patients with liver disease, autoimmune hemolytic anemia, sickle cell anemia, or active bleeding. In chronic liver disease there is often a positive DAT, hyperbilirubinemia, and elevated lactate dehydrogenase (LDH). The clinical and laboratory presentation of AIHA may be identical to HTR. Concern has been raised that transfusion may aggravate hemolysis in

**Table 52-3.** Differential Diagnosis of Hemolytic Transfusion Reactions

- 
- Alloantibody-induced hemolysis
  - Delayed serologic transfusion reaction
  - Autoimmune hemolytic anemia
  - Cold hemagglutinin disease
  - Nonimmune hemolysis
    - Incompatible fluids
    - Improper storage
    - Malfunctioning blood warmer
    - Small needles, high hematocrit
    - Improper deglycerolization
    - Infusion pumps
    - Bacterial contamination
    - Mechanical thrombectomy
  - Hemolytic anemia
    - G6PD deficiency
    - Congenital spherocytic anemia
  - Hemoglobinopathies
    - Sickle cell disease
    - Sickle cell transfusion reaction syndrome
  - Drug-induced hemolysis
  - Microangiopathic hemolytic anemias
    - Thrombotic thrombocytopenic purpura
    - Hemolytic uremic syndrome
    - HELLP syndrome
  - Bleeding
  - Artificial heart valve dysfunction
  - Paroxysmal nocturnal hemoglobinuria
  - Polyagglutination
  - Infections
    - *Clostridium perfringens*
    - Malaria
    - Babesiosis
- 

G6PD = glucose-6-phosphate dehydrogenase; HELLP = hemolysis, elevated liver enzymes, and low platelet count.

AIHA, although one published study has suggested that this is not usually the case even in the face of serologic incompatibility.<sup>58</sup> Characteristically, in both bleeding and AIHA there is proportionate loss of both autologous and transfused red cells. One indication of HTR in these settings is the persistence of transfused red cells that lack the implicated antigen, but the absence of transfused cells bearing the antigen.

Resorption of a hematoma can have manifestations very similar to extravascular HTR. Such patients have an unconjugated hyperbilirubinemia, elevated LDH, and depressed haptoglobin levels. In addition, the presence in the serum of fibrin degradation products (FDPs) from the hematoma may be confused with DIC. In these patients, as in bleeding patients, persistent circulating antigen-positive red cells and a negative posttransfusion DAT are evidence against the diagnosis of HTR.

The serologic specificity of a red cell antibody is an indication of its clinical significance. However, there is not an absolute correlation between specificity and presence or absence of red cell destruction. The general clinical significance of many red cell antibody specificities is summarized in Table 52-4.

## Pathophysiology

The pathophysiologic mechanisms involved in HTR are not well understood. There are essentially three phases: antibody-antigen interaction, phagocytosis and inflammatory cell activation, and systemic response. Initially, there is a binding of antibody to red cell antigens, which can result in complement activation. Second, immunoglobulin- and complement-coated cells interact with phagocytes, resulting in clearance of red cells and activation of phagocytes. Third, the inflammatory mediators produced in the first two phases act on a variety of cell types, causing a clinical manifestations of HTR.

The course of immune hemolysis is determined by antigen site density, immunoglobulin class of the alloantibody, and activation of complement. ABO antigens are present in high numbers on a red cell surface, approximately  $5 \times 10^5$  per cell.<sup>50</sup> In contrast, there are  $10^3$  to  $10^4$  antigens per cell in the Rh, Kell, Kidd, and Duffy systems. Complement fixation is facilitated by close proximity of antigens that allows bridging of IgG molecules by C1q. However, IgM antibodies can fix complement without a requirement for bridging between molecules. IgM antibodies are common in the ABO system, but relatively unusual as alloantibodies to other antigens. Activation of the classical pathway of complement proceeds from C1q binding through C3 activation. Cleavage of C3 results in C3a liberation into circulation and C3b deposition on the red cell membrane. Activated C3 may then cleave C5 with release of C5a. Assembly of the membrane attack complex then may proceed with resultant intravascular hemolysis. Factor I, also known as C3b inactivator, is the major regulator of C3b activity. Cleavage of membrane-bound C3b by factor I results in the generation of iC3b and release of the small peptide fragment C3c. This terminates the complement cascade

because iC3b is enzymatically inactive. iC3b is further degraded into C3dg and C3d by factor I and trypsin-like proteinases.

Erythrophagocytosis results from interaction of immunoglobulin- and/or complement-coated red cells with phagocyte receptors. Cell-bound antibodies promote red cell clearance primarily through interaction of the Fc portion of IgG with specific receptors. Among the IgG receptors, Fc $\gamma$ RI principally mediates red cell phagocytosis by monocytes.<sup>59</sup> However, this receptor has a high affinity for monomeric IgG, and is blocked by normal serum concentrations of IgG.<sup>60</sup> Fc $\gamma$ RIII appears to be the most important IgG receptor on splenic macrophages in alloimmune and autoimmune red cell clearance, as well as in autoimmune thrombocytopenia.<sup>61-63</sup> The principal complement receptor expressed by macrophages and monocytes, CR3, primarily recognizes iC3b. Receptors for C3a and C5a are present on a wide variety of cells including monocytes, macrophages, neutrophils, platelets, endothelium, and smooth muscle. The physiologic

\*Resulting in hemolytic transfusion reaction or decreased red cell survival.

effects of C3a and C5a include oxygen radical production, granule enzyme release, leukotriene production, NO production, and cytokine production. These low-molecular-weight peptides can also produce vasodilation and bronchoconstriction.

Ligation of phagocyte receptors results in cellular activation and production of inflammatory response factors. An experimental model of ABO incompatibility has suggested that monocytes are the leukocyte subpopulation most directly involved in AHTR.<sup>64</sup> Incompatible red cells induce a reduction in CD14 and increase in CD44 expression on monocytes in whole blood. After 24 hours incubation with incompatible red cells, monocytes showed particularly high levels of CD44. These data demonstrate that monocyte activation is critical in the development of intravascular HTR.

Immune hemolysis stimulates the production of a variety of cytokines that are crucial to the initiation, maintenance, and ultimate resolution of HTR (Table 52-5). ABO incompatibility with intravascular HTR strongly stimulates production of TNF- $\alpha$  and the chemokines CXCL8 (IL-8) and CCL2 (MCP-1).<sup>65-68</sup> TNF- $\alpha$  is an early response, appearing in plasma within 2 hours, and has potent proinflammatory effects, including pyrogenic activity, leukocyte activation, stimulation of procoagulant activity, and expression of a large number of gene products related to the inflammatory response. TNF- $\alpha$  produced in blood during ABO incompatibility will stimulate endothelial cells to express leukocyte adhesion molecules, chemotactic cytokines, and

procoagulant activity.<sup>69</sup> CXCL8 and CCL2 produced in blood during ABO incompatibility appear later than TNF- $\alpha$  and reach very high levels. CXCL8 primarily activates neutrophils to undergo the respiratory burst, release granule contents and alter surface adhesion molecules.<sup>70</sup> CCL2 is primarily a chemotactic and activating factor for monocytes.<sup>71</sup>

There is also evidence for the production of cytokines in IgG-mediated extravascular hemolysis.<sup>72,73</sup> There appear to be two categories of cytokine responses in this setting: those produced at high levels (greater than 1 ng/mL by 24 hours), and others produced at lower level (in the range of 100 pg/mL).<sup>72</sup> Low-level cytokine responses include IL-1 $\beta$ , IL-6, and TNF- $\alpha$ . CXCL8 is a high-level response with a time course similar to that of ABO incompatibility. In contrast to the setting of ABO incompatibility, TNF- $\alpha$  is produced in a delayed fashion in response to IgG-coated red cells, achieving a level of less than 100 pg/mL. However, cell-associated TNF- $\alpha$  can be demonstrated by immunocytochemical staining in monocytes engaged in erythrophagocytosis.

While the in-vitro models employed in these studies are not directly comparable, these findings do suggest a possible reason for the clinical differences between intravascular and extravascular HTRs. In the former case, TNF- $\alpha$  is released into systemic circulation where it can have diverse effects on many cell types; in the latter case, TNF- $\alpha$  effects may be confined to the site of erythrophagocytosis, primarily the spleen. Both IL-1 $\beta$  and IL-6 produced by monocytes in response to IgG-coated red cells increase progressively over 24 hours to levels approximating 100 pg/mL. Because IL-1 $\beta$  and IL-6 are B-cell growth and differentiation factors, the production of these two cytokines promotes the production of red cell allo- and autoantibodies that are often associated with DHTRs.

IgG-mediated hemolysis also results in the production of the IL-1 $\beta$  inhibitor IL-1ra.<sup>74</sup> Significant levels of IL-1ra appear in a parallel fashion to IL-1 $\beta$ . Immunocytochemical staining has demonstrated strong reactivity for IL-1ra in monocytes engaged in erythrophagocytosis. Northern blot analysis of mononuclear cell RNA shows that IL-1 $\beta$  gene expression precedes that of IL-1ra in response to IgG-coated red cells. However, neutralizing antibodies to IL-1 $\beta$  do not suppress either IL-1ra or IL-1 $\beta$  gene expression in this setting. Therefore, it appears that IL-1ra production is a primary response to the IgG-coated red cell stimulus, rather than an autocrine phenomenon induced by initial IL-1 $\beta$  production. Treatment of mononuclear cells with the steroid dexamethasone inhibits IL-1ra production in response to IgG-coated red cells. These data suggest the possibility that the clinical variability of DHTR, and some of the clinical differences from intravascular HTR, may be accounted for, in part, by the relative balance of IL-1 $\beta$  and IL-1ra production.

Labile blood pressure is a feature of severe HTR, particularly with intravascular hemolysis. Both complement activation products such as C5a and cytokines such as IL-1 $\beta$  and TNF- $\alpha$  can contribute to hypotension. The common pathway of these mediators is the production of NO by endothelial cells. NO, in

turn, causes relaxation of vascular smooth muscle. Hypotension and deposition of thrombi in arterioles, which impair cortical blood flow, are the major factors that contribute to renal failure. In addition, there may be direct effects of inflammatory mediators on the kidneys.

There are several mechanisms by which HTR results in intravascular coagulation. TNF- $\alpha$  produced during immune hemolysis can induce tissue factor expression by endothelial cells.<sup>69</sup> Tissue factor is an initiator of the extrinsic pathway that functions as a cofactor for Factors VII and VIIa to accelerate the activation of Factors IX and X. TNF- $\alpha$  and IL-1 $\beta$ , acting on endothelial cells, will also decrease the cell surface expression of thrombomodulin. Thrombomodulin is normally present on endothelial cells, and binds thrombin to activate the coagulation inhibitor protein C. Intravascular hemolysis, as in ABO incompatibility, will also induce procoagulant activity in blood leukocytes, largely because of tissue factor expression.<sup>74</sup> This cellular procoagulant is partly inhibited by blocking antibodies to tissue factor and partly dependent of the multifunctional adhesion protein CD11b.

Knowledge of the pathophysiology of HTR has been limited by the lack of good animal models. However, a recently developed model using transgenic mice expressing human glyophorin A holds promise.<sup>75</sup> Administration of IgM and IgG anti-GPA results in intravascular or extravascular hemolysis, respectively. Dependence on active complement and Fc $\gamma$  receptors has been shown.

## Therapy

Patients who have minimal symptoms are best managed by careful observation. However, early vigorous intervention in severe reactions saves lives. Therapeutic options in HTR are

summarized in Table 52-6. The severity of HTR is directly related to volume and rate of infusion of incompatible blood. Thus, early recognition, stopping transfusion, and preventing the transfusion of additional incompatible units is the first essential step of treatment. Initial attention must be paid to cardiovascular support. If hypotension is present, fluid resuscitation and pressor support should be considered. Care should be taken to avoid fluid overload, however, especially in patients with impaired cardiac or renal function. Pulmonary artery catheterization is useful in selected patients to guide resuscitation.

Because intravascular hemolysis is an expected consequence of the infusion of ABO-incompatible marrow, some guidance can be obtained from published reports. Isoagglutinin titer clearly influences the clinical response to ABO-incompatible marrow infusion. In general, antibody titers below 64 are associated with mild or no reactions while high titers such as 1024 are associated with significant clinical reactions. The volume of incompatible red cells infused with the marrow also determines the magnitude of the response. One protocol reported to be successful in patients receiving major ABO-incompatible transplants involved preparatory hydration with 5% dextrose in one-half normal saline with 30 to 40 mEq sodium bicarbonate/L and 15 mEq potassium chloride/L at a rate of 3000 mL/m<sup>2</sup>/day, and 100 mL/m<sup>2</sup>. Mannitol 20% was given 1 hour before marrow infusion.<sup>76</sup> During marrow infusion, the infusion rate of fluids was increased to 4500 to 6000 mL/m<sup>2</sup>/day and additional mannitol was given at a rate of 30 mL/m<sup>2</sup>/hour for the next 12 hours. The rationale for this protocol was to maintain a high rate of urine output and prevent precipitation of hemoglobin in the renal tubules. All these patients had a preinfusion antibody titer no greater than 32. None experienced a clinical reaction to the infusion of approximately 120 to 160 mL of incompatible red cells.

The deliberate transfusion of ABO-incompatible red cells before transplantation has been employed to reduce

<sup>†</sup>Investigational. Not standard therapy.

isoagglutinin titers. In one such protocol, 1 incompatible RBC unit was given over 8 hours on each of 2 days immediately before transplant.<sup>39</sup> These patients were monitored in an intensive care unit and hydrated with normal saline and 5% dextrose (1:1 ratio) at a rate of 3000 mL/m<sup>2</sup>/day. Sodium bicarbonate was administered to maintain the urine pH above 7.0. Of the 12 patients reported in this series, isoagglutinin titers before transfusion ranged from 32 to 1024. One patient developed renal failure requiring hemodialysis for 17 days, but this resolved. In another series of deliberate administration of ABO-incompatible red cells, 35 patients received 50 to 150 mL of incompatible red cells before marrow transplantation.<sup>40</sup> All patients received prednisolone 250 mg, dimethindene 4 mg, and ranitidine 150 mg 30 minutes before the transfusion. No clinical reaction was observed in 23 patients (66%), while severe reactions (chest pain, headache or agues, and/or high changes of heart rate, blood pressure, and/or oxygen saturation) occurred in 4 patients (11%). The highest pretransfusion titer in this series was 64.

Because the severity and course of HTR is dictated by the load of incompatible red cells in circulation, exchange transfusion with antigen-negative blood may be considered. Although it is not appropriate to expose a patient to added risk of transfusion-related infectious disease if the hemolytic process is well tolerated, with a severe reaction to ABO incompatibility exchange transfusion might greatly reduce the chance of morbidity or death.

Early treatment of hypotension and DIC are the most important interventions to limit the extent of possible renal impairment. Maintenance of urine output with intravenous fluids and diuretics, such as mannitol or furosemide, early in the course of the reaction has been used successfully. However, if oliguria in the face of normovolemia is present, fluid loading is contraindicated. The use of vasopressor agents with direct vasodilatory effects on the renal vascular bed, such as low-dose dopamine (1–5 µg/kg/min) has been suggested, but is controversial.<sup>77,78</sup>

The prevention and treatment of DIC is also controversial. Heparin has been advocated by some authors as a treatment for DIC.<sup>79</sup> In addition, heparin may have a direct anticomplement effect, which limits intravascular hemolysis and the sequelae of complement activation.<sup>80</sup> An obvious drawback of heparin therapy, especially in the intraoperative or postoperative patient, is the potential for hemorrhage. Therefore, heparin should be reserved for patients with clear evidence of intravascular coagulation (thrombocytopenia, hypofibrinogenemia, presence of FDPs and D-dimers). The use of Fresh Frozen Plasma or platelet concentrates in DIC is also controversial, and transfusion of these components should be limited to those patients with active hemorrhage.

Most extravascular HTRs are not life-threatening and require no acute treatment. However, some patients with extravascular HTR may benefit from intravenous immunoglobulin (IVIG) infusion. A single dose of IVIG, 400 mg/kg infused within 24 hours of transfusion, has been used successfully to prevent transfusion reactions in alloimmunized patients for whom compatible

blood was not obtainable.<sup>41,81</sup> Five patients so treated did not experience transfusion reactions and had sustained increases in hematocrit. IVIG, 1 g/kg or 400 mg/kg, has also been used in the treatment of sickle cell HTR syndrome.<sup>82,83</sup>

The selection of blood components for a hemorrhaging patient undergoing HTR is a critical decision. The first consideration is that no patient should be allowed to suffer a fatal hemorrhage while a search for serologically compatible blood is undertaken. Second, red cells lacking known clinically significant antigens to which the patient currently has an antibody should be obtained, if at all possible. For instance, one should not reflexively issue group O-negative red cells to a patient known to have anti-e. When the specificity of the antibody causing the reaction is not known, the results of serologic tests performed up to that point in time must be considered, and clinical judgment exercised. Although the focus of attention in most HTRs is on red cells, care should be taken to avoid transfusion of type-incompatible plasma or platelets that may aggravate hemolysis, especially when ABO incompatibility is a possible cause. Undue haste in both serologic evaluation and decision making must be avoided, because human errors are often committed under pressure.

Future therapies that have not yet been subjected to clinical trials might be directed against inflammatory mediators produced during HTRs. HTRs have a similar clinical presentation to the systemic inflammatory response syndrome (SIRS) (eg, fever, tachycardia, tachypnea or hypoxemia, and leukocytosis).<sup>84</sup> Cytokine dysregulation is central to the pathophysiology of SIRS, in which elevated levels of TNF-α, IL-1, and IL-6 are associated with mortality.<sup>85,86</sup> These considerations suggest that TNF-α or IL-1 blockade may be beneficial in the treatment of HTR. Presently, there are three TNF-α blocking agents marketed in the United States; etanercept (Enbrel, Amgen, Thousand Oaks, CA), a soluble p75 TNF-α receptor fusion protein to the Fc portion of IgG; infliximab (Remicade, Centocor, Malvern, PA), a chimeric (mouse/human) TNF-α antibody; and adalimumab (Humira, Abbott Laboratories, Abbott Park, IL), a fully human monoclonal antibody. Anakinra (Kineret, Amgen) is recombinant human IL-1ra, which is also approved by the FDA. Unfortunately, clinical trials of these agents in SIRS have been rather disappointing, with most trials not showing improved outcome. Inhibitors of complement show promise in the treatment of HTR. Human recombinant soluble form of complement receptor 1 (sCR1) has been shown to inhibit complement-mediated red cell destruction in vitro and in a mouse model of hemolysis.<sup>87</sup> It should be noted that there are no data at present regarding the safety or effectiveness of drugs that inhibit complement or cytokines in HTR.

## Prevention

Much of the activity in blood banks is directed toward the prevention of HTRs. Proper performance of donor unit typing, pretransfusion testing, antibody identification, and crossmatching are critical and are covered in Chapter 5.

Because human errors are the most common cause of severe HTR, administrative systems designed to analyze errors and prevent future recurrence are the most important protective measure. An event reporting system specifically designed for transfusion services, MERS-TM, has been developed.<sup>88</sup> It allows for the recognition and analysis of errors, determination of patterns of errors, and monitoring for changes in frequency after corrective action is implemented. In one application of MERS-TM, high severity events with the potential for patient harm were discovered to account for 241 (5%) of the 4670 events over a 47-month period.<sup>89</sup>

Proper identification of the transfusion recipient and pretransfusion blood specimen is the single most important aspect of the prevention of HTR. Every transfusion service must establish and enforce the procedures to be followed in its institution. At a minimum, these procedures should include permanent and unique identification of each patient using a permanent identification method such as a wristband, confirmation of the proper labeling of blood specimens by comparison to the wristband, and confirmation of the patient identification before starting the transfusion. Deviation from institutional policies on patient and specimen identification should be taken very seriously.

Because proper identification of the transfusion recipient is crucial to preventing HTRs, barrier systems that are intended to physically prevent the transfusion of blood without correct identification of the patient have been devised. One such system uses a plastic lock that is preset to a three-letter code at the time of blood component issuance by the blood bank. Before the unit can be administered, the identical code must be entered to unlock the system. Use of this system in one hospital over the course of 1 year detected two misidentified pretransfusion blood samples, and prevented one attempt to transfuse blood to the wrong patient.<sup>90</sup> Use of a special wristband for identification of transfusion recipients may prevent some errors. Such systems generally have a unique identifier on the wristband that is only used by the blood bank. A report of the use of one system over a period of 17 years found that potentially ABO-incompatible transfusions were avoided in five of 411,705 samples typed.<sup>91</sup> A report of the use of another identification system found that of 2198 cases, two potentially ABO-incompatible transfusions were avoided.<sup>92</sup> An alternative system uses bar codes on patient wristbands, blood sample tubes, blood component bags, and nurses' identification badges; and point-of-care reading devices to verify identity.<sup>93</sup> Radio frequency identification devices also have great promise for reduction error. These tools require investment in information technology, but can be integrated with other systems, such as medication administration, for overall enhancement of patient safety. However, sole reliance on such a device to prevent incorrect administration of blood may undermine other more important steps in proper patient identification.

Confirmation of the recipient's ABO type by point-of-care testing before transfusion is a possible strategy for avoiding AHTR. In principle, seven out of eight ABO-incompatible transfusions could be thus avoided. However, bedside testing is subject

to analytic and interpretive errors. At one institution performing bedside ABO confirmation, 13 ABO-incompatible RBC transfusions occurred in 8 years.<sup>94</sup> Of these, an error in bedside ABO testing occurred in seven cases. User inexperience is the most important factor in bedside testing errors, although there are device factors as well.<sup>95</sup>

In situations where patient identification error has caused HTR, immediate consideration should be given to the possibility that another patient has been involved in the misidentification, and may, too, be at risk of receiving incompatible blood. This is especially likely if there are two patients with similar names or if two samples are received simultaneously from the same patient care location. Identification of such errors can prevent a second hemolytic reaction.

The selection of donor units lacking antigens corresponding to alloantibodies is essential for the prevention of HTR, but whether phenotype matching of donors and recipients is an appropriate strategy for the prevention of alloimmunization and HTR in the nonimmunized patient is controversial. Arguments in favor of this practice have been put forth in the setting of sickle cell disease where, because of ethnic gene pool diversity, there is often a mismatch between the donor and recipient phenotypes. Examination of alloimmunization rates among children in one urban area indicated that children with non-European ethnic origins had a 42.9% incidence of alloimmunization compared to 17.6% in patients of European ancestry.<sup>96</sup> This was not simply caused by variation in transfusion rates, because the patients of European ethnicity received more transfusions than the others. In another study that compared sickle cell patients to those with other forms of chronic anemia, 30% of the patients with sickle cell anemia were alloimmunized, in contrast to 5% in the group of patients with other forms of anemia.<sup>97</sup> Of the 32 alloimmunized patients with sickle cell anemia, 17 had multiple antibodies and 14 had DHTRs. Although many institutions have not performed phenotype matching for sickle cell patients in the past, it is becoming commonly accepted practice.<sup>98,99</sup>

Phenotype matching may possibly prevent some HTRs in other multitransfused patient populations. In a retrospective study of patients with at least one red cell antibody who received subsequent transfusions, 21% of 653 patients produced additional antibodies.<sup>100</sup> Patients with hematologic disease or malignancy, warm-reacting autoantibodies, antibodies to high- or low-frequency antigens, and those receiving prophylactic antigen matching were excluded. Of those who formed additional antibodies, 57% did so after one transfusion episode of a median of 2 RBC units. The authors predicted that matching for Rh, Jk<sup>a</sup>, and Fy<sup>a</sup> could have prevented the formation of 83% of new antibodies. However, whether prevention of serologic reactions will prevent hemolytic reactions is not clear. In this study, 1% to 10% of potential donors would have been available for 3% of patients and more than 10% of potential donors would have been available for 61% of patients, had phenotype matching been performed. However, the frequency of suitable donors may be different in other locations.

Hemolytic transfusion reactions could be avoided entirely if the responsible antigens on the red cell surface could be removed or camouflaged. Experimental work has suggested that treating red cells with polyethylene glycol (PEG) might be an effective means of camouflaging antigens.<sup>101</sup> PEG modification appears to work by creating a sphere of hydration around the red cell that effectively excludes IgG or IgM from coming into contact with antigenic structures on the membrane surface. PEG-treated red cells have properties of size, shape, intracellular ion content, and oxygen binding that are identical to untreated red cells. However, PEG-treated red cells have a low shear viscosity compared to normal red cells. This also may be advantageous in sickle cell disease in which increased blood viscosity within capillaries can result in occlusive crises.

The effectiveness of PEG modification is dependent on the molecular weight and branching characteristics of PEG molecules and the chemistry of covalent attachment.<sup>102</sup> Use of a dichlorotriazine derivative of 5-kD PEG results in complete inhibition of direct agglutination by anti-D. However, such cells are still agglutinated by anti-D in the indirect antiglobulin test. A and B epitopes are partially, but not completely, masked. In contrast, red cells coated with branched chain 10-kD PEG after treatment with succinimidyl-propionate-modified 20-kD PEG are not agglutinated by anti-A, anti-B, and anti-D. Treatment of red cells with maleimidophenyl-PEG 5kD and 20kD can inhibit agglutination by Rh and ABO antibodies.<sup>103</sup> However, preliminary data from human trials with PEG-treated red cells have shown that antibodies to the modified red cells resulting in accelerated clearance occur in some recipients, which may significantly limit the usefulness of this technique (G. Garratty, personal communication).

Group A and group B red cells can be converted to group O cells by enzymatic cleavage of terminal determinant saccharides with  $\alpha$ -N-acetylgalactosaminidase or  $\alpha$ -D-galactosidase.<sup>104-106</sup> The use of such technology for large-scale conversion of red cells raises the possibility that acute HTRs from ABO incompatibility may be completely avoidable in the future. However, there are issues with regard to completeness of antigen removal and the possibility of exposure of neoantigens by enzymatic treatment. Treatment of red cells with  $\alpha$ -N-acetylgalactosaminidase results in rapid loss of A epitopes binding *Dolichos biflorus* lectin.<sup>104</sup> Inhibition of complement-mediated hemolysis is somewhat slower. However, the epitopes of A antigen that react with human source anti-A are relatively resistant to enzymatic degradation. Additionally, there are differences in the enzymatic sensitivity of A epitopes on the red cell membrane. Glycosphingolipids with short oligosaccharide chains display the greatest resistance to enzymatic treatment.

Work on enzyme-converted group O (ECO) red cells from group B red cells has advanced to the stage of the clinical trials.<sup>107,108</sup> An initial trial of a 2-unit transfusion of ECO RBCs to group O subjects demonstrated good 24-hour posttransfusion survival (95%), with a half-life of 29.5 days.<sup>107</sup> There was no clinical or laboratory evidence of hemolysis. A subsequent study

with larger volume transfusions had similar results. Subjects who received a second transfusion did not show evidence of alloimmunization or increase in anti-B titer.<sup>108</sup> In another study, occasional serologic incompatibility with enzyme-converted red cells was seen, as well as transient positive DAT and increases in anti-B titer after transfusion. However, no adverse effects of whole unit transfusion were seen, and normal posttransfusion red cell survival was demonstrated in the face of incompatibility.<sup>109</sup> A screening technique has recently been used to discover several novel exoglycosidases with high specific activity for the removal of A and B determinants at neutral pH.<sup>110</sup> Complete conversion of whole RBC units from group A and group B to group O, as indicated by no reactivity with licensed typing reagents, was achieved with low enzyme concentrations. Although this technique has not yet been subjected to clinical trials, it is promising as a feasible method of ECO production on a clinical scale.

---

## Summary

Although the prevention of HTRs continues to be a major focus in transfusion medicine, advances in serology and transfusion service practices have significantly reduced their incidence. Simultaneously, advances in the understanding of the pathophysiology of HTRs have given us insights to help guide the management of patients undergoing reactions. It is conceivable that technological advances in red cell modification and oxygen-carrying solutions will significantly change red cell transfusion practice in the future and virtually eliminate the occurrence of HTR. Until such time, however, HTRs will remain a major adverse consequence of blood transfusion.

# Febrile, Allergic, and Nonimmune Transfusion Reactions

**Gregory J. Pomper**

Assistant Professor of Pathology, Department of Pathology, Wake Forest University School of Medicine, Winston-Salem, North Carolina, USA

This chapter reviews a variety of acute, nonhemolytic, and non-infectious transfusion reactions, the most common of which are febrile, nonhemolytic transfusion reactions (FNHTRs) and allergic reactions. Other acute, nonhemolytic reactions are reported less frequently and include transfusion-related acute lung injury (TRALI) and anaphylactic or anaphylactoid reactions. Additional acute adverse effects can occur in massive transfusion because of the large volume of blood components transfused over a short period. The complications of massive transfusion include dilutional coagulopathy, hypothermia, citrate toxicity, and electrolyte disturbances among others. Some patients cannot tolerate the acute increase in intravascular blood volume caused by transfusion and experience the complications of transfusion-associated circulatory overload (TACO). Acute reactions can be caused by the toxicity of chemicals that leach into blood components from blood storage containers or filters or by chemicals added to improve storage conditions, such as dimethyl sulfoxide (DMSO). Other reactions are caused by endogenous mediators generated in the blood during filtration, processing, or storage, such as bradykinin-mediated hypotensive reactions. It is important that these complications of transfusion be recognized by patient care teams and blood bank personnel, and that appropriate treatments and preventive measures be instituted for patient safety and well-being.

## Febrile Nonhemolytic Transfusion Reactions

### Description

An FNHTR is commonly defined as an increase in body temperature of 1°C or more that occurs during or within several hours of transfusion and is unrelated to hemolysis, sepsis, or other known causes of fever. The use of a 1°C increase in body

temperature as a threshold for defining an FNHTR avoids undue concern over small fluctuations in body temperature unrelated to transfusion that do not justify discontinuation of transfusion and follow-up investigation. Many FNHTRs begin with the patient feeling uneasy and experiencing chills. In mild reactions, the signs and symptoms do not progress. Chills with or without an increase in body temperature can be classified as an FNHTR if other possible causes of chills are unlikely and the time course of the reaction correlates with the transfusion. In the most severe reactions, patients may experience rigors (severe shaking chills) or a fever elevation of 2°C or more over baseline. Although signs and symptoms usually are limited to chills and fever, some patients may also rarely experience more severe symptoms such as headache, nausea, and/or vomiting.

The fever of FNHTR usually persists no more than 8 to 12 hours after the start of transfusion. If fever persists 18 to 24 hours or longer, it is unlikely to be transfusion related. Generally, FNHTRs are self-limited and have no sequelae. However, elderly patients, patients with compromised cardiovascular status, or critically ill patients are at risk of cardiorespiratory complications associated with FNHTR. Because fever increases oxygen demand and consumption an estimated 13% for every 1°C over 37°C and shivering increases oxygen demand approximately 300%, FNHTRs can aggravate preexisting cardiac, pulmonary, and cerebrovascular insufficiency. Therefore, prompt recognition and antipyretic management of FNHTRs can be very beneficial.

An FNHTR almost always is associated with transfusion of cellular blood components, such as red cells, platelets, and granulocyte preparations and less commonly with noncellular components, such as plasma and cryoprecipitate. The incidence of FNHTR varies widely and median rates have been reported as higher for platelets (4.6%) than for red cells (0.33%).<sup>1</sup> The reaction risk of blood components, however, varies according to numerous factors, such as method of preparation of the blood component (eg, leukocyte reduction, storage time, medications, patient and donor characteristics, monitoring practices, and many others). These factors vary among different geographic regions and medical centers. In addition, rates based on reactions

*Rossi's Principles of Transfusion Medicine, 4th edn.* Edited by T. L. Simon, E. L. Snyder, B. G. Solheim, C. P. Stowell, R. G. Strauss and M. Petrides. © 2009 AABB published by Blackwell Publishing, ISBN: 978-1-4051-7588-3.

reported to blood banks are lower than those based on systematic surveillance of responses to all transfusions.

The cause of higher FNHTR reaction rates with platelets is not entirely known. Pools of whole-blood-derived concentrates have been reported to cause a higher rate of FNHTR than apheresis platelets.<sup>2,3</sup> Platelet concentrates prepared from platelet-rich plasma are commonly used in the United States. These platelet-rich plasma concentrates are reported to cause a higher rate of FNHTR than are platelet concentrates prepared from the buffy-coat technique. Longer platelet storage times are also associated with higher rates of FNHTR.<sup>4-6</sup> Reactions also are more frequent among certain recipients, such as multitransfused patients or multiparous women who have developed leukocyte or platelet alloantibodies.

### Etiology

An FNHTR appears to be part of the systemic inflammatory response syndrome (SIRS) provoked in transfusion recipients by the immune challenge of transfusing foreign cells or infusing soluble inflammatory mediators present in stored blood components. The term *systemic inflammatory response syndrome* was coined to describe the constellation of observed body responses to various insults, such as infection, trauma, burns, and ischemia. It is defined as the presence of two or more of the following: body temperature more than 38°C or less than 36°C; heart rate more than 90 beats/minute; tachypnea (respiratory rate >20 breaths/minute or PaCO<sub>2</sub> less than 32 mm Hg); white cell count more than 12,000/μL or less than  $4 \times 10^9/L$ , or more than 10% immature neutrophils (band forms). Although a mild FNHTR may not completely fulfill these criteria, FNHTR is nevertheless an inflammatory response.

Exogenous pyrogens such as lipopolysaccharide (LPS) and pyrogenic cytokines initiate a series of responses leading to hyperthermia. These responses include rapid muscle contractions that cause shivering, rigors, and an increase in heat generation. Heat conservation is achieved through cutaneous vasoconstriction, which also contributes to the sensation of a chill. Perceived chills lead to behavioral changes that can further increase body temperature. For example, the patient may cover up, and the result is inhibition of heat dissipation.

An FNHTR appears to have two possible underlying causes: 1) the more “classical” pathway of infused antigens, such as leukocytes, that stimulate the in-vivo generation of cytokines in the recipient and 2) the infusion of pyrogenic cytokines or other inflammatory response mediators (eg, activated complement proteins, LPS, or neutrophil-priming lipids) that accumulate in the plasma portion of cellular blood components during storage.<sup>7,8</sup> A third cause of fever, infusion of blood components contaminated with bacteria or bacterial products, will produce a febrile response but is not usually categorized as a FNHTR but rather as a bacterial septic reaction, if recognized. The common pathway by which these different stimuli induce posttransfusion fever has been attributed to an increase in circulating pyrogenic cytokines in the recipient, such as interleukin-1β (IL-1β),

IL-6, and tumor necrosis factor α (TNF-α). Pyrogenic cytokines induce fever by mediating upregulation of the thermostatic set point for body temperature in the thermoregulatory center of the hypothalamus. This mechanism is supported by the association of febrile reactions with a specific cytokine polymorphism *IL1RN\*2.2* genotype.<sup>9</sup>

Recently, research has lead investigators to a more complex model of fever generation, building on a model where cytokines principally induce fever to one where central nervous system stimulation by prostaglandin E2 (PGE2) is pivotal. Alternative hypotheses have resulted from the finding that a febrile response to LPS occurs even with blockade of either IL-1 or TNF-α and that the presence of circulating cytokines lags behind the development of fever.<sup>10</sup> Research has found that LPS-induced C5a production via complement activation results in rapid peripheral PGE2 production.<sup>11</sup> In addition, LPS binds to toll-like receptor 4 and induces cytokine production, leading to a two-phase rapid and delayed febrile response. Hyperthermic stimuli compete with hypothermic stimuli to achieve a central thermal balance point that may elevate or decrease based upon physiologic stimuli.<sup>12</sup> Central to the febrile response is the presence of EP3 prostaglandin receptors that bind PGE2 in the hypothalamus (Fig 53-1).<sup>13</sup> These newer models of the fever response provide possible explanations for why FNHTRs continue to occur despite prestorage leukocyte reduction that minimizes cytokine accumulation in storage. Clinical evidence supports the hypothesis that febrile reactions can be caused by noncytokine hyperthermic stimuli present in cellular transfusion products.<sup>14</sup> The active field of febrile response research shows promise for the development of more targeted antipyretic medications that may eventually lead to the extinction of FNHTRs.

### Alloimmunization to Leukocytes or Platelets

Transfusion recipients at greatest risk of an FNHTR are those with leukocyte or platelet antibodies who receive transfusions with blood components containing large numbers of passenger leukocytes or platelets.<sup>15,16</sup> Less frequently, donor antibodies to leukocytes, present in the plasma portion of blood components, are associated with FNHTRs. The implicated antibodies most often have HLA specificity, although they also may be platelet- or granulocyte-specific. A minimum of approximately  $1 \times 10^7$  leukocytes per unit of Red Blood Cells (RBCs) appears necessary to cause an FNHTR, although this number varies among individuals.<sup>17,18</sup> The role of donor leukocytes in FNHTR is supported by the finding that decreasing the leukocyte content of blood components below this threshold reduces the incidence of FNHTRs.

A variety of mechanisms are possible by which antibody-leukocyte or antibody-platelet interactions cause fever. For example, donor monocytes may be activated and secrete pyrogenic cytokines when recipient antibodies bind to them. An alternative explanation is that immune complex formation between recipient antibodies and donor leukocytes or platelets leads to generation of activated complement components such as C5a, which stimulate the production of PGE2.

**Figure 53-1.** A model for neuronal action of the EP3 receptors (EP3Rs) in the fever response after systemic immune challenge. In response to lipopolysaccharides or cytokines, prostaglandin E2 (PGE2) is generated by macrophages of the liver and lung and endothelial cells lining venules in the brain. PGE2 is transported or diffuses across the blood-brain barrier and acts on EP3Rs in the median preoptic area (MnPO). These are hypothesized to be GABAergic

neurons that inhibit thermogenic systems in the hypothalamic paraventricular nucleus (PVH), the dorsomedial nucleus/dorsal area (DMH/DHA), and the raphe pallidus nucleus in the medulla (RPa). These thermogenic nuclei activate sympathetic preganglionic neurons in the spinal cord, resulting in cutaneous vasoconstriction and activation of brown adipose tissue that ultimately raise body temperature. Used with permission from Lazarus et al.<sup>13</sup>

### Storage-Generated Cytokines

Antibodies to leukocytes or platelets do not appear to account for all FNHTRs, particularly those caused by platelet transfusions. For example, some patients with no history of transfusion or pregnancy experience an FNHTR to their first transfusion of platelets.<sup>2</sup> It is unlikely that these reactions are mediated by recipient leukocyte or platelet antibodies because these recipients have no previous exposure to foreign cells. In addition, the rate of FNHTRs to platelet transfusion increases with increasing blood bank storage time of the transfused platelet concentrate.<sup>4-6</sup> This indicates that time-dependent change occurs in the platelet concentrate during storage that has a role in stimulating an FNHTR in some patients. Furthermore, febrile reactions still occur with the use of prestorage leukocyte reduction.<sup>19,20</sup> In some cases, this is the result of inappropriate filter use or filter failure. However, this observation also supports the possibility that a substance or substances in the plasma portion of blood components not removed by filtration may be responsible for mediating at least some FNHTRs. The discovery that proinflammatory cytokines accumulate in the plasma portion of platelet concentrates may account for many of these findings.

A variety of leukocyte-derived, proinflammatory cytokines, including IL-1 $\beta$ , IL-6, IL-8, TNF- $\alpha$ , macrophage inflammatory protein 1 $\alpha$  (MIP-1 $\alpha$ ), and growth-related oncogene  $\alpha$  (GRO- $\alpha$ ), are generated and accumulate in the plasma portion of platelet concentrates during storage.<sup>8,21-23</sup> Extracellular levels of these cytokines generally increase with increasing component storage time and are roughly proportional to the passenger leukocyte content of the blood component bag. Prestorage or early-storage leukocyte reduction (within 1 to 2 days of collection) prevents or greatly reduces generation of these cytokines. Because they have pyrogenic activity, many of these cytokines (if present in high enough concentration) can induce febrile responses in

transfusion recipients. Elevated levels of IL-1 $\beta$ , IL-6, and TNF- $\alpha$  in the plasma portion of platelet concentrates correlate positively with the occurrence of an FNHTR. Some studies have shown that IL-6 levels in the plasma portion of platelet concentrates correlate best with the occurrence of FNHTR. In one study, chills, fever, or both occurred more frequently after infusion of the plasma portion of the platelet concentrates than after infusion of the cellular portion containing platelets and leukocytes.<sup>21</sup> The plasma portions that caused an FNHTR contained higher levels of IL-1 $\beta$  and IL-6 than did those that did not cause chills or fever. These data support the role of the plasma portion of platelet concentrates as a source of inflammatory mediators and as a possible stimulus of FNHTR in some transfusion recipients. Although levels of a variety of proinflammatory cytokines in the plasma portion of platelet concentrates correlate with the occurrence of FNHTRs, it is unknown which, if any, of these actually mediate FNHTRs. Other inflammatory mediators, such as C5a and biologically active lipids, accumulate in platelet concentrates during storage and also may be implicated.<sup>24,25</sup>

Platelet-derived cytokines, such as CD40L (CD154), CCL5 (RANTES), transforming growth factor  $\beta$ 1 (TGF- $\beta$ 1), CXCL4 (platelet factor 4; PF4), CXCL8 (IL-8), and MIP-1 $\alpha$  are present in the plasma portion of platelet concentrates and apheresis platelets. All platelet-derived cytokines accumulate during platelet storage and CD40L has been associated with clinical FNHTRs.<sup>26</sup> These cytokines are not known to be directly pyrogenic, but they stimulate the synthesis of proinflammatory mediator, IL-1 $\beta$ , IL-6, IL-8, and TNF- $\alpha$ . Because RANTES can activate basophils and mast cells and stimulate histamine release, it may play a role in mediating some allergic reactions (see later, Allergic Reactions).<sup>27</sup> RANTES data are conflicting as to the extent of accumulation during storage; however, it seems that some increase in levels does occur.<sup>28</sup>

Some proinflammatory cytokines, such as IL-1 $\beta$  and IL-8, have been detected in the supernatant portion of stored RBCs, although at much lower levels than in platelet concentrates.<sup>29</sup> Because the cold storage temperature of RBC units, 1-6°C, has an inhibitory effect on cellular metabolism, the capacity of passenger leukocytes in RBC units to synthesize and secrete cytokines is less than those in platelet concentrates. As a result, the levels of cytokines in RBC units appear to be too low to mediate significant physiologic reactions.

The stimulus for cytokine generation during storage of blood components remains unknown. Measurements of cytokine messenger RNA levels and total cytokine levels (intracellular plus extracellular) in platelet concentrates indicate that accumulation of leukocyte-derived cytokines is caused in part by new synthesis and secretion. The stimulus for synthesis and secretion of leukocyte-derived cytokines may be, for example, contact activation of monocytes after these cells interact with the plastic of the storage containers or tubing.<sup>30</sup> Other possibilities include the direct stimulatory effects of C5a on PGE2 or the stimulatory effects of activated complement components on monocytes or other leukocytes in the blood component bag. The presence of platelet-derived cytokines (such as CD40L, RANTES, and TGF- $\beta$ 1) in the plasma portion of platelet concentrates likely results from their release from preexisting stores, because the biosynthetic activity of platelets is limited.

### Bacterial Contamination of Blood Components

An FNHTR may result from infusion of a blood component contaminated with bacteria or bacterial products such as LPS. Unless a Gram's stain and bacterial cultures are performed, mild septic transfusion reactions characterized by only fever and chills are likely to be classified clinically as FNHTR (see Chapter 49).<sup>31,32</sup>

Transfusion reactions caused by contaminating bacteria, whether mild or severe, are manifestations of the SIRS, described earlier. Proinflammatory cytokines (such as IL-1 $\beta$ , IL-6, IL-8, and TNF- $\alpha$ ) are implicated in the pathogenesis of SIRS associated with sepsis.<sup>33</sup> If bacterial contamination of blood components has occurred, the greatest source of cytokines is likely the transfusion recipient's cells stimulated by the infused bacteria or bacterial products. However, cytokine production by leukocytes in the component bag during storage stimulated by bacteria or bacterial products also may contribute to the reaction.

### Diagnosis

As a routine part of the transfusion procedure, the vital signs of transfusion recipients (pulse, temperature, and respiratory rate) should be measured immediately before transfusion and at intervals during and soon after transfusion. The patient should be watched closely, particularly in the first 30 to 60 minutes of transfusion, for the onset of chills, shivering, or rigors, which often precede a fever.

A transfusion reaction is a possibility if chills, fever (1°C or more over pretransfusion temperature), or both develop any time during transfusion or up to several hours after the transfusion

has ended. A febrile response to transfusion, however, is not specific for an FNHTR. For example, a fever may be the early manifestation of a more serious acute hemolytic or septic transfusion reaction. When a patient has a febrile reaction to transfusion, an evaluation to rule out hemolysis and possibly bacterial contamination should be undertaken promptly. Nursing staff should stop the transfusion immediately and notify the physician caring for the patient. They should verify that the identity of the transfusion recipient, based on the patient's identification bracelet and verbal confirmation with the recipient, if possible, matches that of the intended recipient, as indicated on the blood component tag. All containers and transfusion sets should be sent to the laboratory along with a posttransfusion blood specimen and a report that summarizes the clinical reaction. The clinical team should also have verbal communication with the blood bank staff to ensure that the postreaction blood specimen, component bag, and infusion set are received by the blood bank as soon as possible.

Investigation of a febrile reaction in the blood bank generally begins with a recheck of the records for clerical errors. The posttransfusion serum must be visually evaluated for hemolysis and should be compared with the pretransfusion serum. A direct antiglobulin test must be performed on the posttransfusion blood specimen and ideally on a pretransfusion specimen for comparison. The ABO grouping of the patient sample and the donor unit should be repeated. When suggested by the preliminary serologic results, the crossmatch may be repeated for RBC transfusions to confirm patient-donor compatibility. The results of these tests confirm or exclude a hemolytic transfusion reaction as the basis for the fever. When a septic reaction is highly suspected, for example if the patient arrives with a high fever (2°C or more) or accompanying hypotension, the bag contents should be examined by means of a Gram's stain and culture for bacterial contamination. Blood cultures also should be obtained from the transfusion recipient's posttransfusion blood specimen to correlate bacteremia with the same organism that may be detected in the blood component bag. Most blood banks do not test for HLA-specific, platelet-specific, or granulocyte-specific antibodies in the recipient's serum as possible causes of an FNHTR. Identification of these antibodies and pyrogenic cytokines is reserved for specialized laboratories and does not play a role in the immediate evaluation of most reactions.

The patient is examined by the primary team and the blood bank physician to determine whether associated symptoms or circumstances can explain the fever, such as drug reactions, sepsis, or other inflammatory conditions unrelated to transfusion. The time course of the development and resolution of fever should be examined in relation to the transfusion. In cases in which the transfusion recipient has a fever at the start of transfusion or is experiencing intermittent spiking fevers, a posttransfusion increase in body temperature can be difficult to interpret. In such cases *possible FNHTR* may be the most definitive diagnosis that can be made. An FNHTR is a diagnosis of exclusion, arrived at by means of eliminating the possibility of immune hemolysis, bacterial contamination of the blood component, TRALI, or other causes of fever unrelated to transfusion.

## Treatment

The transfusion should be stopped immediately. The intravenous line should be kept open with normal saline solution to provide ready access for the possible infusion of crystalloid and intravenous medication in case the fever is a sign of a more serious hemolytic or septic reaction. Most patients, however, should be reassured that febrile transfusion reactions usually are harmless and that the fever typically responds to antipyretic therapy. The antipyretic agent of choice is acetaminophen (adults, 325 to 650 mg orally; children, 10 to 15 mg/kg orally or rectally). Aspirin and nonsteroidal antiinflammatory drugs are contraindicated in the treatment of many transfusion recipients, such as those receiving platelets. Unless the patient has signs of an allergic reaction, such as urticaria, erythema, or pruritus, antihistamines are not indicated in the management of FNHTR. However, it is not unusual for physicians to prescribe both an antipyretic and an antihistamine in combination for mild reactions.

Patients occasionally develop rigors (severe shaking chills) after a transfusion and meperidine had been a mainstay therapy for many years. Because shivering can increase oxygen demand significantly, it is important to control the shaking chills, particularly for patients with cardiac or respiratory insufficiency. When administered to adults at doses of 25 to 50 mg intravenously, meperidine remains a very effective treatment for rigors. Meperidine is effective in rapidly arresting rigors through mechanisms not clearly understood. Unfortunately, meperidine has fallen out of favor with some hospitals because of unacceptable central nervous system toxicities and other downsides. Use of meperidine is generally contraindicated in the care of patients with renal failure because of accumulation of the proconvulsant metabolite normeperidine. Use of meperidine also is contraindicated in the care of patients who have taken monoamine oxidase inhibitors within the previous 14 days because of the risk of serotonin syndrome (excess serotonin activity). Toxicities secondary to metabolite accumulation, short half-life, and higher equianalgesic dose compared to morphine has decreased interest and formulary availability for this opioid.<sup>34</sup> On the basis of anecdotal evidence, morphine may be slightly less efficacious for the treatment of rigors, but its safety profile is more acceptable when given as a one-time dose of 2 to 4 mg intravenously.

After symptoms of an acute febrile reaction have been treated and the patient has been stabilized, any unused portion of the blood component should be returned to the blood bank and not transfused, even if blood bank testing rapidly rules out hemolysis. This is because no quick test is currently available that is sensitive enough to also rule out with confidence bacterial contamination of the blood component. The use of Gram's stain helps detect heavily contaminated units (with detection limits not less than  $10^6$  organisms per mL), and lower levels of contamination may be missed. If the febrile reaction is caused by bacterial contamination of the component bag, restarting transfusion of the same component can cause a severe and even fatal septic transfusion reaction as more bacteria or bacterial products are infused. For this reason, a new blood component unit should

be used if transfusion is still needed after the patient's condition has been stabilized.

Restarting transfusion with the same platelet preparation that caused an FNHTR may be considered as a last resort in the treatment of patients who repeatedly have mild and uncomplicated febrile responses to platelet transfusions despite prophylactic measures.<sup>35</sup> In this situation, it may be necessary to cautiously complete the transfusion with the same component, because the patient is likely to react to other platelet preparations. The patient should have no other symptoms and the fever should be less than 1.5°C over the pretransfusion baseline. A septic reaction caused by bacterial contamination of a unit is generally the major concern in this setting. Hemolysis of either donor or recipient red cells usually is not significant because of the small amount of red cells and plasma in platelet preparations. The transfusion should generally not be restarted for at least 30 minutes as a precaution to allow other possible signs or symptoms of a serious reaction to develop. High transfusion-related fevers, such as a 2°C increment or more, are more likely to be associated with septic reactions and should preclude restarting the transfusion. However, lesser fevers do not rule out bacterial contamination of the blood component. If the transfusion is restarted, the patient should be made as comfortable as possible with appropriate antipyretic therapy, as described earlier. The transfusion should proceed slowly and the patient observed closely for further signs of a reaction or further temperature elevation throughout the transfusion, which should be stopped if symptoms recur. Restarting transfusion of a blood component that has caused an FNHTR should not be routine.

## Prevention

### Premedication

Premedication with acetaminophen but not diphenhydramine should be considered for patients with a history of FNHTR. Patients who have no history of FNHTR do not need premedication. Despite a number of studies showing no benefit to premedication in preventing transfusion reactions, the practice remains commonplace in many institutions.<sup>36</sup> Premedication with the glucocorticoid hydrocortisone sodium succinate (adults, 100 mg intravenously) may be useful in the care of reaction-prone patients when an antipyretic agent alone is ineffective. Glucocorticoids have antiinflammatory effects that may help prevent or reduce the severity of FNHTRs. For example, they inhibit the enzyme phospholipase A<sub>2</sub>, thereby blocking production of arachidonic acid and its metabolites such as PGE<sub>2</sub>, a key mediator of fever. Glucocorticoids also inhibit synthesis of pyrogenic cytokines, such as IL-1 and IL-6. A variety of glucocorticoids other than hydrocortisone are available. However, hydrocortisone has the advantage of being a short-acting glucocorticoid (biologic half-life, 8 to 12 hours), and it induces a shorter period of immunosuppression than do many other glucocorticoid preparations. Because glucocorticoids generally act through changes in gene expression, hydrocortisone should be administered at least 4 to 6 hours before transfusion so that its antiinflammatory action has time to take effect.

### Rate of Infusion

Slowing the speed of infusion of a blood component can possibly prevent or decrease the severity of FNHTR. The rate of increase in body temperature in FNHTR caused by leukocyte alloimmunization appears to be directly related to the rate of infusion of leukocytes in the blood components.<sup>18</sup> A slower rate of infusion is of theoretic advantage in decreasing the severity of reactions caused by bacterial contamination or storage-generated cytokines. Slower infusion avoids a sudden bolus of bacterial toxins or cytokines that may provoke an immediate and possibly massive inflammatory response.

### Leukocyte Reduction

The prophylactic transfusion of leukocyte-reduced components in the treatment of patients receiving repeated transfusions is effective in avoiding alloimmunization to leukocytes, which is one of the major causes of FNHTR. Leukocyte-reduced blood components ideally should be transfused to such patients beginning with the first transfusion. Leukocyte reduction is effective in the care of patients already alloimmunized to leukocytes, because FNHTRs in these patients are directly related to the number and rate of infusion of passenger leukocytes. The threshold number of white cells associated with the development of an FNHTR generally ranges from  $0.25 \times 10^9$  to  $2.5 \times 10^9$ .<sup>18</sup> The removal of approximately 90% of leukocytes ( $10^{10}$ ), which usually leaves less than  $5 \times 10^8$  white cells per RBC unit, is sufficient to prevent most FNHTRs.<sup>17,37</sup> For that reason, leukocyte reduction for the purpose of preventing FNHTRs often is defined as decreasing the passenger leukocytes to less than  $5 \times 10^8$  per transfusion. Leukocyte reduction of blood components can be performed either at the time of component preparation (prestorage leukocyte reduction) or immediately before transfusion (poststorage leukocyte reduction). Poststorage leukocyte reduction by means of filtration can be performed in the blood bank before distribution of the component for transfusion or during administration of blood components. The latter often is called *bedside leukocyte reduction*.

Leukocyte-reduced RBC units have in the past been prepared by various poststorage techniques, including simple centrifugation with buffy-coat removal, saline washing, and deglycerolization of frozen RBCs.<sup>38,39</sup> Saline-washed and frozen deglycerolized RBCs are rendered leukocyte reduced because approximately 1 to 2  $\log_{10}$  leukocytes are removed by repeated centrifugation and washing steps on automated cell washers. Filtration of RBCs units through microaggregate filters designed to remove microaggregate debris more than 40 microns in diameter after an extra centrifugation step or after centrifugation and cooling (spin, cool, filter) also has been shown to reduce leukocytes in RBC units sufficiently to reduce the incidence of FNHTRs.<sup>40-43</sup>

High-efficiency leukocyte reduction filters for red cells and platelets have been developed that are capable of removing both microaggregate debris and nonaggregated leukocytes.<sup>44</sup> These leukocyte reduction filters can remove 3 or more log (99.9% or more) leukocytes, thereby decreasing the leukocyte content to approximately  $1 \times 10^6$ /unit or less. Despite their efficacy in

leukocyte reduction, the use of bedside leukocyte reduction filters has had variable and sometimes disappointing results in reducing the incidence of FNHTRs to platelet concentrates.<sup>3</sup> This may be the result of causes of FNHTR other than leukocyte antibodies in the transfusion recipient. For example, storage-generated, extracellular cytokines in the component bag that either are not removed or are inadequately removed by means of poststorage filtration are now believed to mediate some reactions. As a result, the practice of prestorage leukocyte reduction is increasingly replacing poststorage leukocyte reduction. Prestorage leukocyte reduction not only removes leukocytes but also removes leukocytes before they have a chance to release cytokines that can accumulate extracellularly in blood component bags during storage. Prestorage leukocyte reduction has also yielded conflicting results on the efficacy of leukocyte reduction to mitigate FNHTRs.<sup>19,20,45</sup>

Prestorage leukocyte reduction of platelet concentrates or RBC units is achieved by use of blood component containers with in-line leukocyte reduction filters in a closed system between the primary collection bag and satellite containers. Prestorage leukocyte-reduced platelets also can be prepared with some automated apheresis instruments equipped with centrifugation chambers designed to minimize leukocyte collection (so-called *process leukocyte reduction*). Because some data indicate that only approximately 15% of patients who experience an FNHTR will have a similar reaction to the next transfusion, some blood banks provide a leukocyte-reduced component (either prestorage or bedside leukocyte reduced) only when a patient has had two or more documented febrile reactions.<sup>46</sup> This practice is cost-effective but has the disadvantage of subjecting some patients to two uncomfortable reactions before a preventive measure is taken.

Poststorage plasma removal from platelet preparations by saline washing techniques is an alternative to prestorage leukocyte reduction for eliminating extracellular cytokines.<sup>14,22</sup> Prestorage leukocyte reduction by means of filtration is a more efficient and cost-effective way to eliminate extracellular leukocyte-derived cytokines while reducing passenger leukocytes. Moreover, in evaluations of plasma removal from platelet concentrates to reduce the risk of FNHTR, this technique still is associated with FNHTR in a relatively large percentage of recipients. Neither leukocyte reduction nor poststorage plasma removal has been effective in eliminating all FNHTRs to platelet transfusions.

---

## Allergic Reactions

### Description

An allergic reaction can be classified as an immediate hypersensitivity response consisting of transient localized or generalized urticaria, erythema, and pruritus. More serious allergic reactions can be complicated by hypotension and angioedema of the face and larynx. Allergic reactions can be categorized as those that

have only cutaneous manifestations and usually are mild, resolving soon after administration of antihistamines. If other organ systems—cardiovascular, respiratory, or gastrointestinal—are involved beyond mild hypotension, particularly if the reaction is serious enough to necessitate treatment beyond antihistamines, the reaction would be considered *anaphylactic* or *anaphylactoid* (see later). Allergic and anaphylactic reactions, however, are part of a continuum. Allergic reactions occur during or soon after transfusion of plasma-containing blood components. Atopic individuals—those with other known allergies—appear at greater risk of allergic reactions. A large retrospective review of reported transfusion reactions noted that 17% of all reactions in a 9-year period were allergic and 1% of reactions were very severe.<sup>47</sup> Other papers report allergic reaction rates of approximately 0.1% for red cells and 0.5% for platelet transfusions.<sup>19,45</sup>

### Etiology

Allergic reactions are mediated by recipient immunoglobulin E (IgE) or non-IgE antibodies to proteins or other allergenic soluble substances in the donor plasma. The result of the hypersensitivity reaction is secretion of histamine from mast cells and basophils, which mediates cutaneous reactions by increasing vascular permeability.

Although the source of histamine in allergic reactions is believed in many cases to be the transfusion recipient's mast cells and basophils, it has been hypothesized that histamine generated by leukocytes in stored cellular blood components may play a role. Several studies have shown that histamine accumulates in the plasma portion of platelet concentrates and RBC units with increasing storage time. However, histamine is not synthesized during storage but rather it leaks into the extracellular plasma.<sup>48,49</sup> These data are consistent with the observation that allergic transfusion reactions also are more common with increasing storage time of blood components.<sup>50</sup> Several of the chemokines that accumulate in the plasma portion of platelet concentrates during blood bank storage, such as IL-8, RANTES, and MIP-1 $\alpha$ , can recruit and activate basophils and stimulate histamine release. Therefore, it is theoretically possible that the infusion of storage-generated donor cytokines during transfusion may contribute to the onset of allergic reactions among transfusion recipients. Consistent with this hypothesis, the platelet-derived cytokine, RANTES, is present at higher levels in platelet concentrates that cause allergic reactions.<sup>51</sup>

Allergic (and anaphylactic) reactions have been reported after infusion of antibodies in donor plasma, such as penicillin antibody infused into recipients receiving penicillin or related antibiotics, and after infusion of drugs in donor plasma, such as penicillin infused into recipients already sensitized to penicillin.

### Diagnosis

Urticaria is readily diagnosed clinically by the presence of the cutaneous wheal-and-flare reaction. Because allergic symptoms usually are mild and are not characteristic of hemolytic transfusion reactions, serologic blood bank investigations to rule out

hemolysis usually are unrevealing. Isolated, mild urticarial reactions not accompanied by other signs and symptoms necessitate minimal diagnostic evaluation. If the reaction is severe, has atypical manifestations, or is accompanied by fever (uncharacteristic of allergic reactions), a more elaborate laboratory evaluation to rule out a hemolytic or septic transfusion reaction is indicated. In the diagnosis of an allergic reaction as transfusion-related, it is important to rule out, if possible, urticarial drug reactions that may be circumstantially attributed to transfusions. Careful attention to the timing of onset of urticaria relative to the transfusion may help avoid this confusion. Administration of medications should generally be discouraged in the peritransfusion period to avoid such confusion.

Even mild allergic reactions should be reported to the blood bank. Monitoring allergic reactions and correlating reactions with any newly implemented changes in blood component collection, processing, storage, or filtration are important in detecting new and unexpected causes of reactions. In the care of patients with repeated allergic reactions, notification of the blood bank allows the blood bank medical director to consult on measures to manage or prevent such reactions in the future.

### Treatment

The patient can be treated with a first-generation, H<sub>1</sub>-blocking antihistamine (adults, 25 to 50 mg diphenhydramine intravenously or orally). If the sedating side effects of first-generation antihistamines must be avoided, newer, less-sedating antihistamines are available for oral administration (adults, cetirizine 10 mg orally, loratadine 10 mg orally, or fexofenadine 60 mg orally); however, parenteral antihistamines are preferred in the management of acute reactions because of their more rapid bioavailability. An H<sub>2</sub> blocker, such as cimetidine (adults, 300 mg intravenously) or ranitidine (adults, 50 mg intravenously) may be added to the H<sub>1</sub> blocker to speed resolution of the reaction. Combining H<sub>1</sub> and H<sub>2</sub> antagonists has given better results in treating patients with allergic reactions in nontransfusion settings than has use of an H<sub>1</sub> antagonist alone.<sup>52,53</sup> For reactions characterized by only localized urticaria, such as a few hives, the transfusion can be temporarily discontinued while an antihistamine is administered. The transfusion can be resumed in approximately 30 minutes if the urticaria has cleared and if no further symptoms occur. For patients with generalized urticaria or a more serious allergic reaction accompanied by facial or laryngeal edema or hypotension, the transfusion should be discontinued and the infusion set with any untransfused blood returned to the blood bank. If laryngeal edema causes breathing difficulties or if hypotension is severe, epinephrine [adult dose, 0.2 to 0.5 mL of 1:1000 solution (0.2 to 0.5 mg) subcutaneously] can be administered.

### Prevention

Transfusion recipients often are given routine premedication with an antihistamine such as diphenhydramine in an effort to prevent or reduce the severity of allergic transfusion reactions,

even when they have had no previous reactions. The value of this approach is uncertain, because few patients have allergic reactions. At least two randomized double-blind placebo-controlled studies of premedication using diphenhydramine and acetaminophen have failed to show a benefit of premedication to reduce reactions.<sup>54,55</sup> When premedication is restricted to patients who have had two or more previous allergic reactions, overall reaction rates do not increase. Accordingly, premedication with an antihistamine should probably be reserved for recipients who have had a previous allergic reaction. For patients with repeated reactions not eliminated by premedication with an H<sub>1</sub> blocker alone, a combination of H<sub>1</sub> and H<sub>2</sub> blockers has been shown more effective.<sup>52,53</sup>

Should premedication not prevent repeated allergic transfusion reactions, another option is to reduce the plasma content of transfused blood components. This can be achieved in RBC and platelet preparations with automated saline “washing.”<sup>56,57</sup> However, washing or plasma removal steps generally should be reserved for patients with two or more serious allergic reactions (eg, those that include angioedema or hypotension) that are not prevented with premedication with both H<sub>1</sub> and H<sub>2</sub> blockers, because cell washing is time-consuming and can delay transfusion. Patients with two or more allergic reactions can undergo testing for IgA deficiency, because this is a reported cause of both allergic and anaphylactic reactions.

## Anaphylactic and Anaphylactoid Reactions

### Description

Anaphylactic reactions are serious and potentially life-threatening immediate hypersensitivity reactions to allergens in the plasma of transfused blood components.<sup>58</sup> These reactions can have a rapid onset beginning as early as seconds to minutes after the start of the transfusion, and can occur with small transfused volumes. Anaphylactic reactions are differentiated from other allergic (urticarial) transfusion reactions by their systemic nature and severity. These reactions generally affect multiple organ systems, as evidenced by cutaneous, respiratory, cardiovascular, and gastrointestinal effects. The symptom complex often includes the rapid onset of laryngeal edema and bronchospasm with stridor, wheezing, coughing, and respiratory distress. Other symptoms include generalized urticaria, erythema, tachycardia, hypotension, nausea, vomiting, diarrhea, and cramping abdominal or pelvic pain. Severe reactions can proceed rapidly to shock, syncope, respiratory failure, and death. Fatal anaphylactic reactions are less common than are fatal hemolytic or septic reactions.

### Etiology

Anaphylactic reactions occur when an allergen present in plasma is transfused to a patient who through previous sensitization has an IgE directed against that allergen.<sup>59</sup> Immunoglobulin E is bound by means of Fc receptors to mast cells and basophils. The

binding of allergen to cell-bound IgE results in cross-linking of IgE and Fc receptors. This cross-linking activates the mast cells and basophils to secrete preformed mediators, such as histamine, as well as newly synthesized mediators, such as leukotrienes, prostaglandins, cytokines, and platelet-activating factor (PAF) (Fig 53-2).<sup>60</sup> PAF induces downstream production of nitric oxide (NO) through inducible and possibly constitutively expressed NO synthase.<sup>61</sup> As a potent vasodilator, NO is believed to be the principal compound causing hypotensive and cardiovascular collapse during anaphylaxis, although the exact mechanism remains under debate.

Anaphylactoid reactions are clinically identical to anaphylactic reactions but occur by mechanisms that do not involve IgE. For example, immune complexes involving antibodies other than IgE may result in complement fixation and generation of

**Figure 53-2.** (A) Mast cell with its activation products. (B) Basophil with its activation products. Note that currently only two products of mast cell activation (histamine and total tryptase) and one product of basophil activation (histamine) can be measured in clinical laboratories as markers of acute anaphylaxis events. Used with permission from Simons FE.<sup>60</sup> IL = interleukin; GM-CSF = granulocyte-macrophage colony-stimulating factor; TNF- $\alpha$  = tumor necrosis factor alpha; MIP = macrophage inflammatory protein.

the anaphylatoxins C3a, C4a, and C5a, which activate basophils and mast cells. Some cytokines secreted by monocytes as part of the inflammatory cascade initiated by non-IgE immune complex formation also can directly activate basophils and mast cells and initiate anaphylactoid reactions. Moreover, IgG4 subclass antibodies can bind to Fc receptors of mast cells and basophils and, in a manner analogous to that of IgE, mediate cellular activation and degranulation after binding of allergen. The term *anaphylactoid* is sometimes used to describe mild or clinically atypical anaphylactic reactions. However, *anaphylactoid* is better used to differentiate the mechanism of the reaction, not its clinical severity or presentation.

The best documented anaphylactoid reactions have resulted from the transfusion of donor plasma containing IgA to IgA-deficient recipients who have produced a class-specific IgG anti-IgA that reacts with all IgA subclasses. Less commonly, patients with normal total IgA levels have a subclass-specific IgA deficiency and may make an anti-IgA of restricted specificity. Although IgA deficiency is relatively common (approximately 1 case among 700 persons), anaphylactoid reactions occur only among some IgA-deficient transfusion recipients, because not all make anti-IgA. Anaphylactic or anaphylactoid reactions have been documented among patients with deficiencies of other plasma proteins, such as complement, von Willebrand factor, and haptoglobin.<sup>62,63</sup> In an analogous manner, these patients produce an antibody to the missing factor that reacts with transfused, plasma-containing blood components. In most anaphylactic or anaphylactoid reactions, however, the allergen is never identified, nor is evidence obtained to differentiate anaphylactic from anaphylactoid mechanisms.

### Diagnosis

Anaphylactic and anaphylactoid reactions are diagnosed from clinical signs and symptoms.<sup>64</sup> The cutaneous signs and symptoms and the often rapid onset of the reaction help differentiate anaphylactic reactions from acute hemolytic and septic transfusion reactions. Serum  $\beta$ -tryptase levels may be measured to confirm an anaphylactic reaction, because it is a marker for mast cell degranulation. However, no laboratory measurement is available in time to meaningfully affect recognition and management of an anaphylactic reaction.

Recipient IgA levels should be measured in a pretransfusion blood specimen to determine if the recipient is IgA-deficient. Although the results of tests for IgA deficiency do not affect diagnosis or management of the reaction at hand, it is important for avoiding future reactions.<sup>58</sup> Testing should be performed on a specimen drawn before transfusion, because IgA deficiency can be masked by any IgA provided by the transfusion. Recipient anti-IgA also can be measured, especially for rare cases in which the anti-IgA is subtype-specific and total IgA levels are within the reference range. Although IgA is the most commonly known allergen in anaphylactoid reactions, in most anaphylactic and anaphylactoid reactions, the offending allergen is not IgA and is never identified.

### Treatment

Anaphylactic and anaphylactoid reactions are managed identically.<sup>64</sup> Severe reactions are true medical emergencies and should be managed by experienced critical care staff, if possible. The patient should be placed in an intensive care unit as soon as it is practical without jeopardizing emergency care. Once anaphylaxis is evident clinically, 1:1000 epinephrine solution (1 mg/mL) should be administered subcutaneously in a dose of 0.2 to 0.5 mL for adults (0.01 mL/kg of body weight for children). The dose may be repeated every 15 to 30 minutes as needed. Intravenous crystalloid or colloid solution should be administered as needed to support the patient's blood pressure. For example, 500 mL to 1 L of normal saline solution can be administered in the first 15 to 30 minutes. Further infusion should be titrated to blood pressure. If the systolic blood pressure is less than 60 mm Hg, intravenous epinephrine in a dose of 1 to 5 mL of a 1:10,000 solution (0.1 mg/mL) for adults and 0.1 mL/kg for children, is administered over 2 to 5 minutes by means of intravenous push. An epinephrine drip (1 to 4  $\mu$ g/minute) may be started, and administration of other pressors, such as dopamine, can be considered. Blood pressure, pulse, and urine output should be monitored. It may be necessary to monitor the effectiveness of fluid replacement and pressor infusion through measurement of central venous pressure.

Respiratory distress is managed with supplemental oxygen. The patient's upper airway may have to be secured with endotracheal intubation if obstruction from laryngeal edema is imminent. Stridor is a sign of laryngeal edema. Endotracheal intubation and mechanical assistance with ventilation are indicated if the PaCO<sub>2</sub> increases to more than 65 mm Hg. When intubation is difficult or impossible because of laryngeal obstruction, cricothyrotomy or tracheostomy is an option. Wheezing caused by obstruction of small bronchi and bronchioles by increased mucus production and smooth muscle contraction can be managed with nebulized albuterol or metaproterenol and intravenous aminophylline.

Urticaria, angioedema, or gastrointestinal distress is managed with an antihistamine (adults, 50 mg diphenhydramine intravenously; children, 1 to 2 mg/kg intravenously). H<sub>2</sub>-blocking antihistamines may be added as an adjunct to H<sub>1</sub> blockers. Glucocorticoids, such as hydrocortisone, 200 mg given intravenously every 6 hours, are also administered because they reduce late-phase inflammatory responses. Glucocorticoids, however, are not expected to be of benefit in the initial management of anaphylaxis because of their delayed onset of action.

### Prevention

Patients with IgA deficiency who have already had an anaphylactic reaction or who are known to have anti-IgA should receive transfusion of RBC and platelet preparations that have been saline-washed with an automated cell washer.<sup>56,58</sup> If plasma transfusion is necessary, only IgA-deficient donors should be used. Patients who have anaphylactic reactions to any other known plasma allergen also should be treated with transfusion

of saline-washed RBCs or platelet preparations. Because anaphylactic reactions can be induced by very small amounts of allergen, washing must be extensive. Washing and saline replacement by means of automated cell washers have been shown generally successful in removing IgA sufficiently to prevent recurrences of anaphylactoid reactions.

If a patient has had one anaphylactic reaction of unknown causation, the next transfusion need not necessarily be performed with washed RBCs or platelets, because the reaction might have been donor-specific. The next transfusion may be administered slowly with vigilance after premedication with both H<sub>1</sub> and H<sub>2</sub> blockers and a glucocorticoid. The patient care team should be prepared to respond to an anaphylactic reaction. The patient ideally should be in a critical care unit with monitoring at the time of transfusion and with a critical care physician and nurses in attendance. Some blood banks with the capability of automated cell washing, nevertheless, may choose to provide saline-washed RBCs and platelet concentrates for future transfusions after a single anaphylactic reaction as a precautionary measure, particularly if the patient is not expected to receive many more transfusions.

## Complications of Massive and Rapid Transfusion

Massive transfusion is defined as the replacement of one blood volume within a 24-hour period. For adults of average size, this is roughly equivalent to 10 units of RBCs with any accompanying crystalloid, colloid, platelet, or plasma infusions. The possible complications include citrate toxicity, electrolyte imbalance (hyperkalemia from transfusion of older RBCs, hypokalemia from citrate toxicity), circulatory overload, and hypothermia. Recipients of massive transfusions are at increased risk of hemolytic transfusion reactions (including ABO incompatibility), FNHTR, and allergic reactions because of the number of units they receive. Reactions can be more severe with massive transfusion because rapid infusion means the implicated unit often has been completely administered before the onset of symptoms. The large number of units transfused in a short time complicates the investigation of transfusion reactions, because each transfused component must be investigated.

The lethal triad of severe trauma consists of hypothermia, acidosis, and coagulopathy. "Damage control" resuscitation methods have been developed to directly address the coagulopathy of trauma. The coagulopathy of trauma develops because of severe injury and is already present when a patient presents for emergency medical care. Trauma coagulopathy is not caused by the resuscitation efforts of emergency medical interventions as traditionally understood.<sup>65</sup> Recent advances in trauma research have shown that early application of damage control resuscitation can greatly improve survival through an application of a 1:1 plasma:red cell ratio from patient presentation. In well-coordinated trauma centers, massive transfusion protocols are under investigation that provide 6 units of plasma, 6 units of RBCs,

6 whole-blood-derived platelet concentrates (or 1 apheresis platelet), and 10 units of cryoprecipitate as a part of a predefined effort to treat the coagulopathy of trauma.<sup>65-67</sup> Aggressive damage control transfusion has been associated with a number of risks including hyperkalemia, and when a walking blood donor program is employed, increased infectious disease transmission.<sup>68,69</sup> Despite these risks, retrospective studies have shown that the application of early, aggressive transfusion support improves overall survival in this severely injured population that would otherwise have very poor prognosis.

Rapid transfusion can also occur during therapeutic apheresis and red cell exchange apheresis (erythrocytapheresis). During apheresis procedures, as many as 10 to 20 units of Fresh Frozen Plasma or 4 to 8 units of RBCs can be transfused over 1.5 to 2 hours. Although any acute transfusion reaction can occur during apheresis-associated transfusion, citrate toxicity in particular is a common but usually mild complication.

### Citrate Toxicity

Rapid blood transfusion can cause a transient decrease in the level of ionized calcium because of the calcium-chelating properties of the citrate anticoagulant in stored blood components.<sup>70</sup> The clinical presentation of citrate-induced symptoms is also termed citrate toxicity. Citrate toxicity can occur whenever large volumes of plasma that contain citrate are transfused, such as during massive transfusion, plasma exchange, or other apheresis procedures.<sup>71,72</sup> Citrate infusion can induce hypocalcemia, hypomagnesemia, and other electrolyte imbalances, and these imbalances are associated with clinical symptoms. Apheresis procedures can produce a unique clinical paradox of urinary calcium excretion in the setting of hypocalcemia.<sup>72,73</sup> Hypocalcemia is a recognized complication of liver transplantation, in which large amounts of plasma are transfused. However, the precise mechanism of hypocalcemia is not well understood and may not be caused entirely by citrated plasma.<sup>74,75</sup>

Citrate ordinarily is rapidly metabolized to bicarbonate in mitochondria-rich tissue, such as liver, skeletal muscle, and kidney.<sup>70</sup> In the routine transfusion of blood components, patients with normal liver function usually tolerate the citrate infusion without significant complications. However, patients with liver or renal failure or parathyroid dysfunction are at greater risk of citrate toxicity when they receive rapid transfusions of plasma or plasma-containing blood components.

Citrate anticoagulates blood by binding divalent cations such as calcium, thus hypocalcemia is a primary symptom. Other divalent cations such as magnesium and zinc can also be bound by citrate, but the contribution of hypomagnesemia to clinical symptoms is less pronounced.<sup>76</sup> During apheresis, citrate is administered as acid-citrate-dextrose formula A (ACD-A) in constant proportion to the whole-blood flow rate. Healthy plateletpheresis donors receive relatively large doses of citrate, and many experience mild symptoms of the citrate effect, but the symptoms usually do not progress because of the short duration of the procedure. Donors of peripheral blood stem cells (PBSCs),

however, receive smaller doses of citrate per unit of time but usually experience more severe citrate toxicity because of the longer duration of the procedure. Paresthesia caused by transient hypocalcemia is common in apheresis. It typically occurs after the initial infusion of the priming solution (if citrate is used) or later as apheresis progresses. Apheresis practitioners should be aware that peripheral paresthesia caused by hypocalcemia can be masked in patients with a preexisting neuropathy as a result of chemotherapy (vincristine) or as part of a neurologic condition.

Citrate toxicity is recognized clinically because of the signs and symptoms of hypocalcemia. It can be confirmed by measuring the plasma ionized calcium level in the patient. Symptoms of hypocalcemia include peripheral and perioral paresthesia (Chvostek and Trousseau signs can occasionally be elucidated), muscle spasm, cramping, nausea, vomiting, cardiac arrhythmia, bradycardia, hypotension, and if severe, tetany. An electrocardiogram (ECG) can show prolongation of the QT interval with hypocalcemia, but the relation is not linear with the ionized calcium level, and ECG findings are an unreliable guide to calcium therapy.

Mild citrate toxicity during transfusion or apheresis is managed or prevented in part by means of slowing the rate of transfusion or reinfusion. When slowing the infusion rate is impossible or ineffective and the patient has signs and symptoms of hypocalcemia, calcium supplementation is indicated. The best guide to determining a need for calcium supplementation is measurement of the patient's ionized calcium levels, if results can be obtained rapidly. Calcium replacement during apheresis should generally be given when a patient has symptoms, when the patient's clinical condition may exacerbate citrate effects, or when prolonged large-volume leukapheresis is expected to cause citrate toxicity. Infusion of calcium itself, however, is associated with development of ventricular arrhythmia and even cardiac arrest. Therefore, intravenous calcium replacement for the management or prophylaxis of apheresis-induced citrate toxicity should be administered only by experienced apheresis staff. Under no circumstances should calcium be added directly to a unit of blood, because it causes clots to form in the bag.

Citrate toxicity during apheresis is related to the citrate concentration of the reinfused blood or colloid solution, the infusion rate, the blood volume of the patient, and the total time over which the citrate is infused.<sup>77</sup> It is difficult to establish a definitive safe rate of citrate infusion because of the large number of variables involved. However, citrate dosages of up to 1 mg/kg/minute given during plateletpheresis usually are well tolerated. A safe rate of calcium replacement for controlling citrate toxicity during PBSC apheresis is 0.5 to 0.6 mg of calcium ion for every 1.0 mL of infused ACD-A.<sup>78,79</sup> These dosages have been successful for prophylaxis against citrate toxicity during large-volume leukapheresis. To avoid excessive volume during PBSC apheresis, administration of a concentrated calcium solution (calcium chloride or calcium gluconate) is appropriate. Care must be taken to coordinate the calcium infusion with whole blood flow during the apheresis procedure to avoid the potential for catheter

thrombosis. Calcium administration should be halted soon after interruptions in whole blood flow.

### Electrolyte Disorders

Because of inhibition of sodium-potassium-adenosine triphosphatase in red cell membranes by the cold storage temperature of RBC units, extracellular potassium accumulates with increasing blood bank storage times. Extracellular potassium increases at the rate of approximately 1 mEq/day during the first 3 weeks of RBC storage in citrate-phosphate-dextrose-adenine-1 (CPDA-1).<sup>80</sup> Potassium levels in additive solution-1 (Adsol) units are markedly higher on Day 7 of storage (17 mmol/L) than on Day 0 (1.6 mmol/L). The increase is even greater by Day 42 (46 mmol/L).<sup>81</sup>

Hyperkalemia resulting from massive transfusion of older RBC units with an elevated amount of extracellular potassium can cause significant cardiac complications and possibly death in some patients.<sup>68</sup> Acidosis can contribute to hyperkalemia and severely injured patients presenting with a potassium level greater than 4 mmol/L are at increased risk. Other patients at risk of hyperkalemic complications are neonates and those with renal failure. The diagnosis of hyperkalemia is made by means of measurement of potassium in the serum and observation of ECG changes, which include peaked T waves, prolongation of the PR interval, and ventricular arrhythmia.<sup>82</sup> In neonatal transfusions, hyperkalemia can be avoided by use of fresh RBC units (less than 7 days old) or older units that have been saline-washed to remove the extracellular fraction containing the potassium.<sup>83,84</sup> However, transfusion of older RBC units does not place neonates at risk of hyperkalemia if small-volume transfusions (10 to 15 mL/kg) are given slowly.<sup>85</sup>

Hypokalemia can also develop during massive transfusion or large volume apheresis.<sup>72</sup> As the anticoagulant citrate in blood components is metabolized to bicarbonate, the blood can become alkalotic, producing hypokalemia. The degree of hypokalemia may be sufficient to necessitate infusion of potassium if symptoms develop. However, the use of newer RBC additive solutions such as Adsol has helped to decrease the effect of hypokalemia. RBC units are plasma-reduced before the addition of additive solution, which itself contains no additional citrate. Therefore, most of the citrated plasma is removed from additive solution RBC units during production. Animal studies have shown fewer physiologic aberrations during massive transfusion with Adsol RBCs than with CPDA-1 units.<sup>86</sup> The complications of hypokalemia, therefore, are more likely when large numbers of units of plasma rather than RBC units are transfused.

### Hypothermia

Hypothermia, defined as a core body temperature of less than 35°C, may be caused by rapid infusion of large quantities of cold (1°C to 10°C) blood or RBC units. Hypothermia during massive transfusion has been shown to induce cardiac arrhythmia and arrest.<sup>87</sup> Even smaller quantities of cold blood can be cardiotoxic if transfused into central venous lines, because the newly infused cold blood can reach the heart before sufficient warming has

occurred. Data published in the early 1960s showed that massive transfusion at a rate of approximately 1 unit every 5 to 10 minutes was sufficient to lower the temperature of an esophageal probe behind the right atrium to nearly 30°C.<sup>87</sup> The resulting decrease in sinoatrial node temperature was associated with the development of ventricular fibrillation.

For most routine transfusions given at a standard rate of administration, blood does not have to be warmed.<sup>88</sup> The patient may experience minor chills, but this is easily remedied by warming the patient, as with extra blankets. Transfusion of cold RBC units through central venous lines, however, should be avoided. Indications for warming blood include rapid transfusion, which are generally considered to be more than 50 mL/kg/hour for an adult and more than 15 mL/kg per hour for a child, and exchange transfusion for infants. Because blood warming during certain massive transfusions sometimes delays infusion and impedes resuscitation, it is not always practical. Warming blood for transfusion in the treatment of patients with cold agglutinin disease has a theoretic basis but is debatable because supportive outcome data are lacking.

If blood has to be warmed, an approved warming device should be used and the temperature must be kept below a point where hemolysis occurs.<sup>88</sup> Infusion of thermally injured cells can induce disseminated intravascular coagulation and shock. Heating blood with a device other than an approved blood-warming device, such as a commercial microwave oven, is unacceptable. Blood that has been warmed but not used should not be reissued for another patient because of the increased risk of bacterial proliferation at warmer temperatures.

The maximum flow rate that can be achieved with commercially available blood warmers is 850 mL/minute; however, most can provide a rate of only 150 mL/minute. Most recent research has focused on comparisons between commercial warming devices and the comparison studies usually evaluate warming capability in the rapid transfusion setting.<sup>89</sup> Most of the available federally approved blood warming devices safely warm blood and other intravenous fluids across a range of flow rates. However, while little recent data exist correlating the clinical benefits of warming blood, many emergency centers and trauma services use such devices routinely without incident.

An alternative to using mechanical blood warmers that circumvents such flow limitations is rapid admixture with warm or hot saline solution immediately before transfusion.<sup>88,90</sup> This technique immediately warms a unit of RBCs, yet does not cause significant hemolysis. However, it necessitates that warmed saline solution be available at all times in trauma care and requires attention to technique to avoid the direct infusion of hot saline solution into the patient.

### Reactions Attributed to Microaggregate Debris

Microaggregate debris ranges in diameter from 20 to 120 microns and consists of nonviable platelets, white cells, and strands of fibrin that form in blood during storage.<sup>91,92</sup> Because of their size, microaggregates are not removed from transfused blood with the standard 170- to 260-micron screen filters. A variety of

adverse events have been attributed to the presence of microaggregate debris after large-volume and massive transfusion.

Studies in the 1960s showed that patients undergoing open-heart surgery with cardiopulmonary bypass experienced postperfusion syndrome during the postoperative period. This symptom complex consisted of cerebral and renal dysfunction attributed in part to occlusion of end-organ capillaries with microaggregate debris. Cotton wool (Swank) microaggregate blood filters capable of retaining particles or debris with a size of 40 microns or more appeared to eliminate many of these reactions. During the Vietnam War, some soldiers who underwent massive transfusion experienced respiratory distress syndrome (shock lung). At autopsy, the cause was presumed to be the material found in soldiers' lungs that was positive on a periodic acid-Schiff (PAS) test. Because microaggregate debris stains PAS-positive, this was taken at the time as evidence of the pathologic nature of microaggregate debris.

During the 1970s and 1980s, studies were undertaken to determine whether removal of microaggregate debris from blood was clinically significant.<sup>91</sup> Several studies showed that microaggregate filtration of up to 6 units of blood during either hip or cardiac surgery provided no benefit. Collins et al<sup>93</sup> concluded that the underlying clinical condition rather than the infusion of the microaggregate debris in blood led to the development of the respiratory distress syndrome reported earlier among patients undergoing massive transfusions. Microaggregate blood filters today are used mostly in conjunction with cardiopulmonary bypass pumps and are only rarely used otherwise. With the widespread adoption of leukocyte reduction filtration, routine leukocyte-reduced red cell transfusions are no longer complicated by microaggregate debris because these filters can remove not only leukocytes, but also the larger microaggregate particles. Current studies are investigating the utility of washing stored blood to remove microaggregate debris that accumulates during storage.<sup>94</sup>

---

### Circulatory Overload

Hypervolemia, termed transfusion-associated circulatory overload, is a possible consequence of transfusion in the care of patients with cardiac insufficiency, renal impairment, or already expanded blood volumes, such as patients with chronic anemia. Moreover, patients with restricted blood volumes (such as infants and small children) are at risk of TACO if transfused blood is not reduced to an amount proportional to body mass and intravascular blood volume. The risk of TACO increases with rapid infusion. Circulatory overload increases central venous pressure, causes congestion of the pulmonary vasculature, and decreases lung compliance, manifesting as dyspnea, tachycardia, acute hypertension, and in the extreme, pulmonary edema and left- or right-sided heart failure. Other signs and symptoms of circulatory overload include tachypnea, dry cough, chest or throat tightness, jugular venous distention, and pulmonary rales. Laboratory measurements of circulatory overload include PaO<sub>2</sub>, atrial natriuretic peptide and B-type natriuretic peptide.<sup>95,96</sup> The

latter has a reported 81% sensitivity for detecting circulatory overload in the appropriate clinical setting. Diagnosing TACO can be difficult and confounded by other concomitant pathology. There is no accepted clinical definition of TACO and the symptoms of TACO can overlap significantly with other transfusion reactions such as TRALI (Table 53-1).<sup>97,98</sup> Some rapid methods of differentiating the overlapping symptoms include blood pressure, response to diuretic therapy, white cell count, and heart auscultation for an S3 (third heart sound).

If symptoms of overload appear, the transfusion should be stopped, and intravascular volume reduction through diuresis should be instituted as needed (eg, administration of 40 mg furosemide intravenously). The patient should be placed in an upright (reverse Trendelenburg) position, if possible, with supplemental oxygen as necessary. Phlebotomy may be considered for severe volume overload, although this is not usually prudent in the setting of anemia or hypoxemia.

Rapid transfusion of any blood component into a patient who is not actively hemorrhaging produces no benefit and can cause harm. As a general guide, infusion should be at a rate not to exceed 2 to 4 mL/kg/hour, and the rate should be lower (~1 mL/kg/hour) for patients at high risk of circulatory overload.<sup>99</sup> In neonates, a slower blood infusion rate increases the hematocrit and decreases cardiac demand without affecting pulmonary artery pressure. More rapid infusion rates are associated with decreased lung compliance and increased pulmonary airflow resistance.<sup>100,101</sup>

For patients with volume overload caused by medical reasons existing before transfusion, furosemide can be given prophylactically, and transfusion should proceed slowly. The rate of transfusion can be even further slowed, if necessary, by dividing a unit of RBCs or another component into smaller

aliquots and transfusing a portion at a time over as much as 4 hours, the maximum allowable time a blood component should be kept outside blood-bank-monitored storage. For RBCs and thawed plasma, the unused portion can be stored in the blood bank at 1°C to 6°C for up to 24 hours while the initial aliquot is administered. Platelet aliquots can be sampled from a single apheresis platelet unit, and with this practice, donor exposures can be minimized. It is important that transfusion of all or part of a blood component be completed within 4 hours and that any unused portion be stored under regulated blood bank conditions because of concerns about increased risk of bacterial contamination during improper storage. RBC units, apheresis platelets, and whole-blood-derived platelet pools can be further concentrated by means of centrifugation and plasma removal, if other measures to prevent volume overload are inadequate.

**Toxic Reactions Resulting from Blood Manufacture or Processing**

**Hypotensive Reactions**

Hypotension has been reported among patients receiving bedside, leukocyte-reduced platelets who are also medicated with angiotensin-converting enzyme (ACE) inhibitors.<sup>102</sup> These reactions appear to be caused by generation of bradykinin in transfused blood just as it is being passed through negatively charged leukocyte reduction filters. The mechanism is believed to involve the formation of activated Factor XIIa when Factor XII, a contact factor, is exposed to the negatively charged filter surface. The filter surface can mimic exposed, negatively charged subendothelium, which is the natural activating stimulus for the contact factors

**Table 53-1.** Features in TRALI and TACO

| Feature               | TRALI                                                                                      | TACO                                                                                                               |
|-----------------------|--------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------|
| Body temperature      | Fever can be present                                                                       | Unchanged                                                                                                          |
| Blood pressure        | Hypotension                                                                                | Hypertension                                                                                                       |
| Respiratory symptoms  | Acute dyspnea                                                                              | Acute dyspnea                                                                                                      |
| Neck veins            | Unchanged                                                                                  | Can be distended                                                                                                   |

| Leukocyte antibodies  | Donor leukocyte antibodies present, crossmatch incompatibility between donor and recipient | Donor leukocyte antibodies may or may not be present, positive results can suggest TRALI even with true TACO cases |

The typical patterns that would be expected for cases of transfusion-related acute lung injury (TRALI) or transfusion-associated circulatory overload (TACO) are represented. A given case of TRALI or TACO may lack some of the typical features. Also, a case of TRALI may have some features suggesting TACO or vice versa, and TRALI and TACO can be present together. The best strategy is to develop a full clinical profile of the case using the feature list above, and determine which diagnosis is most supported.

BNP = brain natriuretic peptide; PA = pulmonary artery.

of the intrinsic coagulation pathway after blood vessel damage *in vivo*. Factor XIIa converts prekallikrein to kallikrein, which cleaves high-molecular-weight kininogen to form bradykinin. The biologic activity of the infused bradykinin is prolonged in transfusion recipients who are also receiving ACE inhibitors (eg, captopril, enalapril), which inhibit kininase II, the enzyme that breaks down bradykinin. The combination of bradykinin generation just as the blood is being infused with inhibition of the transfusion recipient's ability to break down bradykinin produces prolonged bradykinin activity conducive to hypotensive reactions.

These reactions are less likely with use of prestorage leukocyte-reduced blood components, because the bradykinin is broken down rapidly in the component bag during storage before transfusion. Although hypotensive reactions have been reported more frequently with negatively charged bedside leukocyte reduction filters, they also have been rarely reported with positively charged filters. This can be explained in part by the possibility that patients taking ACE inhibitors may be more prone to hypotensive reactions in general because of their relative inability to rapidly break down bradykinin generated *in vivo* by any allergic mechanism. Hypotensive reactions to bedside leukocyte reduction among patients taking ACE inhibitors can be prevented by use of prestorage leukocyte-reduced blood components or by means of temporary discontinuation of ACE inhibitor treatment.

Apheresis procedures are also associated with hypotensive reactions and the literature has described hypotensive reactions in both adult and pediatric apheresis patients.<sup>103,104</sup> Apheresis may contribute to hypotensive reactions through several mechanisms including the potentiation of bradykinin-mediated effects by albumin and secondary to hypocalcemia.<sup>104,105</sup> Data suggest that calcium infusions can mitigate some atypical apheresis reactions, while withholding ACE inhibitor medications 24 to 48 hours before apheresis may also contribute to lessening reactions.

### Ocular Reaction to Leukocyte-Reduced Blood Components: Red Eye Syndrome

Some patients receiving transfusions of RBCs prestorage leukocyte reduced with a specific filtration system (LeukoNet Prestorage Leukocyte Reduction Filtration System, HemaSure, Marlborough, MA) sustained bilateral conjunctival erythema (red eye syndrome).<sup>106</sup> The conjunctival erythema occurred within 24 hours of transfusion. Resolution occurred spontaneously within 2 to 21 days with a median duration of 5 days. The implicated prestorage leukocyte reduction system has been discontinued, and red eye syndrome has not been reported with other leukocyte reduction filters.<sup>107</sup> The red eye symptoms are hypothesized to be an allergic or toxic reaction to cellulose acetate derivatives that leached from the filter membrane.

### Plasticizer Toxicity

Plasticizers are chemicals used to make rigid polyvinyl chloride plastics more malleable. The traditional plasticizer for blood storage bags is di(2-ethylhexyl)phthalate (DEHP), which leaches over time from the plastic into the blood and blood components

with increasing exposure. The DEHP metabolite, mono(2-ethylhexyl)phthalate (MEHP), also accumulates during storage.<sup>108</sup> Infusion of blood that contains DEHP results in deposition of DEHP in various tissues; the greatest accumulation is in body fat. Results of some studies with animals have suggested that DEHP is toxic and may even be carcinogenic in large quantities.<sup>109</sup> Other studies with animals have shown that MEHP is associated with formation of peroxisomes, indicating tissue alteration and toxicity. Although there have been no reports of transfusion-related plasticizer toxicity among humans, results of some *in-vitro* experiments suggest that high concentrations of MEHP have a negative inotropic effect and can cause irregular contractions in isolated human myocardial cells. Some clinical data have described the production of antiplasticizer IgE in transfusion recipients and the incorporation of plasticizer into red cells during storage.<sup>110</sup> Despite the possible adverse effects of DEHP plasticizers, other data indicate that these substances stabilize red cell membranes and improve the morphologic features of platelets during storage.<sup>111,112</sup> No good evidence exists, however, of actual improvement in posttransfusion outcomes as the result of these effects.

Formulations for plastic blood bags are being developed with plasticizers other than DEHP that have a decreased capacity to leach into plasma. For example, one polyvinyl-chloride-based material is made with plasticizer butyryl tri-*n*-hexyl citrate (BTHC). Although BTHC also leaches into blood components, it does so at a significantly slower rate than does DEHP. It also provides an antihemolytic effect similar to that of DEHP.<sup>113</sup> Studies have shown this citrate-based plasticizer is suitable for storage of both RBCs and platelets.<sup>114</sup> Given the concerns over the risk of DEHP toxicity, other plasticizers and storage materials continue to be sought in an attempt to replace traditional storage materials. The possible human toxicity of DEHP continues to be evaluated.<sup>115-117</sup> (See also Chapter 4.)

### Dimethyl Sulfoxide Toxicity During Infusion of Cryopreserved Progenitor Cells

Dimethyl sulfoxide is a versatile solvent that has been used as the principal cryopreservative for mononuclear cells since the 1950s. It is widely used as a cryopreservative for marrow and PBSCs used in human hematopoietic progenitor cell transplantation. Despite this, DMSO is not approved by the Food and Drug Administration as a pharmacologic agent for intravenous administration, and guidelines for intravenous administration are obscure. Toxicologic studies, however, have established the general safety of intravenous DMSO infusion.<sup>118,119</sup> The metabolism of DMSO yields a characteristic harmless odor, described as a malodorous garlic or sulfur-like smell. Because of the exceptional solvent properties of the compound, DMSO is distributed throughout all tissues after administration. The two metabolites of DMSO are dimethyl sulf dioxide and dimethyl sulfide (DMS). Dimethyl sulf dioxide is an odorless compound excreted by the kidney, and DMS is excreted through the lungs and through other tissues and contributes to the characteristic odor.

The clinical toxicity of DMSO in marrow transplantation has been studied. Anaphylactoid symptoms attributable to the release

of histamine and other mediators are common. Other toxic clinical signs and symptoms include hemolysis with hemoglobinuria, hyperosmolality, increased serum transaminase values, nausea, vomiting, abdominal cramping, fever, chills, tachypnea, cough, diarrhea, flushing, and headache.<sup>120,121</sup> Patients who have been conditioned with chemotherapy or who have smaller body mass (<70 kg), seem more likely to experience nausea and vomiting after infusion of DMSO-preserved cells. Cardiovascular toxicities include decreased heart rate and bradycardia, occasionally increased heart rate and tachycardia, ectopic heartbeat, heart block, hypotension, hypertension, and other lesser blood pressure changes.<sup>120,122</sup> Some studies, however, raise the question whether there is any significant cardiovascular toxicity of DMSO.<sup>123</sup> It is possible that some adverse effects attributed to DMSO may be caused by the cellular infusion itself.

The mechanism of the clinical toxicities associated with DMSO infusion has not been well established. Histamine receptor binding of DMSO, histamine release, direct vagal tonic effects, cold thermal vagal responses, and renal failure secondary to hemolysis explain many of the symptoms observed during cryopreserved cellular infusion.<sup>120,124</sup> Increases in thrombin-antithrombin complex,  $\beta$ -thromboglobulin, platelet factor 4, and von Willebrand factor caused by DMSO have been described.

Several measures can be taken to prevent or reduce DMSO toxicity. Antihistamine prophylaxis is recommended routinely before any administration of DMSO. Intravenous DMSO should be given as a 10% to 40% solution to avoid local irritation. The recommended maximum daily dose of DMSO is 1 g/kg/day. Slowing an infusion containing DMSO or increasing the time between infusions of multiple aliquots greatly diminishes DMSO-related toxicity, which appears to be a dose-dependent but short-lived response. However, because DMSO is toxic to thawed mononuclear cells, hematopoietic progenitor cells can tolerate exposure to 10% DMSO for only as long as 1 hour.<sup>125</sup> This limits how much the infusion rate can be slowed. Antiemetics and sedatives can help to ameliorate symptoms, and cellular products can be carefully washed before infusion to remove DMSO and other substances.

## Reactions in Special Transfusion Settings

### Granulocyte Transfusion Reactions

Granulocyte transfusions remain in use as a treatment option for neutropenic patients because of improved granulocyte collection yields after donor treatment with steroids and granulocyte colony-stimulating factor (G-CSF). Febrile nonhemolytic transfusion reactions after granulocyte transfusion are common. Severe reactions can be accompanied by pulmonary complications (eg, TRALI, dyspnea, pulmonary infiltrates, and hypoxia), hypotension, and even cardiovascular collapse.<sup>126</sup> In a recent study of dexamethasone- and G-CSF-stimulated granulocyte transfusions, 37% of patients (7% of transfusions) experienced chills, 32% of patients (7% of transfusions) experienced a fever, and 11% of patients (2% of transfusions) experienced hives

or itching during a course of therapy.<sup>127</sup> Oxygen desaturation of greater than 3% occurred in 7% of transfusions, and severe desaturation of greater than 6% occurred in three of 11 patients experiencing oxygen desaturation. In addition, granulocyte transfusions carry further risk of leukocyte alloimmunization and cytomegalovirus infection.<sup>128</sup>

Concurrent administration of amphotericin B and granulocytes has been linked to severe pulmonary reactions, although the association has not been confirmed and remains in doubt. Nevertheless, it is prudent to separate amphotericin B administration and granulocyte therapy by at least 6 hours to avoid confusion about the cause of a severe reaction, which can occur with either of these reaction-prone treatments. Because of the relatively high rate and severity of febrile, pulmonary, and allergic reactions, it is prudent to give premedication with acetaminophen and diphenhydramine to recipients of granulocyte transfusions. Hydrocortisone may be added as premedication in the treatment of patients with severe reactions who otherwise cannot tolerate granulocyte transfusion, although the immunosuppressive effects of this agent are unwelcome among patients who need granulocyte transfusions to fight serious and life-threatening infections. Granulocyte concentrates should be transfused slowly.

### Autologous Transfusion Reactions

A variety of reactions to autologous blood occur despite the complete compatibility. In a study involving 596 hospitals, the rate of reported FNHTRs to autologous blood was 0.12% and the rate of allergic reactions was 0.01% per transfused unit.<sup>129</sup> Such rates are approximately fivefold to 10-fold lower than those reported for allogeneic units. The cause of autologous transfusion reactions has not been clearly established. Mechanisms in many cases presumably are the same as for allogeneic transfusions. For example, autologous units can be contaminated with bacteria as can allogeneic units, and contamination leads to febrile reactions or septic complications.<sup>130</sup> Because autologous donors are patients, not healthy volunteers, they may have various medical problems that put them at increased risk of bacteremia.

Accumulation of inflammatory mediators in blood component bags during storage, released from passenger leukocytes or platelets, may result in the infusion of pyrogenic substances. Autologous leukocytes, rather than allogeneic leukocytes, can also generate endogenous pyrogens. Allergic reactions may be provoked by histamine generation during storage of blood components or by chemicals leached from blood storage containers or filters. Moreover, autologous transfusions may contribute to volume overload and hypervolemic reactions through mechanisms identical to allogeneic transfusions.

## Summary

A variety of acute, nonhemolytic and noninfectious reactions are reported after transfusion (Table 53-2). Many of these reactions

**Table 53-2.** Transfusion Reaction Summary

| Type                                                      | Cause                                                                                                                                                                                                  | Signs and Symptoms                                                                                                                                                                                | Treatment                                                                                                                                                                                                                                                                  | Prevention                                                                                                                                                                                                                                           |

| <i>Febrile, nonhemolytic</i>                              | Recipient antibodies against leukocytes or platelets in donor blood components; cytokines in plasma or supernatant portion of stored components; undetected bacterial contamination of blood component | Chills, fever ( $>1^{\circ}\text{C}$ increase in body temperature); rigors in severe reactions                                                                                                    | Stop transfusion, notify physician and blood bank, maintain IV line, monitor vital signs; physician may order acetaminophen                                                                                                                                                | Premedicate with acetaminophen (or glucocorticoid for refractory cases); give leukocyte-reduced RBCs                                                                                                                                                 |
| <i>Allergic</i>                                           | Allergen is a soluble substance in donor plasma                                                                                                                                                        | Localized or generalized urticaria, erythema and pruritus; if severe, may have laryngeal or facial angioedema, and hypotension                                                                    | Hold transfusion, notify physician, monitor vital signs; physician may order antihistamines or restart of transfusion if mild urticaria clears and no other symptoms in 30 minutes                                                                                         | Premedicate with $\text{H}_1$ blocking antihistamine; add $\text{H}_2$ blocker or glucocorticoid for refractory cases; consider washed RBCs and platelets for repeated or severe reactions                                                           |
| <i>Anaphylactic or anaphylactoid</i>                      | Recipient antibodies to a soluble substance in donor plasma; infusion of plasma with IgA into IgA-deficient recipient with anti-IgA                                                                    | Urticaria, flushing, angioedema, stridor, wheezing, tachycardia, hypotension, shock, abdominal pain, diarrhea, pelvic pain                                                                        | Stop transfusion; maintain IV line; notify physician and blood bank, monitor vital signs; physician may order antihistamines, epinephrine, oxygen, IV crystalloid, or glucocorticoids                                                                                      | Premedicate with antihistamines and glucocorticoid; transfuse washed RBCs and platelets for recurrent reactions; use IgA-deficient donors or washed RBCs and platelets for sensitized patients with IgA deficiency                                   |
| <i>Transfusion-associated circulatory overload (TACO)</i> | Blood volume too large or infusion too fast for compromised cardiovascular system                                                                                                                      | Dyspnea, orthopnea, systolic hypertension, headache, peripheral edema, coughing, cyanosis                                                                                                         | Slow or stop transfusion; keep IV line open; notify physician; monitor vital signs and input and output; physician may order diuretics and oxygen                                                                                                                          | Transfuse slowly; use split units; consider premedication with diuretics; carefully monitor aged, debilitated, or cardiac patients                                                                                                                   |
| <i>Hypothermia</i>                                        | Core body temperature $<35^{\circ}\text{C}$ caused by rapid infusion of cold blood products, such as RBCs, FFP, cryoprecipitate                                                                        | Decreased body temperature, chills, cardiac arrhythmia (ventricular fibrillation)                                                                                                                 | Slow or stop transfusion; use an approved blood warmer, blankets, and other patient warming techniques (warm lavages, lamps)                                                                                                                                               | Transfuse slowly, use an approved blood warmer                                                                                                                                                                                                       |
| <i>Citrate toxicity</i>                                   | Excessive infusion of citrate during apheresis procedure or massive or rapid transfusion; patients with liver failure are at increased risk                                                            | Perioral or peripheral paresthesia, tingling, buzzing, teeth chattering, bed or chair moving, cramps, nausea, vomiting, arrhythmia, bradycardia, hypotension, prolongation of QT interval, tetany | Slow or stop transfusion; slow or stop apheresis procedure; give IV calcium chloride or gluconate (for PBSC apheresis: 0.5 mg $\text{Ca}^{2+}$ /1.0 mL ACD-A), or check ionized $\text{Ca}^{2+}$ and dose per results; monitor relief of symptoms; consider hypomagnesemia | More likely in lightweight patients ( $<70$ kg) and patients with liver dysfunction, renal failure, or less skeletal muscle; observe patients closely for any symptoms, give IV calcium (for PBSC apheresis: 0.5 mg $\text{Ca}^{2+}$ /1.0 mL ACD-A). |

Table 53-2. (Continued)

| Type                        | Cause                                                                                                                                                                                                                                                                     | Signs and Symptoms                                                                                                                                                                                   | Treatment                                                                                                                                | Prevention                                                                                                                                                                                                                                                                     |
|-----------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <i>Electrolyte disorder</i> | Hyperkalemia: transfusion of older blood components or massive transfusion of RBCs                                                                                                                                                                                        | Hyperkalemia: cardiac arrhythmia, ECG changes—peaked T waves, prolongation of PR interval (if severe, flat or lost P wave), widened QRS, ventricular arrhythmia                                      | Hyperkalemia: give calcium to protect against cardiac effect, alkalinize blood, D50 plus insulin, sodium polystyrene sulfonate; dialysis | Hyperkalemia: give fresh products (<7 days old), or washed products                                                                                                                                                                                                            |
|                             | Hypokalemia: massive or rapid transfusion of citrate and metabolic alkalosis                                                                                                                                                                                              | Hypokalemia: cardiac arrhythmia, ECG changes—ST depression, U waves                                                                                                                                  | Hypokalemia: give potassium                                                                                                              | Hypokalemia: give Adsol-preserved RBCs (not Nutricel).                                                                                                                                                                                                                         |
| <i>Hypotensive</i>          | Bradykinin generation with use of negatively charged bedside leukocyte reduction filters in patients taking angiotension-converting enzyme (ACE) inhibitors; apheresis procedures using albumin, especially in patient's taking ACE inhibitors; see also citrate toxicity | Hypotension; sometimes also flushing, respiratory distress, nausea, abdominal pain, and loss of consciousness                                                                                        | Stop transfusion, notify physician and blood bank; support blood pressure.                                                               | Avoid use of bedside leukocyte reduction filters in patients taking ACE inhibitors; use prestorage leukocyte-reduced components or discontinue ACE inhibitor before transfusion or apheresis procedure; if during apheresis, correct electrolyte disorder such as hypocalcemia |
| <i>DMSO toxicity</i>        | Cryopreservative for bone marrow, PBSCs, donor lymphocyte infusions, or any frozen cellular component; toxicity with DMSO >1.0 g/kg/day                                                                                                                                   | Flushing, nausea, vomiting, abdominal cramping, throat tightness and cough, hypotension, hypertension, arrhythmia, fever, chills, headache, hemoglobinuria, hyperosmolality, increased liver enzymes | Antihistamines; antiemetics; slow or stop the infusion; supportive care; wait between infusions for symptoms to clear                    | Antihistamines; washed or plasma or volume depleted cellular infusions; antiemetics                                                                                                                                                                                            |

IV = intravenous; RBCs = Red Blood Cells; FFP = Fresh Frozen Plasma; PBSC = peripheral blood stem cell; ACD-A = acid-citrate-dextrose-adenine; D50 = dextrose 50% in water; ECG = electrocardiogram; DMSO = dimethyl sulfoxide.

have an immune basis and represent inflammatory or allergic responses to infused cells (eg, many FNHTRs) or plasma (eg, some FNHTRs, allergic, and anaphylactic reactions). Although urgent transfusion can be lifesaving, it is important to recognize that a large volume of blood components given too quickly can itself have adverse chemical or physical effects, such as hypothermia, hyperkalemia, hypokalemia, hypocalcemia, and circulatory overload. Some reactions also are caused by unintended consequences of blood storage conditions or processing, such as generation of bradykinin by the contact of blood with some filter surfaces, leaching of toxic chemicals from filters or containers, and use of the chemical DMSO during hematopoietic progenitor cell preservation. It is important that these reactions and toxicities be recognized rapidly by the patient care team and blood bank personnel so that appropriate treatment and preventive measures can be instituted quickly. Care providers who administer transfusions must recognize that some symptoms of transfusion reactions, such as fever, are nonspecific and may be early manifestations of potentially life-threatening reactions, such as hemolysis or sepsis (Table 53-3). For that reason, the guiding rule regarding most transfusion reactions is to err on the side of conservatism and stop the transfusion immediately. Transfusion of a blood component that causes a reaction before complete infusion should not be restarted, with the possible exception of mild urticarial reactions. Several strategies are available to prevent repeated reactions among patients who are reaction-prone. These include leukocyte reduction for the prevention of FNHTR, cell washing for the prevention of allergic and anaphylactic reactions and possibly some FNHTRs, and various premedication regimens.

**Table 53-3.** Overlapping Signs and Symptoms of Transfusion Reactions

| Sign or Symptom     | Possible Reaction                                          | Most Likely > Less Likely Blood Component*     |
|---------------------|------------------------------------------------------------|------------------------------------------------|
| Fever, chills       | Febrile nonhemolytic<br>Septic<br>Acute hemolytic<br>TRALI | Platelets (especially septic)<br>>RBCs >Plasma |
| Urticaria, pruritus | Allergic<br>Anaphylactic                                   | Plasma >Platelets >RBCs                        |
| Dyspnea             | TACO<br>TRALI<br>Anaphylactic                              | Any                                            |
| Hypotension         | Septic<br>Hypotensive<br>Acute hemolytic<br>Anaphylactic   | Platelets >plasma >RBCs                        |

\*Granulocytes would very likely cause febrile reactions and dyspnea. However, granulocytes are not listed in the table because they are infrequently transfused compared to other blood components.

RBCs = Red Blood Cells; TRALI = transfusion-related acute lung injury; TACO = transfusion-associated circulatory overload.

**John E. Levine<sup>1</sup> & James L. M. Ferrara<sup>2</sup>**<sup>1</sup>Professor of Pediatrics and Internal Medicine, and Clinical Director, Pediatric Blood and Marrow Stem Cell Transplantation Program, University of Michigan, Ann Arbor, Michigan, USA<sup>2</sup>Professor of Pediatrics and Internal Medicine, and Director, Combined Blood and Marrow Transplantation Program, University of Michigan, Ann Arbor, Michigan, USA

Transfusion-associated graft-vs-host disease (TA-GVHD) is a phenomenon that can occur after blood transfusion in which donor T cells, responding to proteins on host cells, proliferate and target host organs, primarily the skin, liver, intestinal tract, and marrow. Although this complication is uncommon, considerable effort has been devoted to GVHD prevention, because of the lack of effective treatment and very high mortality rate. Immunocompromised patients are at greatest risk for TA-GVHD; therefore, prevention strategies initially focused on this population. More recently it has become recognized that TA-GVHD can develop in the apparently immunocompetent transfusion recipient. Patients most likely to develop TA-GVHD include very low birthweight premature infants, critically ill patients receiving extracorporeal membrane oxygenation, patients who require cardiopulmonary bypass, and recipients of blood transfusions from family members. This chapter outlines the pathophysiology and clinical manifestations of TA-GVHD, defines the risk factors, and identifies measures to prevent TA-GVHD.

### Pathophysiology of GVHD

In 1966, Billingham postulated that three requirements existed for the development of GVHD: the graft must contain immunologically competent cells, there must be antigenic differences between the donor and the recipient, and the recipient must be unable to mount an effective immunologic response to eradicate the transplanted immunologically competent cells.<sup>1</sup> T cells are the immunologically competent cells that induce GVHD and can be transferred from one person to another in a variety of clinical settings, including blood component transfusions and organ and marrow transplants. Under most circumstances, the recipient immune system is able to eliminate the transferred T cells. However, when the recipient is immunosuppressed (either from

inherited or acquired immunodeficiency or induced immunosuppression, as is the case in transplant recipients) GVHD can develop. Immunocompetent individuals can develop TA-GVHD, although this is a very rare event.

Most of our understanding of the pathophysiology of GVHD comes from the hematopoietic stem cell transplant (HSCT) setting. In HSCT, presentation of host antigen to donor cells often occurs in the context of host tissue damage and inflammation, from a combination of factors including the underlying disease, infection, and the HSCT conditioning regimen, which often includes high-dose chemotherapy and radiation therapy. Donor cells are transplanted into an environment of ubiquitous foreign antigens, activated cytokines, enhanced expression of adhesion molecules, and cell surface recognition molecules. Donor cells that participate in the resulting immune process include T cells, natural killer (NK) cells, and monocytes.

A modern paradigm for GVHD development considers three consecutive phases: 1) the presentation of host protein to donor T cells by antigen-presenting cells (APCs); 2) donor T-cell activation, proliferation, and migration; and 3) host target tissue damage (Fig 54-1). Host APCs are both necessary and sufficient to stimulate donor T cells to proliferate in response to host antigen.<sup>2-5</sup> T-cell receptors (TCRs) recognize fragments of proteins known as minor histocompatibility antigens bound to Class I and II major histocompatibility complex (MHC) molecules on the surface of APCs. The Class I MHC molecules (HLA-A, -B, -C) stimulate CD8+ T cells, while the Class II MHC molecules (HLA-DR, -DP, -DQ) present to CD4+ T cells.<sup>6,7</sup> The additional presence of “danger signals”—such as lipopolysaccharide (LPS) or inflammatory cytokines—help APCs activate T cells<sup>8,9</sup> and the presence/absence of “danger signals” may make the difference between an immune response and tolerance.<sup>10</sup>

Activated T cells can have proinflammatory (Th1) or anti-inflammatory (Th2) phenotypes. Th1 cells secrete interleukin (IL)-2, interferon (IFN)- $\gamma$ , and tumor necrosis factor alpha (TNF- $\alpha$ ) while Th2 cells secrete IL-4, IL-5, IL-10, and IL-13.<sup>11</sup> Th1 cells are important in the pathogenesis of acute GVHD and targeting these cells reduced acute GVHD in an experimental

## GVHD pathology

**Figure 54-1.** The pathophysiology of acute GVHD.

In Step I, the conditioning regimen of chemotherapy, radiotherapy, or both leads to host tissue damage, especially in the intestines. This allows translocation of lipopolysaccharide (LPS) from the intestine into the circulation, stimulating the secretion of inflammatory cytokines, including interleukin (IL)-1, IL-6, and tumor necrosis factor alpha (TNF- $\alpha$ ). In Step II, cytokine-stimulated host antigen-presenting cells (APCs) present host antigen to donor T cells, resulting in activation of donor T cells with a predominance of the Th1 phenotype that secrete interferon- $\gamma$  (IFN- $\gamma$ ) and IL-2. In Step III, effector cells, cytotoxic T cells, and natural killer cells, induce target cell apoptosis both by direct cell-mediated lysis and the secretion of inflammatory cytokines that independently induce target cell apoptosis.

model.<sup>12</sup> In clinical practice, decreasing IL-2 production by donor T cells is a primary target of current GVHD prophylaxis strategies by using the calcineurin inhibitors cyclosporine or tacrolimus. In contrast, the Th2 cytokine IL-10 plays a key role in suppression of immune responses and may have a role in regulating acute GVHD severity.<sup>13,14</sup> Regulatory T cells, a third subset of T cells, also influence the development of GVHD. In animal models, adding regulatory T cells to the donor graft suppresses the proliferation of conventional T cells, and prevents GVHD.<sup>15</sup> Murine regulatory T cells, which are identifiable by Foxp3 expression, normally constitute 5% of the CD4+ T-cell population. These cells secrete IL-10 and transforming growth factor beta (TGF- $\beta$ ), which inhibit the immune response. The regulatory T cells also inhibit APCs by a contact-dependent pathway.<sup>15</sup>

Migration of T cells from lymphoid tissues to target organs is controlled by chemokines. In experimental GVHD, proinflammatory chemokines, such as macrophage inflammatory protein-1 alpha (MIP-1 $\alpha$ ), CCL2-5, CXCL2, CXCL9-11, CCL27 are overexpressed. The chemokines may have organ-specific roles. For example, CXCR3+ cells cause acute GVHD in the liver and intestine.<sup>16</sup> In animal models, migration of CCR5+ regulatory T cells to lymphoid tissues and target organs is necessary for GVHD control.<sup>17</sup>

Experimental and clinical data indicate that target organ injury results from both soluble inflammatory mediators and cell-mediated cytotoxicity. The principal effector mechanism by which cytotoxic T lymphocytes (CTLs) and NK cells lyse target cells are the Fas/Fas

ligand (FasL) and perforin/granzyme pathways.<sup>18,19</sup> Fas is an apoptosis-signaling receptor molecule on the surface of a number of different cells. When FasL binds to Fas, a death-inducing signaling complex is formed, which results in the subsequent activation of caspases.<sup>20</sup> CTLs and NK cells store perforin with granzyme in cytotoxic granules. Perforin inserts itself into the target cell membrane, forming pores that allow granzymes to enter the cells and induce apoptosis through various downstream effector pathways.<sup>21</sup> Inflammatory cytokines synergize with CTLs, resulting in amplification of local tissue injury and development of target organ dysfunction. A key inflammatory cytokine, especially for intestinal GVHD, is TNF- $\alpha$ , which plays a major role in the amplification and propagation of the “cytokine storm” characteristic of acute GVHD developing early after HSCT.<sup>22</sup> TNF- $\alpha$ , which is produced by both donor and host cells, promotes GVHD and target organ damage by three different ways: first, it activates dendritic cells and enhances alloantigen presentation; second, it recruits effector cells to target organs via the induction of inflammatory chemokines; and third, it directly causes tissue necrosis, as its name suggests.<sup>23-25</sup>

## Features of TA-GVHD

### Incidence of TA-GVHD

The incidence of TA-GVHD is unknown because the diagnosis can be missed; other conditions, such as infection or drug

reactions, may have similar clinical features. However, changes in practice appear to have lowered the already low incidence even further. The use of cellular components that have been gamma irradiated to 25 Gy appears to offer essentially complete protection to patients known to be at high risk for TA-GVHD.<sup>26</sup> In the 10 year period from 1996 to 2005, 13 cases of TA-GVHD were reported via a national identification program. The implementation of universal leukocyte reduction in the United Kingdom (UK) in 1999 appears to have resulted in a statistically significant further reduction of TA-GVHD; of the 13 cases, 11 occurred in patients who received non-leukocyte-reduced (LR) components and only two occurred following transfusion of LR components. No cases of TA-GVHD have been reported in the UK since 2001.<sup>27</sup>

### Risk Factors for Developing TA-GVHD

As noted above, the transfusion of viable T cells is necessary to develop TA-GVHD. GVHD can develop after transplantation of as few as  $4 \times 10^3$  T cells/kg recipient weight,<sup>28</sup> although other studies indicate that acute GVHD is not seen when fewer than  $1$  to  $5 \times 10^5$  T cells/kg recipient weight are transplanted.<sup>29,30</sup> The average unit of Red Blood Cells (RBCs) contains approximately  $2 \times 10^9$  leukocytes, each whole-blood-derived platelet unit contains approximately  $4 \times 10^7$  leukocytes, and apheresis platelets contain approximately  $1 \times 10^8$  leukocytes.<sup>31</sup> Leukocyte reduction reduces the number of passenger T cells by 2 to 3 logs, but has not been able to completely prevent TA-GVHD.<sup>32-34</sup> A 2-log reduction of viable leukocytes can be achieved by washing red cells<sup>34</sup> and a 2 to 3 log reduction is attained by freezing-deglycerolization.<sup>34,35</sup> For obvious reasons, leukocyte reduction is not performed with therapeutic white cell transfusions, and these can lead to TA-GVHD.<sup>36,37</sup> Irradiating these cells can prevent GVHD (as discussed below), but donor leukocyte transfusions given to induce a graft-vs-leukemia effect following post-HSCT relapse are not irradiated and GVHD often results.<sup>38</sup> TA-GVHD has not been reported with the use of cell-free plasma products, including Fresh Frozen Plasma, because the freezing-thawing process destroys T cells.<sup>39</sup> Unfrozen plasma has caused TA-GVHD,<sup>40</sup> but is now rarely used.

Because TA-GVHD is caused by the engraftment of viable T lymphocytes, the primary risk factor for development of TA-GVHD is an inability to reject donor T lymphocytes. The mechanisms are the same as those discussed for HSCT GVHD. It is of interest that TA-GVHD has been reported in only one patient with human immunodeficiency virus (HIV)/AIDS.<sup>41</sup> Despite their immunodeficiency, HIV/AIDS patients appear to be resistant to engraftment of donor T lymphocytes, for unclear reasons.<sup>42</sup>

### Fetuses and Neonates

Maternal lymphocytes regularly cross over into fetal circulation, but under most circumstances GVHD does not develop, indicating that the fetus has immunologic defense mechanisms against maternal lymphocyte engraftment.<sup>43</sup> Nonstimulated bidirectional mixed lymphocyte cultures have shown that neonatal lymphocytes specifically dominate against maternal lymphocytes, which may partly account for the neonatal protection against

maternal lymphocytes.<sup>44</sup> However, the fetal immune system does not completely protect against adult lymphocytes as demonstrated by the development of TA-GVHD following intrauterine transfusion (IUT). Liley performed the first successful intraperitoneal IUT to treat hemolytic disease in 1963.<sup>45</sup> Not long afterwards, it became apparent that IUT could lead to TA-GVHD.<sup>46,47</sup> As a result, transfusion with LR and irradiated blood was initiated to prevent TA-GVHD. However, up to one-third of recipients of nonirradiated, non-LR transfusions engrafted donor leukocytes, without any GVHD or other apparent disorder of the immune system, and these donor leukocytes were detectable up to 25 years following IUT.<sup>48</sup> The mechanisms behind this selective tolerance for the donor cells are unclear, but may involve downregulation of molecules essential for immune recognition. It is also possible that tolerance between the fetus and the donor may develop because of the following:<sup>49</sup>

1. Lack of host immune surveillance because of immaturity.
2. Inadequate expression of target antigens in fetal tissue.
3. Presence of maternal lymphocytes that protect against GVHD.

TA-GVHD in neonates transfused postnatally is very rare. Most cases of TA-GVHD in immunocompetent newborns occur following transfusions from haploidentical or homozygous donors. Therefore, it is not surprising that most reports come from Japan, where there is a high degree of HLA homozygosity. Another risk factor may be prematurity. In one Japanese study, 20 of 27 newborns who developed TA-GVHD were premature.<sup>50</sup> Most of the newborns received a blood component from a relative. TA-GVHD developed a median of 28 days from transfusion with fever typically the presenting sign, followed by GVHD rash. The mortality rate was 100%. The implementation of routine irradiation of blood and blood components before transfusion in newborns; congenital immunodeficient recipients; elderly recipients; and cardiac, cancer, and severe trauma surgery patients, has reduced the number of TA-GVHD cases in Japan to just a few cases in recent years.<sup>51</sup>

### TA-GVHD in Immunodeficient Patients

TA-GVHD occurs in T-cell deficient patients, who lack the ability to reject the donor T cells, usually caused by a congenital immunodeficiency syndrome, treatment for malignancy, or solid-organ transplantation (Table 54-1).

### Congenital Immunodeficiency Syndromes

TA-GVHD has been reported in a wide array of congenital immunodeficiency syndromes, including severe combined immunodeficiency (SCID) syndrome, Wiskott-Aldrich syndrome, purine nucleoside phosphorylase deficiency, and DiGeorge syndrome.<sup>52-56</sup> As expected, a common feature to these disease entities is abnormal or absent T-cell function.

### Malignancies

TA-GVHD has been reported to occur following nonirradiated transfusion in patients undergoing treatment for cancer.<sup>37,57-69</sup> It is not clear if the presence of malignancy alone increases the

risk of TA-GVHD, or if the problem is caused by the immunosuppressive effects of treatment. Most cases of TA-GVHD have been reported for patients with hematologic malignancies such as leukemia or lymphoma but there have been rare cases of TA-GVHD in patients with solid tumors such as neuroblastoma and rhabdomyosarcoma. This observation suggests that it is the immunosuppressive effect of the cancer treatment that increases the risk of TA-GVHD because antileukemia and antilymphoma treatment tends to be more immunosuppressive than treatment for solid tumors. However, there has been no systematic attempt to correlate the extent or duration of therapy to the development of TA-GVHD. One specific chemotherapeutic agent, the purine analog fludarabine, has been associated with TA-GVHD.<sup>69-71</sup> Fludarabine very efficiently depletes T cells and is used to treat a variety of indolent lymphomas, especially chronic lymphocytic leukemia.<sup>72</sup> Immunosuppressive therapy with fludarabine, even in the absence of malignancy, has also been associated with the development of TA-GVHD.<sup>73</sup> Because fludarabine is often used as a single agent, the connection between its use and TA-GVHD may be easier to discern. It appears prudent to consider the use of any immunosuppressive chemotherapy agent to be a risk factor for TA-GVHD. In any event, the routine use of preventive

measures against TA-GVHD in cancer patients regardless of diagnosis or treatment appears to have reduced the incidence of TA-GVHD. A review of the literature finds very few reports of TA-GVHD in cancer patients since 1997,<sup>70,74,75</sup> although this may, in part, reflect underreporting.

Autologous stem cell collections are also at risk for contamination with donor lymphocytes if nonirradiated blood components are given during the marrow or peripheral stem cell collection. This can lead to the subsequent development of TA-GVHD following reinfusion of the autologous stem cells and passenger donor lymphocytes.<sup>76</sup> A syndrome consisting of features reminiscent of GVHD, occurring generally around the time of engraftment following autologous stem cell transplant, has been reported.<sup>77</sup> This syndrome, termed engraftment syndrome, presents with noninfectious fever, skin rash, capillary leak, pulmonary infiltrates, and hypoxia. Biopsies of the skin rash are often equivocal with respect to establishing a diagnosis. TA-GVHD has not been ruled out in all of these cases, but it is generally felt that this syndrome represents changes associated with proinflammatory cytokine release around the time of engraftment. Likewise, the phenomena of autologous GVHD, which occurs after autologous stem cell transplant, can be induced by administration of cyclosporin A for a short period following transplantation, leading to the generation of autoreactive T cells.<sup>78</sup> One way to distinguish between autologous GVHD and TA-GVHD is to demonstrate engraftment of transfused donor lymphocytes through techniques such as HLA Class I or II antigen differences or other genetic variations such as differences in short tandem repeat.<sup>79</sup>

**Solid-Organ Transplantation**

GVHD in solid-organ transplantation is usually caused by donor lymphocytes transported with the donor organ but can also occur from transfusions given when the recipient is intensely immunosuppressed to prevent organ rejection. GVHD has been reported following cadaveric liver, heart, kidney, and pancreas-spleen transplants.<sup>80-86</sup> In one study,<sup>82</sup> 12 cases of GVHD occurred in 1082 liver transplants performed at a single institution. GVHD symptoms (fever, skin rash, diarrhea, or pancytopenia) typically developed within 2 to 6 weeks after the transplant. Mortality was over 90%.

Another risk factor for GVHD following organ transplant is HLA homology between the donor and the recipient.<sup>87,88</sup> Matching at the HLA-B locus appears to particularly dispose patients to the development of GVHD following liver transplantation.<sup>89</sup>

**TA-GVHD in Immunocompetent Patients****HLA Homozygosity**

One risk factor for TA-GVHD in immunocompetent patients is transfusion from a donor who is HLA homologous to the recipient. This situation is most likely to occur when the donor is a family member,<sup>90-92</sup> but there are also many reports from Japan, where a genetically homogenous population increases the risk of transfusion from a partially HLA-matched random

donor.<sup>91,93</sup> The transfusion recipient is less likely to reject donor lymphocytes when the donor is homozygous for an HLA haplotype for which the recipient is heterozygous. In this situation, the donor does not carry HLA antigens that trigger allogeneic recognition on the part of the recipient and thus are able to engraft. However, the recipient possesses HLA antigens that are foreign to the donor, and thus alloreaction culminating in TA-GVHD can occur.<sup>94,95</sup> Most recent reports of TA-GVHD come from settings or locales where blood irradiation is not routine.<sup>95</sup>

### Surgery

TA-GVHD has been reported in immunocompetent individuals undergoing cardiac surgery.<sup>96-98</sup> Cardiopulmonary bypass may increase the risk of TA-GVHD through the induction of transient immunodeficiency as evidenced by reduced mitogenic lymphocyte transformation and reduced production of the pro-immune response cytokines, TNF- $\alpha$ , and IL-2.<sup>99-101</sup> Likewise, TA-GVHD has been seen following extracorporeal membrane oxygenation.<sup>102</sup> An additional risk factor contributing to the development of TA-GVHD is transfusion of cellular blood components from donors who share HLA antigens with the recipient, such as related donors and donor-recipient dyads from areas with low HLA diversity, such as Japan.<sup>97,99,103,104</sup>

### Fresh Blood

Another risk factor appears to be the use of freshly donated blood. In a series of 2686 consecutive adult patients who underwent cardiac surgery between 1980 and 1996, four cases of TA-GVHD developed, all following transfusion of cellular blood components donated within 48 hours.<sup>104</sup> Transfusion of fresh blood components has been associated with TA-GVHD in other studies, as well.<sup>94,95,105</sup> Fresh blood presumably predisposes patients to TA-GVHD because it contains maximal numbers of viable lymphocytes. During storage the number of viable lymphocytes declines<sup>106</sup> as does the expression of cell-surface lymphocyte activation antigens.<sup>107</sup> The decrease in cell surface lymphocyte antigen expression directly correlates with a reduced ability to activate T cells as measured by a mixed lymphocyte culture by Day 3 of storage. This finding helps explain the rarity of TA-GVHD following transfusion of blood that is more than 4 days old.<sup>103,107</sup>

In summary, in immunocompetent recipients, the factors most likely to lead to TA-GVHD are as follows:

1. HLA-homozygous donor to haploidentical recipient, particularly likely if the donor is a relative or transfusion takes place in a region with low HLA genetic diversity.
2. Cardiac bypass.
3. Use of blood less than 4 days old.

## Clinical Presentation and Diagnosis of TA-GVHD

Unlike GVHD occurring after HSCT, which can take weeks to months to develop (median onset: 23 days),<sup>108-111</sup> GVHD following transfusion typically occurs sooner, usually within a

**Table 54-2.** Comparison of GVHD Following Hematopoietic Stem Cell Transplantation with Transfusion-Associated GVHD\*

| Manifestation                | HSCT GVHD             | TA-GVHD             |

\*Modified from Brubaker.<sup>113</sup>

**Figure 54-2.** A patient with Stage III skin GVHD following hematopoietic cell transplantation. (A) Generalized skin erythema with the characteristic maculopapular rash. (B) Two days later, the rash is more intense with areas of confluence.

few days, but up to 4 weeks (median onset: 10 days) from transfusion<sup>95,112</sup> (Table 54-2<sup>113</sup>). Fever is often the first symptom, but is soon followed by target organ involvement of skin, gastrointestinal tract, and/or the liver.<sup>114</sup> The host hematopoietic system is also a target in GVHD resulting in pancytopenia, a major contributor to mortality, in the transfusion-associated version.<sup>115</sup> Pancytopenia is less commonly seen in GVHD following allogeneic HSCT because the transplanted donor hematopoietic stem cells are spared from donor attack. Consistent with the observation that the hematopoietic system is a specific target in TA-GVHD, newborns with TA-GVHD reveal striking thymic damage.<sup>50</sup> There is no grading system for pancytopenia, but other target organs are staged using a scale developed for HSCT-associated GVHD (see Chapter 35).

The skin is usually the first organ involved. The characteristic maculopapular rash is pruritic, often involves the palms of the hands and soles of the feet, and spreads throughout the body (Fig 54-2). In severe cases the skin may blister and ulcerate.<sup>111,114</sup> Apoptosis at the base of epidermal rete pegs is a characteristic pathologic finding. Other features include dyskeratosis, exocytosis of lymphocytes, satellite lymphocytes adjacent to dyskeratotic epidermal keratinocytes, and a perivascular lymphocytic infiltration in the dermis.<sup>116,117</sup>

Gastrointestinal tract GVHD usually presents as diarrhea but may also include vomiting, anorexia, and/or abdominal pain when severe.<sup>116</sup> The diarrhea of GVHD is secretory and often voluminous (greater than 2 L/day). Bleeding occurs as a result of mucosal ulceration and can lead to hemorrhagic death.<sup>118</sup> Endoscopic examination with biopsies can confirm gastrointestinal tract involvement. Histologic features include lymphocytic infiltration, patchy ulcerations, apoptosis of crypt epithelial cells, crypt abscesses, and loss as well as flattening of the surface epithelium.<sup>119,120</sup>

Liver involvement in GVHD is characterized by laboratory and clinical features of cholestasis, with elevated bilirubin levels in the blood and clinical jaundice.<sup>111</sup> The histologic features of hepatic GVHD are bile duct damage, portal and lobular inflammation, endothelialitis, and canalicular cholestasis.<sup>121</sup> However, the liver is rarely biopsied because thrombocytopenia greatly increases the risks of the procedure.

Diagnosis of TA-GVHD is usually made on clinical grounds, but detection of donor lymphocytes in the recipient's circulating blood confirms the diagnosis. Techniques to establish donor lymphocyte engraftment are based on genetic differences between the donor and the host and include chromosome differences by standard cytogenetics,<sup>122</sup> fluorescent *in situ* hybridization of a biopsy,<sup>123</sup> detection of small genetic differences in highly polymorphic regions,<sup>79</sup> and differences in tissue typing.<sup>61,67,97</sup> A source of recipient chromosomes or DNA is necessary and can be obtained by buccal scraping or skin biopsy.

## Treatment of GVHD

Transfusion-associated GVHD carries a very poor prognosis with mortality rates over 90% despite aggressive treatment that has included agents such as high-dose steroids, azathioprine, methotrexate, cyclosporine, intravenous immunoglobulin, and growth factors.<sup>39,74,105</sup> The principles of treatment for TA-GVHD come primarily from the HSCT literature. Steroids, with their potent antilymphocyte and antiinflammatory activity, are the gold standard for treatment of GVHD. However, steroid therapy results in durable complete or partial remission in only around 50% of patients, primarily those with less severe GVHD.<sup>108,124</sup> Antithymocyte globulin (ATG) has been used together with steroids to improve outcome. In a prospective randomized study of 100 patients, the combination of steroids and ATG was no more effective than steroids alone as front-line therapy for GVHD; however, there was a better-than-expected response rate to steroids alone.<sup>124</sup> In a retrospective study, 1-year survival was better when ATG was added within 4 to 7 days of steroid therapy for those patients who showed early signs of steroid resistance.<sup>126</sup> Other studies have not shown benefit when ATG is added to steroid therapy to treat GVHD.<sup>127,128</sup> Because ATG increases the risk of infection in patients with GVHD, it is not used routinely.<sup>125,127,128</sup> This increased risk of infection is of particular importance in the treatment of TA-GVHD, because death from overwhelming infection is common.<sup>94-96</sup>

One treatment that may be less immunosuppressive is extracorporeal photopheresis (ECP). During ECP, the patient's white cells are collected by apheresis, incubated with the DNA-intercalating agent, 8-methoxypsoralen, exposed to ultraviolet A (UVA) light, and returned to the patient. ECP is known to induce cellular apoptosis, which has strong antiinflammatory effects in a number of systems, including prevention of rejection of solid-organ grafts.<sup>129</sup> A Phase II study of ECP in steroid-dependent or steroid-refractory GVHD showed complete and durable resolution of GVHD in a large majority of patients. High response rates in the skin (82%), liver (61%), and intestine (61%) translated into 50% long-term survival in this very high-risk group.<sup>130</sup> Another possible strategy to treat GVHD is inhibition of the inflammatory cytokine TNF- $\alpha$ , a molecule that plays a critical role in the development of GVHD as discussed earlier. A Phase II trial of etanercept, a solubilized dimeric TNF-receptor-2, showed significant efficacy when added to systemic steroids as primary therapy for acute GVHD. Seventy percent of patients had complete resolution of all GVHD symptoms within 1 month, with 80% complete responses in the gastrointestinal tract and the skin. The authors also showed that plasma levels of TNF-receptor-1 were a significant biomarker for clinical GVHD.<sup>131</sup>

Given the very high mortality from TA-GVHD, only a few cases of successful treatment have been reported. An infant with X-linked SCID developed TA-GVHD following non-irradiated blood transfusion. The TA-GVHD was initially controlled with high-dose steroid therapy. A haploidentical transplant from his mother was initially rejected by the engrafted blood donor T lymphocytes, but on second transplant engraftment was achieved with eventual eradication of blood transfusion donor T cells. The blood donor, patient, and marrow donor all shared an HLA haplotype.<sup>54</sup> In two cases, GVHD was successfully treated by infusion of patient lymphocytes.<sup>71,132</sup> Anti-CD3 treatment, together with cyclosporine, showed effectiveness in one case.<sup>133</sup> A spontaneous remission has also been reported.<sup>134</sup>

## Prevention of TA-GVHD

### $\gamma$ -Irradiation

Although TA-GVHD is a preventable disease, there remains considerable controversy regarding the optimal prevention strategies, primarily because of the rarity of the diagnosis. Treating cellular blood components with 25 Gy  $\gamma$ -irradiation reliably inactivates donor lymphocytes through cross-linkage of DNA, and prevents TA-GVHD.<sup>39,135</sup> Irradiation does not damage platelets or granulocytes, and therefore can be performed safely at any time following the collection.<sup>112</sup> However, irradiation does shorten the shelf life of red cell components and it is recommended that irradiated red cells be used within 28 days from the time of irradiation.<sup>39</sup> The effects of irradiation on red cells include increased plasma membrane permeability, with potassium leakage, hemolysis, and problems with adenosine triphosphate maintenance.<sup>136</sup> Prestorage leukocyte reduction may lessen some of the effects of

irradiation on red cell storage parameters.<sup>137</sup> Irradiation incurs additional cost and is not available at all hospitals. Therefore, although universal irradiation of all cellular components would eliminate TA-GVHD, this strategy has not been adopted in all countries.<sup>138,139</sup>

In Japan, TA-GVHD has been a particularly significant issue because of the genetically homogenous population. In 2000, Japanese experts recommended blood component irradiation for the following identified risk situations: transfusions from blood relatives, granulocyte transfusions, and all transfusions to immunodeficient recipients including any cancer patients, newborns, elderly patients, and those undergoing cardiac surgery.<sup>51</sup> Subsequently, universal blood component irradiation was adopted in Japan.<sup>139</sup> In the United States and Europe, there is no well-established consensus on the indications for blood irradiation. Most transfusion services perform their own assessment of the risk and develop a list of indications for which blood irradiation is provided routinely. The indications most frequently included in such a list are: transfusions from blood relatives; intrauterine transfusions; granulocyte transfusions (except when given to patients with congenital neutrophil disorders); patients with congenital cellular immunodeficiency syndromes, Hodgkin disease, and other leukemias and lymphomas; patients taking fludarabine; and patients undergoing HSCT. Many authorities irradiate fresh blood (less than 24 hours old) when used for transfusion. Other indications are assessed differently at different institutions.

Blood irradiation can be performed with commercial irradiators designed specifically for this purpose. The most appropriate dose for blood component irradiation is 25 Gy at midplane.<sup>135,140</sup> Commercial irradiators incorporate one to four gamma ray sources, generally cesium-137, and deliver 300 to 1000 cGy per minute.<sup>141</sup> Linear accelerators and cobalt-60 can also be used as a source of  $\gamma$ -irradiation.<sup>135,141</sup> Alternatives to cesium-137 as a radiation source are preferred because of concerns about security risks, despite the increased costs of such alternatives. Radioactive cesium chloride used in blood irradiators and other medical equipment is widely used in significant quantities, is soluble and easily dispersible, and often lacks secure disposal options.<sup>142</sup>

### Nonirradiation Prevention Strategies

Leukocyte reduction has been shown to reduce the risk of TA-GVHD, especially in a genetically diverse population,<sup>27</sup> but is not a substitute for irradiation in at-risk populations. Photochemical treatment using psoralens and long-wavelength ultraviolet irradiation inactivates T cells and has also been shown to inactivate blood-borne pathogens, such as cytomegalovirus.<sup>143,144</sup>

### Summary

Transfusion-associated GVHD is a rare and preventable disease that occurs when sufficient numbers of viable T cells are transfused into a susceptible host. Immunodeficient states, either inherited or

acquired, are well recognized as a risk factor, but TA-GVHD can develop in immunocompetent patients, especially if fresh blood components, with their high numbers of viable leukocytes, are transfused. Immunocompetent recipients are generally only at risk if they receive HLA haploidentical T cells, which is most likely to happen if the donor is a relative, or if the patient lives in a region with low HLA genetic diversity. TA-GVHD usually develops within days of the transfusion and follows a fulminant course with death from severe pancytopenia and infection. The disease is generally recognized by classical features of rash, diarrhea, and liver dysfunction. Irradiation of blood components is highly effective at preventing this disease, but is not universally employed. Careful attention must be paid to identifying at-risk patients, because, once established, the disease is almost always fatal.

**Sujit Sheth**

Associate Clinical Professor, Department of Pediatrics, Columbia University Medical Center, New York, New York, USA

Tissue iron overload inevitably results in patients who receive regular red cell transfusions for congenital or acquired anemias. Iron is deposited initially in the liver and monocyte-macrophage (reticuloendothelial) system, but as these tissues become saturated, iron begins to deposit in other organs such as the endocrine glands and the heart. The body lacks an effective means of eliminating this excess iron, and without therapy, cirrhosis, heart disease, diabetes, and other disorders develop; death is usually the result of cardiac failure. Transfusional iron overload, with its resulting morbidity and mortality, is an important health issue in patients of all ages. Children with thalassemia major, or other inherited disorders such as Diamond-Blackfan anemia (DBA), congenital dyserythropoietic anemia, and congenital aplastic anemia are dependent on regular red cell transfusions to maintain their well being. Children with sickle cell disease who are found to be at increased risk of stroke may be placed on a chronic transfusion program to reduce this risk substantially.<sup>1</sup> Some adults with aplastic anemia or myelodysplastic syndrome (MDS) may also become dependent on regular red cell transfusions. In addition, with chemotherapeutic regimens becoming more intense and myelosuppressive, patients undergoing treatment for various forms of cancer, particularly leukemias and lymphomas, may also receive a large number of red cell transfusions. Some of these individuals may also undergo stem cell transplantation, during the course of which they may receive numerous such transfusions. With advances in the medical management of some of these conditions, including improved chelation regimens, patients also have a better survival probability, thus increasing the number of individuals in whom transfusional iron overload requires close medical attention. Until recently, the most long-term experience in the pathogenesis and management of transfusional iron overload came from studies in patients with thalassemia major. Although these individuals differ from other

transfusion-dependent patients in some important ways, experience with patients with thalassemia helps guide many of the recommendations made here.<sup>2</sup>

### Pathophysiology

Iron is an essential nutrient required by every cell. It is present in the human body in hemoglobin, myoglobin, and several mitochondrial respiratory enzymes. It serves as a carrier for oxygen and electrons and acts as a catalyst for a variety of oxygenation reactions. It is able to perform these functions in part because of its ability to reversibly and readily cycle between its ferrous and ferric forms. This very property also makes it potentially toxic and capable of producing free radicals, which can cause cellular damage (Fig 55-1).

The normal body iron concentration is approximately 40 to 50 mg/kg body weight; women have lower amounts and men somewhat higher.<sup>4</sup> Three-quarters of this iron, about 30 mg/kg, is contained in the circulating red cell compartment as hemoglobin. Approximately 5 to 6 mg/kg is present in functional form in a variety of heme compounds (myoglobin and cytochromes) and iron-dependent enzymes. The remainder (5 mg/kg in women, 10-12 mg/kg in men) is held in reserve in two primary

**Figure 55-1.** Iron-induced oxidative tissue damage via the Fenton Reaction.<sup>3</sup>

storage forms (ferritin and hemosiderin) in the liver, marrow, spleen, and muscle—readily available when required for erythropoiesis. Iron balance is maintained by controlling iron absorption; iron stores and iron absorption are reciprocally related so that as stores increase, absorption declines. These processes are closely managed by the iron regulatory “hormone” hepcidin,<sup>5</sup> which plays a critical role in iron metabolism. It regulates the absorption of iron from the gastrointestinal tract through its effect on levels of ferroportin, the protein responsible for transporting iron out of the enterocyte. Red cells are normally broken down by cells of the monocyte-macrophage system, and the iron contained in hemoglobin is usually returned via transferrin to the erythroid precursors in the marrow, for recycling into new red cells. Hepcidin controls the release of iron from macrophages, an effect also mediated by ferroportin. In the healthy host, when the body has adequate or increased amounts of iron, hepcidin is upregulated, iron absorption from the intestine is inhibited, and iron is sequestered in its storage sites, the macrophages and hepatocytes. The body lacks any effective mechanism for the excretion of excess iron. Iron exchange is limited so that the adult male absorbs and loses only about 0.01 mg/kg/day.

Iron overload results from repeated blood transfusion, excessive iron absorption from the gastrointestinal tract, or of a combination of these processes.<sup>4</sup> In patients with severe congenital anemias (such as the thalassemias, DBA, or congenital dyserythropoietic anemia), death from severe anemia in infancy is averted by a regular transfusion program which, if adequate, allows for normal growth and development during the first decade of life. Individuals with MDS or aplastic anemia may begin transfusions later in life. As in healthy individuals, macrophages process senescent red cells (transfused in these patients) and extract iron from heme. With no effective means for the excretion of this iron, there is gradual tissue accumulation of this iron, which eventually exceeds the body's capacity for safe storage. As the amount of iron increases, there is virtually no change in the amount that is contained within the functional or transport (transferrin-bound) pools, and almost all of the excess iron is stored. Initially, the iron is sequestered in the cells of the monocyte-macrophage system, but with continued accumulation, iron spills over and is deposited in other tissues, usually the liver (hepatocytes), heart, pancreas, and other endocrine organs.

Transfusion-dependent individuals may be broadly categorized as those having ineffective erythropoiesis (such as individuals with thalassemia or some forms of sideroblastic anemia), those with effective erythropoiesis (such as individuals with sickle cell anemia or hereditary spherocytosis), and those with decreased or absent erythropoiesis (such as patients with aplastic anemia or DBA). The “effectiveness” of erythropoiesis, with the ability to incorporate iron into hemoglobin in mature red cells, is a critical determinant of the pathophysiology of iron loading in transfusion-dependent patients. Once transfused red cells are phagocytosed by macrophages, hepcidin levels determine the fate of iron released from heme. If hepcidin levels are high, more iron remains sequestered in these storage cells, and less is released for

potential deposit in other tissues. Iron stored in the hepatocyte is similarly retained. In contrast, if hepcidin levels are low, more iron is released from these cells and may be available for deposition in other parenchymal tissues. Thus, hepcidin helps determine the partition and internal redistribution of the excess iron between the monocyte-macrophage and parenchymal sites,<sup>6</sup> another crucial factor in tissue toxicity.

Ineffective erythropoiesis—and, to a lesser degree, anemia—result in a downregulation of hepcidin expression and enhanced absorption of iron from the intestine.<sup>7</sup> Patients with thalassemia major or intermedia, paradoxically have relatively low levels of hepcidin even in the presence of iron overload, as a result of their marked ineffective erythropoiesis. In patients with sickle cell disease, who have intact erythropoiesis, hepcidin expression varies inversely with erythropoietic drive,<sup>8</sup> with untransfused patients excreting less hepcidin in the urine. Similarly, patients with DBA or aplastic anemia, who have almost no erythropoiesis, likely have appropriately elevated hepcidin levels when iron loading occurs. Thus, patients with thalassemia major or intermedia not only have higher iron burdens because of increased intestinal absorption, but also have a greater risk of parenchymal tissue deposition than the latter groups. In fact, patients with thalassemia intermedia who have received very few or no red cell transfusions may have profound iron overload because of marked hepcidin inhibition<sup>7</sup> as a result of their ineffective erythropoiesis. In patients with thalassemia major or intermedia, regular transfusion suppresses ineffective erythropoiesis to some extent, and hepcidin levels may rise somewhat. However, the levels remain inappropriately low in relation to the higher body iron burden, resulting in iron loading through gastrointestinal absorption. Recently, a growth factor (GDF15) has been identified that is secreted during erythroblast maturation, and suppresses hepcidin production. There is increased expression of this factor in thalassemia, likely because of the ineffective erythropoiesis.<sup>9</sup> In contrast, levels of this factor are not elevated in patients with homozygous sickle cell anemia. Therefore, although the volume of red cells transfused is similar, variability in the hepcidin response to the underlying erythropoietic status produces differences in the partition and distribution of the excess iron.

While hepcidin levels are critical in modifying the pathophysiology of iron loading in transfusion-dependent patients, several other variables are important in determining the morbidity related to the increased body iron burden. These include 1) the age at which transfusion therapy began, 2) the duration of transfusion therapy, and 3) the initiation and maintenance of effective chelation. Additional modifying factors include other genetic determinants, alcohol use, coexisting viral hepatitis, and other drugs and medications that the patient may be taking. The complex interplay between the underlying disorder and these factors in each individual plays a key role in the pathophysiology of iron toxicity.

Even though the body has the ability to safely store increased amounts of iron, deposition in nonstorage tissues eventually occurs as the body iron burden rises. Without treatment,

patients with thalassemia, who begin transfusions in infancy, develop growth retardation, diabetes, and other endocrine disturbances in the first decade of life, and death from iron loading of the myocardium occurs during the second decade. Patients with sickle cell disease, who receive regular transfusions to prevent the occurrence of strokes, may begin these transfusions later in childhood, and may achieve normal growth and sexual maturation before the threshold for tissue damage is reached. A comparative study of regularly transfused patients with thalassemia major and sickle cell disease with similar iron burdens showed that the latter group had fewer cardiac and endocrine complications.<sup>10-12</sup> The patients with sickle cell disease began regular transfusions at a later age, and had been transfused for approximately half as long as the thalassemia patients, possibly contributing to the observed differences in clinical manifestations. These observations emphasize the relevance of the age at which transfusions are begun, particularly with regard to growth, development, and sexual maturation. As the duration of transfusion increases, severe iron loading may occur in all transfusion-dependent patients who are not effectively chelated. Diabetes and cardiac disease may develop, the latter remaining the major cause for morbidity in all of these patients.

As the body accumulates iron from transfused red cells, chelation therapy is usually begun to prevent deposition and damage to parenchymal tissues. Just as the rate of uptake of iron by these tissues is influenced by transfusion parameters and hepcidin levels, the variability of the chelation regimen also plays an important role. The timing of initiation, choice of chelator and dosing, and compliance with the regimen are some of these variables. When transfusion and chelation are occurring simultaneously, there is likely a complex and dynamic balance between transfusional iron loading and chelator-induced iron purging.<sup>13</sup> Different organs may take up iron at different rates and likely have different thresholds for when tissue damage occurs. It has been demonstrated that in transfused and chelated patients with thalassemia and sickle cell disease, the relationship the liver iron concentration (LIC) and myocardial iron levels is nonlinear and variable.<sup>13,14</sup>

In summary, the pathophysiology of iron metabolism in the condition underlying the transfusion-dependent anemia, as well as the factors directly related to the initiation, intensity, duration, and effectiveness of both the transfusion regimen and the chelation regimen, contribute to the pathology of transfusional iron overload.

Storage iron is present in the body predominantly in two high-molecular-weight forms, ferritin and hemosiderin. Both forms are stained on pathologic specimens by Prussian blue, via the Pearl's reaction. Hemosiderin is insoluble and is deposited in aggregates of varying sizes, while ferritin is soluble and more homogeneously distributed within cells. Under physiologic conditions, iron is distributed approximately equally between these storage forms, but as the body's iron load increases, the proportion stored as hemosiderin increases dramatically. A small amount of iron is present in a low-molecular-weight intracellular

pool—likely the most toxic form of iron, because of its propensity for producing free radicals, which cause oxidative damage. It is likely that the ferritin fraction is in closer equilibrium with the low-molecular-weight iron pool.<sup>15</sup> As the magnitude of iron excess grows, some stored iron may be mobilized into the circulation from macrophages or hepatocytes. As transferrin is increasingly saturated, some plasma non-transferrin-bound iron (NTBI) appears. This iron may be more easily taken up by parenchymal tissues that do not normally store iron, leading to toxicity. Thus, it is critical to ensure that effective chelation therapy is ongoing, to bind this iron and prevent its entry into cells, thereby avoiding organ damage.

Histopathologic examination of the liver in mild transfusional iron overload reveals predominant Kupffer cell iron deposition, with preserved hepatocyte architecture and no fibrosis. As iron loading continues, the hepatocytes also demonstrate increased iron uptake; there is some disruption of the architecture and some scarring/fibrosis. Until this point, these changes are reversible with appropriate chelation. With massive overload, there is bridging fibrosis, and progression to cirrhosis, which may or may not be reversible.<sup>16</sup> Myocardial iron distribution is heterogeneous, with more in the left heart than the right, more in the ventricles than the atria, and more in the epicardium than the endocardium.<sup>17</sup> It has been suggested, based on studies in the iron-loaded gerbil model, that iron in myocardial fibers may cause impaired repolarization of the myocytes.<sup>18</sup> This may interfere with generation and orderly propagation of the electrical impulse and lead to a variety of arrhythmias. With progressive loading, fibers may not contract normally, and a restrictive cardiomyopathy with impaired filling and diastolic dysfunction may result. This can eventually lead to congestive heart failure. Heart failure is reversible in part, and with improved chelation, cardiac function may be recovered substantially.<sup>19,20</sup> Therefore, long-term monitoring of transfused and chelated patients should include serial measurement of myocardial iron deposition as well as the LIC.

---

## Transfusional Iron Burden

The total amount of iron that enters the body via red cell transfusion can be estimated. Because the magnitude of the iron burden is critical in the development of complications, it is of great importance to maintain accurate records, for each patient, of the amount of red cells transfused. The total amount of transfused red cells is calculated as the total amount of blood in mL multiplied by the hematocrit of each unit (as a percentage) divided by 100. Each mL of red cells contains 1.08 mg of iron, and the total amount of iron introduced (Kin) is calculated as follows:

$$\text{Kin} = (\text{total amount of red cells transfused, in mL}) \times 1.08$$

Alternatively, if the exact volume is not available, the iron burden can be estimated from the number of units transfused.

Each Red Blood Cell (RBC) unit transfused contains 200 to 250 mg of iron. The total iron burden can be calculated with use of one of these methods. Transfusion-dependent patients usually require 200 to 300 mL/kg/year of blood, an amount equivalent to 0.25 to 0.40 mg/kg/day of iron.

With no physiologic means of excreting this excess iron, and the inapplicability of phlebotomy in patients who are regularly transfused, these individuals must receive iron chelation therapy in order to facilitate excretion. A minimum chelator-induced excretion of 0.25 to 0.40 mg/kg/day would maintain iron balance in such individuals. Higher levels of excretion would be necessary produce a negative iron balance.

Iron balance should be monitored during chelation therapy to assess the efficacy of such treatment. The total body iron (Us) at any point in time (t) may be extrapolated from the LIC (in mg/g dry weight) using the formula published by Angelucci et al<sup>21</sup> as follows:

$$Us(t) = 10.6 \times LIC \times (\text{body weight in kg})$$

For patients who are being chelated as well, there is an ongoing change in the body iron balance as the iron entering the body through transfused red cells is removed by the chelator. In these situations, it is important to monitor the total body iron excretion between LIC measurements. This can be calculated based on the amount of red cells transfused ( $K_{in}$  = iron introduced in mg), and on the changes in total body iron between measurements of liver iron concentrations at baseline ( $t_0$ ) and a later time (t), expressed as milligrams of iron excreted per day.<sup>22</sup>

$$\text{Total body iron excretion} = (K_{in} + [Us(t_0) - Us(t)]) / (t - t_0)$$

## Clinical Features

Although iron deposition in tissues begins soon after the initiation of regular transfusions, signs and symptoms of iron toxicity usually occur after a few years of iron loading. By then the usual storage sites for iron have been almost saturated, and there is deposition in other tissues that do not normally store iron. Organs suffer damage, often irreversible, resulting in significant morbidity. Early death is sometimes seen, generally as a result of cardiac failure.<sup>23,24</sup> In a recent cross-sectional study of patients with thalassemia born after 1970 in Italy, it was found that 7% had heart failure, 6% had diabetes, 11% had hypothyroidism, and 55% had hypogonadism.<sup>25</sup> A third of these patients had died, the cause of death in 68% being heart failure.

Liver disease of transfusional iron overload may be manifested as hepatomegaly, abnormalities in function, fibrosis (which may lead to scarring, bridging fibrosis, and micronodular regeneration and cirrhosis), and hepatocellular carcinoma.<sup>25,26</sup> Patients are asymptomatic, or have mild to moderate icterus, and with progression, symptoms and signs of cirrhosis and hepatic failure.

Heart failure remains the leading cause of mortality in transfusional iron overload. Unfortunately, symptoms do not appear until the myocardium has large amounts of deposited iron, and routine testing by conventional echocardiography and Holter monitoring early in the course almost always yields normal results. With progressive deposition, patients manifest symptoms. Early signs may include a variety of arrhythmias including supraventricular or ventricular tachycardias, premature or extra systoles, heart block, and atrial fibrillation. Contractile dysfunction affects diastole early,<sup>28</sup> likely the reason that conventional echocardiography, which assesses mainly systolic function, indicates “normal” function. The onset of cardiac failure is late, and often sudden, and is an ominous sign. Both complications are often refractory to treatment. Therefore, prevention of myocardial iron loading is critical.

In patients who begin receiving transfusions in early childhood, the developing endocrine organs are particularly susceptible to iron deposition if effective chelation is not initiated at the appropriate time. The anterior pituitary is most often involved, resulting in slow growth, delayed sexual maturation, and often infertility, the latter being the result of direct iron deposition in the gonads as well. Supplemental growth hormone or sex hormone therapy is often required to treat these complications. The pancreatic islet cells are also susceptible to the toxic effects of iron. Impaired insulin secretion and abnormal glucose tolerance usually precedes the development of insulin-dependent (type 1) diabetes and may occur in highly loaded individuals at any age.<sup>29,30</sup> Older males may experience dysfunction in sexual performance, and females may develop secondary amenorrhea related to gonadal iron deposition and disturbances in sex hormone secretion. Thyroid dysfunction, although uncommon, may also manifest at any age.<sup>26</sup>

Other manifestations include arthropathy and skin pigmentation, which are directly related to iron deposition in these tissues. Patients with marked hemosiderosis appear bronzed initially, and with progression, may appear darker, or grayish. Complicating the manifestations of iron toxicity are the clinical signs and symptoms of chelator side effects, which are described below.

## Measurement of Iron Burden

The goal of therapy for individuals with transfusional iron overload is to maintain iron balance at low levels of tissue iron, thereby preventing the development of overload and complications. When there is little or no ineffective erythropoiesis, simply keeping track of the volume of red cells transfused provides a measure of the body iron burden in transfused patients who are not being chelated. Different tissues load iron at different rates and the balance between loading via transfusion and removal by chelation is also a determinant in the differential deposition of iron. Thus, monitoring iron deposition in any one organ is not representative of the others. The ideal means of monitoring iron overload is to periodically assess tissue iron levels in each of the

different organs affected, but this is currently feasible only in the liver and heart.

The LIC has been used to assess the body iron burden. In patients with thalassemia major, who had been cured by stem cell transplantation, phlebotomy was used as a means of removing excess iron that had accumulated from years of red cell transfusions. A serial decline in the LIC correlated well ( $R = 0.98$ ;  $p < 0.001$ ) with the amount of iron removed by phlebotomy, supporting the idea that the LIC is a reflection of total body iron load.<sup>21</sup> Patients with thalassemia who had LICs of 6 to 13 mg/g dry weight had an almost twofold risk of progression of fibrosis; in those with liver iron concentrations of 13 to 41 mg/g dry weight, the hazard rate was almost ninefold.<sup>31</sup> Coexisting infection with the hepatitis C virus (HCV) independently increased the risk for progression of fibrosis threefold. These observations confirmed the results of previous studies: LIC  $> 7$  mg/g dry weight is associated with an increased risk of hepatic fibrosis, diabetes, and other complications of iron overload.<sup>32</sup> Maintaining the LIC in the suggested “ideal range” of 3 to 7 mg/g dry weight in regularly transfused and chelated patients should minimize iron deposition in nonstorage parenchymal sites, and prevent significant toxicity. Because correlation between hepatic and cardiac iron concentrations is not satisfactory,<sup>13,14</sup> independent assessment of myocardial iron should be performed, as discussed in the next section.

Whereas the LIC can be measured directly by biopsy or noninvasive means, direct quantification of myocardial iron is not feasible. A surrogate for cardiac iron burden, myocardial T2\*, has been shown to correlate with function,<sup>33</sup> and is currently used in several centers. In the absence of methods for assessing iron deposition in other tissues such as the pancreas and anterior pituitary, current ideal monitoring includes periodic assessment of hepatic and myocardial iron deposition.

Serial measurement of the LIC over time is an accurate and reliable means of monitoring the progression of iron loading and the efficacy of chelation therapy. The ideal method for measuring the LIC is one that is safe, accurate, noninvasive, and valid over a wide range of concentrations. Magnetic resonance (MR)-based methods meet almost all of these criteria, although access to centers offering them may be limited.

The reference method has been the quantitative chemical estimation of nonheme iron in liver tissue obtained by biopsy. To obtain accurate results by this method, several requirements must be met: the patient should not have cirrhosis or focal lesions, the biopsy must weigh at least 1 mg dry weight (or 4 mg wet weight), and should be processed using strictly iron-free methods. Serial biopsies would ideally allow monitoring not only of the rate of iron loading and the efficacy of chelation therapy in the liver, but also the development and rate of progression of fibrosis or scarring. Liver biopsy is an invasive procedure with considerable risks, and is not ideal for the frequent measurement of LIC that is necessary for the monitoring of regularly transfused and chelated individuals.

A recent workshop by the National Institute of Diabetes and Digestive and Kidney Diseases concluded that a clinical need

was evident for quantitative means of measuring body storage iron that are noninvasive, safe, accurate, and readily available to improve the diagnosis and management of patients with iron overload, including hereditary hemochromatosis (HH), thalassemia major, sickle cell disease, aplastic anemia, myelodysplasia, and other disorders.<sup>34</sup> Several noninvasive methods have been used to estimate the LIC. These include direct methods such as magnetic biosusceptometry, and indirect methods such as MR.

Recently, there has been tremendous interest in using MR techniques to study tissue iron.<sup>35-37</sup> A brief description of the application of these techniques is presented here; a more in-depth analysis has recently been published.<sup>38</sup> Hemosiderin and ferritin iron affect the relaxation of hydrogen atoms present in the nuclei of tissue water molecules. Initial limitations in the technology have been overcome and more sensitive instruments capable of measuring more rapid signal decay (very short relaxation times) are now used to quantify hepatic and cardiac iron concentration. Several such methods have been used to assess the hepatic iron concentration.<sup>39-41</sup> Two widely used techniques are a gradient-echo T2\*-based sequence that measures the signal intensity ratio of liver to skeletal muscle,<sup>42</sup> and a stimulated spin-echo R2 sequence-based scan (<http://www.resonancehealth.com>).<sup>43</sup> Measurements of hepatic iron concentration obtained by this technique correlate well with hepatic iron chemically estimated directly from liver tissue. T2\* sequences have been used to quantify hepatic iron, but the correlation is less robust.<sup>33</sup> The relationship between estimates of LIC by MR methods and the serum ferritin has been variable.

Iron concentrations in the myocardium are much lower than those in the liver, and the iron is distributed nonhomogeneously in different areas of the heart. A multi-echo spin-echo T2\* technique is the most widely used method of assessing myocardial iron.<sup>44</sup> Although no direct correlation of T2\* with tissue iron has been demonstrated in humans, data are available from the iron-loaded gerbil model.<sup>45</sup> All individuals with clinical cardiac disease had T2\* measures of  $< 20$  msec, and all subjects with T2\* values above 20 msec had normal cardiac function.<sup>33</sup> The threshold for “severe” cardiac disease has also been reduced to a T2\* value of 8 msec, below which there is very high risk for development of cardiac disease.<sup>46</sup> Several studies have compared the efficacy of different chelators in removing myocardial iron using this method.<sup>20,47,48</sup>

Magnetic resonance techniques are being developed to study iron deposition and its effects in other organs as well, including the anterior pituitary and pancreas, enabling better surveillance for development of complications and closer monitoring of the efficacy of chelation in preventing or ameliorating iron deposition.

Magnetic biosusceptometry has been validated to be a safe, accurate, and noninvasive method of quantitatively measuring the LIC over a wide range of body iron burdens. The principle is that storage iron (both hemosiderin and ferritin) is paramagnetic, ie, when a steady magnetic field is applied, these molecules will induce a field change that is proportional to the number of

iron atoms present. An extremely sensitive sensor, or superconducting quantum interference device (SQUID), measures this response. A strong linear correlation ( $R = 0.99$ ) between LIC determined by biopsy and by SQUID susceptometry has validated this technique.<sup>49</sup> SQUID susceptometers have been used extensively in studies of iron-loaded individuals to assess iron burden and guide chelation therapy.<sup>22,32,50-52</sup> Use of this method has been limited because of the complexity and high cost of building, installing, and maintaining the instrument. Currently, only four centers worldwide are using this technique. Other limitations include use in individuals who are obese, are very small, or have metal implants or devices that may not be removed before the study. In addition, susceptometric methods cannot be used to quantify iron in other organs that may be loaded with iron, such as the heart, pancreas, and other endocrine organs. A new high-transition temperature device, cooled using liquid nitrogen and with better resolution of the signal from surrounding tissues, is under development.<sup>53</sup>

Traditionally, the serum ferritin level has been used as an indirect estimate of the body iron burden. Several studies have shown a significant correlation between the serum ferritin level and the LIC estimated by biopsy in patients with thalassemia.<sup>32,54-55</sup> However, the coefficient of correlation in most of these was poor, with marked scatter around the correlation line. A recent study in patients with sickle cell disease also showed poor correlation between serum ferritin levels and the LIC measured in biopsy tissue in patients with sickle cell disease.<sup>57</sup> There are several reasons for this variability in the serum ferritin level, which does not necessarily reflect a change in the body iron burden. Ferritin is well-known to be an acute-phase reactant. Serum levels may be increased by infection, inflammation, hepatic dysfunction, tissue injury, hemolysis, and decreased when there is chronic hypoxia or a deficiency of ascorbic acid. Thus, it is at best an indirect marker of iron overload. Although practical and easy to measure, ferritin is not reliable as an indicator of the total body iron burden or as a parameter for the monitoring of chelator efficacy, and does not in any way identify the differential iron loading that may exist between the liver and the heart.

Without the wide availability of noninvasive measures of hepatic and cardiac iron, there is still reliance on the serum ferritin level as a means of monitoring the iron burden and the efficacy of chelation. However, it may actually be misleading in individual patients, remaining stable in the face of rising body iron burden and ongoing deposition in the heart and endocrine organs. Similarly, measurements of serum iron, transferrin or transferrin saturation, and urinary iron excretion do not provide reliable indication of the level of body iron stores. Plasma A NTBI has been suggested to be a marker of the “toxic iron pool,”<sup>58,59</sup> but its measurement is very complex and is currently still used for research purposes only. These limitations in serum measurement of iron-related moieties underscore the need for assessment of iron in specific tissues.

As discussed previously, there is variability in iron deposition between the heart and the liver, as a result of the changing

balance between transfusional iron loading and chelation.<sup>13,14</sup> Thus, optimal monitoring of iron burden should include assessment of both—the hepatic iron concentration by biopsy, MR, or susceptometry and the myocardial iron by the surrogate T2\* estimate. These noninvasive monitoring methods are not yet widely available, but special effort should be devoted to securing such testing for patients in order to chelate them effectively and prevent the development of complications.

---

## Management

The primary goal of therapy is to prevent tissue deposition of excess iron, thereby preventing organ damage and the resulting morbidity and mortality. Maintaining safe levels of tissue iron requires achieving a balance between the amount of iron entering the body and that being removed. Unlike management of HH patients, phlebotomy to remove excess iron is not an option for those with transfusional iron overload unless the patient has successfully undergone stem cell transplantation, or has completed treatment with intensive chemotherapy regimens. If transfusion therapy is ongoing, iron-overloaded patients must be treated with a chelating agent capable of sequestering iron and permitting its excretion from the body. As discussed previously, a minimum chelator-induced excretion of 0.25 to 0.40 mg/kg/day is necessary to maintain iron balance. The ideal chelator should form a high-affinity 1:1 uncharged complex with iron; be able to chelate intracellular iron; be orally effective, with a long half-life, high chelator efficiency, and low toxicity profile; and be effective in removing iron from (or preventing deposition in) all organs that may be affected with long-term usage. Such a chelator is not yet available. Chelators in current use are described in brief below; more detailed reviews of chelation are available elsewhere.<sup>60,61</sup>

### Chelating Agents

Deferoxamine mesylate (Desferal, Novartis, East Hanover, NJ) (Fig 55-2), a naturally occurring trihydroxamic acid produced by *Streptomyces pilosus*, was first introduced almost 40 years ago and has been found to be a generally safe and effective means of managing iron overload, ameliorating or preventing iron-induced organ damage, and reducing morbidity and mortality. In fact, patients with thalassemia major who were effectively chelated survived significantly longer than those whose chelation was ineffective.<sup>62</sup> Deferoxamine is a hexadentate chelator that forms a charged 1:1 complex with iron. This complex does not readily enter or leave cells and is excreted almost equally by the liver in bile and by the kidneys. Unfortunately, deferoxamine is not absorbed intact when taken orally, has a very short half-life (approximately 15 minutes), and must be administered by subcutaneous infusion using a portable syringe pump over 8 to 12 hours daily for maximal chelation efficiency.<sup>63</sup> It has been shown that levels of NTBI (the form of iron that more easily enters parenchymal cells) rise in the plasma within 16 hours

of the end of the infusion,<sup>63</sup> and maintaining chelator levels in the body is critical to prevent toxic effects of this iron. Patients who receive the drug in this manner often have pain, experience swelling and redness at the site of infusion, and may develop injection abscesses. Rare toxicities occur when deferoxamine is present in excess of chelatable iron, including effects on hearing (usually high-frequency hearing loss) and vision (leading to blindness in severe instances).<sup>63,64</sup> For all of these reasons, compliance with this regimen is not very good, and morbidity from organ deposition and dysfunction is often the result. The dosage range for deferoxamine is between 30 and 50 mg/kg administered over 8 to 12 hours by subcutaneous infusion five to seven times a week.<sup>64</sup> In severely loaded individuals, such as those with iron induced cardiac disease,<sup>19</sup> it may be administered by continuous intravenous infusion, although dosing above 50 mg/kg/day does not increase iron excretion further,<sup>63</sup> and may result in toxicity. Although cardiac function typically improves relatively quickly (2-3 months), such continuous therapy often has to be maintained for many months or even years before there is a substantial decline in the LIC or improvement in the myocardial T2\*.<sup>20</sup>

Deferiprone (1,2-dimethyl-3-hydroxypyridin-4-one) (Fig 55-2) is a bidentate chelator that forms an uncharged 3:1 complex with iron, enabling it to cross membranes easily and remove toxic iron from cells. It is effective orally, but has a short half-life (<2 hours) and must be taken three or four times a day. Excretion occurs in the urine. It is less effective than deferoxamine in reducing the LIC, but seems to have greater effectiveness in removing myocardial iron.<sup>47</sup> A retrospective study of patients who had undergone long-term treatment with deferiprone showed that there were significantly fewer cardiac events in those patients compared to patients who had been treated with deferoxamine alone.<sup>24</sup> Serious idiosyncratic complications have been reported with its use, including neutropenia (up to 5%), agranulocytosis (up to 0.5%), the development of an erosive

arthropathy (5% to >20%), and the development of a neurologic syndrome of cerebellar and psychomotor retardation.<sup>65</sup> In spite of adherence to the suggested weekly monitoring of blood counts, one death from agranulocytosis has been reported.<sup>66</sup> A Canadian study described progression of hepatic fibrosis in several patients who were undergoing long-term therapy.<sup>67</sup> A subsequent study did not confirm this finding<sup>68</sup> but has been criticized.<sup>69</sup> Deferiprone is prescribed at 75 to 100 mg/kg/day divided into three doses, with careful monitoring of blood counts every week. The ability of this drug to move across the cell membrane led to the idea of using it in combination with deferoxamine, with deferiprone acting as a siphon to bind iron and transport it extracellularly. Although one study showed that patients treated with combination deferoxamine and deferiprone showed significantly greater improvements in T2\* than those on deferoxamine alone,<sup>48</sup> the significance of this finding is limited by the small number of subjects and the short duration of evaluation. This drug is not approved for use in the United States, and the conclusion of a recent independent review by the Cochrane Collaboration<sup>70</sup> was that “deferiprone is indicated for the treatment of iron overload in patients with thalassemia major when deferoxamine is contraindicated or inadequate.”

Deferasirox (Exjade, Novartis) (Fig 55-2) is a tridentate N-substituted bis-hydroxyphenyltriazole chelator that forms a 2:1 complex with iron that is primarily excreted in bile. With a plasma half-life of 12 to 16 hours, once-daily administration means the drug is present in the circulation throughout the day, enabling constant effective scavenging of iron. Phase III studies of this agent, comparing it to deferoxamine, have only recently been reported.<sup>32</sup> At the suggested and subsequently approved starting dose of 20 mg/kg, most patients were not able to achieve negative iron balance in this study, although most but not all did appear to maintain their iron balance. Although it was able to cause negative iron balance (reduction in LIC) in the majority of patients at doses of 30 mg/kg/day, there was a high incidence (up to 39%) of hepatic and/or renal toxicity at this dose level. Other side effects include gastrointestinal upset (15%), rash (11%), and, rarely, neutropenia. Patients who are taking this agent should be monitored carefully for hepatic and renal function, and appropriate dose adjustments should be made. As yet, there are no published data on the efficacy of deferasirox in removing myocardial iron, but studies are in progress. Trials using 30 to 40 mg/kg/day of deferasirox are under way for highly iron-loaded patients who are intolerant to deferoxamine. Combination trials with deferoxamine and deferasirox are currently being designed.

**Figure 55-2.** Chemical structure of the different chelator molecules.

### Initiation of Chelation

The optimal range recommended for maintaining the LIC is 3 to 7 mg/g dry weight, as discussed previously. When this range is reached after regular transfusion, chelation therapy should be initiated. There are no immediate clinically apparent consequences of not instituting chelation when the patient reaches this range of iron overload, because such complications usually result at higher levels and after more prolonged loading.

The goal of therapy is to prevent these complications and chelation should be instituted well before they occur. The range for initiation of chelation is usually reached when the total transfused red cell volume reaches 150 to 180 mL/kg. If records of transfused volumes are not available, the LIC (as measured by biopsy) or noninvasive methods (such as SQUID or MR) should be used to guide the decision. In children in whom iron is required for growth, aggressive chelation could potentially reduce the amount of available iron. A conservative LIC of 4 to 5 mg/g dry weight is usually used as the threshold for initiating chelation (Table 55-1). Although an oral chelating agent would be much preferred by patients compared to a parenterally administered one, there is still not enough experience or data with regard to the long-term use of deferasirox as a first-line agent, and deferiprone is recommended only if deferoxamine is contraindicated.<sup>71</sup> Deferoxamine is still recommended as the choice for initiation of chelation.<sup>71</sup> Patient education, compliance, and preference should also be taken into consideration.

### Compliance

Compliance with chelation therapy is the primary determinant of morbidity and survival in such patients, and the responsibility of the medical team caring for such patients in reinforcing this cannot be emphasized enough. If compliance with chelation is poor, iron loading exceeds removal and iron accumulates first in the liver and then in the other parenchymal tissues including the heart. A recent meta-analysis of 18 studies involving patients with thalassemia confirmed that noncompliance results in significant cardiac and endocrine morbidity, and increased risk of death from heart disease.<sup>72</sup> When transfusion and chelation are begun in early childhood, it is usually the responsibility of the parent to ensure that the chelation regimen is followed. In adolescence and young adulthood, when this responsibility shifts to the patient, various distractions and life-changing events may result in poor compliance. Often a lack of physical symptoms in spite of significant iron overload lulls such individuals into a false sense of wellness and invulnerability. This is a particularly critical time for all caregivers to monitor these patients very carefully. Similarly, older individuals who have begun regular transfusion

later in life may feel that it is unnecessary to chelate because the onset of symptoms may be years later. Education and constant reinforcement is necessary to ensure compliance and reduce morbidity and mortality.

Patients undergoing chelation therapy should be vigilant for symptoms and signs of infection, particularly if they have undergone splenectomy. Chelation may be temporarily suspended if there is any suspicion of a bacterial or fungal illness, until this is appropriately managed.

### Intensification of Chelation

Noncompliance resulting in a positive iron balance and an increase in the LIC or shortening of the T2\*, would necessitate changes in the chelation regimen to prevent progression of organ damage. The compliance record should be closely examined and consultation with an expert in the management of iron overload should be undertaken before intensification of chelation is begun. Dosage of deferoxamine can be increased to a maximum of 50 mg/kg/day, beyond which there seems to be no additional increment in urinary iron excretion.<sup>63</sup> Higher doses have also been associated with the development of a pulmonary syndrome.<sup>73</sup> Increasing the frequency of subcutaneous administration to 7 days per week is a more effective strategy (Table 55-1). For patients with symptomatic heart disease, continuous intravenous chelation with deferoxamine at 50 mg/kg/day has been shown to be effective in reversing heart failure, improving cardiac function, and reducing the LIC more effectively<sup>19</sup> (Table 55-1). Generally, an indwelling catheter is required, because deferoxamine may cause sclerosis of peripheral veins. Close monitoring for toxicity and efficacy is necessary. Because noncompliance is the primary cause of severe loading, this regimen may not be acceptable to the patient. Although a combination of deferoxamine and deferiprone has been reported to be effective in reducing the iron burden in the liver and the heart,<sup>48</sup> the number of patients in the study was small, and the duration of follow-up was short. Longer prospective studies with larger numbers of patients are required before combination therapy can be recommended. Results of long-term, prospective, randomized trials of higher doses of deferasirox are not available. Intravenous deferoxamine

**Table 55-1.** Guidelines for Chelation Therapy

|                                                                      | Indication                                                                        | Choice of Product/Regimen                                                                                                                                                          |
|----------------------------------------------------------------------|-----------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Initiation of chelation                                              | LIC 3-7 mg Fe/g dry weight, or total red cell volume transfused 150-180 mL/kg     | Deferoxamine 35-40 mg/kg by subcutaneous infusion over 8-12 hours five to seven times/week; only if deferoxamine is unacceptable, deferasirox 20 mg/kg/day on empty stomach, daily |
| Intensification (in conjunction with expert consultation and advice) | LIC 8-15 mg Fe/g dry weight, or T2* <20 msec, without clinical cardiac disease    | Deferoxamine 50 mg/kg/day by subcutaneous infusion daily                                                                                                                           |
|                                                                      | LIC >15 mg Fe/g dry weight, or T2* <10 msec, or onset of clinical cardiac disease | Deferoxamine 50 mg/kg/day by continuous infusion via central venous catheter                                                                                                       |

LIC = liver iron concentration.

as described above should also be considered for any patient with a severe iron burden, corresponding to LICs above 15 mg/g dry weight even in the absence of clinical cardiac deposition, and for those with myocardial T2\* values below 10 msec.

### Monitoring Chelation Therapy

Once chelation is begun, regular noninvasive assessment of iron deposition in the heart (MRI T2\*) and liver (MRI R2 or SQUID) every 12 to 18 months is recommended (Table 55-2) to ensure the efficacy of chelation and give warning of rising levels, which may be associated with significant iron toxicity. Higher LICs predispose to progression of fibrosis,<sup>31</sup> and the development of cirrhosis; keeping the iron level in the ideal range of 3 to 7 mg/g dry weight is an important preventive measure. Simultaneously, monitoring the cardiac T2\* for myocardial deposition is also critical. A liver biopsy is indicated if there is coexisting hepatitis or liver dysfunction suggestive of fibrosis or progression to cirrhosis. Adjustments in the chelation regimen should be based on changes in the LIC or the cardiac T2\*. More frequent measurements may be indicated after such changes have been made to ensure optimal efficacy of the regimen.

In addition to monitoring iron burden and adherence to chelation therapy, organ function must also be monitored for the development of abnormalities related to the transfusion and

chelation regimen (Table 55-2). The ideal method for assessing cardiac function is MR assessment of chamber dimensions, ventricular filling, and ejection fractions. This would provide indicators of systolic as well as diastolic function. Conventional echocardiography does not provide adequate assessment of diastolic function, and is suboptimal. Cardiac dysfunction in iron-induced cardiac disease is mainly diastolic and systolic function is preserved until late in the course of the iron-induced restrictive cardiomyopathy. Normal results often lead to a false sense of well being and noncompliance with chelation. Serial measurements may provide useful information on trends and may signal the need for closer evaluation by MRI.<sup>74</sup> Despite preserved global function, tissue Doppler echocardiography-detected regional wall motion abnormalities represent an early sign of cardiac disease.<sup>75</sup> These special echocardiographic techniques may be of limited use, but annual MR-based cardiac function assessment, performed at the same time as T2\* measurement, is the ideal method of monitoring. Holter monitoring for development of arrhythmias, is also recommended annually. Regular assessment of hepatic and renal function should also be part of comprehensive care. In addition to screening for transfusion-associated viral infections, frequent assessment is also indicated to monitor for chelator toxicity. Comprehensive annual endocrine evaluation including thyroid and parathyroid

LIC = liver iron concentration; SQUID = superconducting quantum interference device; MRI = magnetic resonance imaging; AST = aspartate transaminase; ALT = alanine transaminase; HBV = hepatitis B virus; HCV = hepatitis C virus; BUN = blood urea nitrogen; hGH = human growth hormone; HIV = human immunodeficiency virus.

function, bone density assessment, glucose tolerance, and gonadal function testing are recommended, especially for growing children and adolescents. Vision and hearing should be evaluated annually in patients on deferoxamine. Testing of pulmonary function is also recommended, although not as frequently. Monitoring for chelator toxicity should also be followed as shown in Table 55-2.

## Summary

Iron overload is a significant cause of transfusion-related morbidity and mortality. With improved survival of patients with inherited or childhood transfusion-dependent anemias, older individuals with marrow failure, and cancer patients who have undergone intensive chemotherapeutic treatments or stem cell transplantation, the prevalence of this entity is likely to continue to grow. New technologies are now available for the noninvasive assessment of the body iron burden, making it easier to quantify the amount of excess storage iron in different tissues and to monitor the efficacy of chelation regimens. New oral drugs have made it easier for patients to be compliant with the chelation therapy that must be instituted in order to prevent tissue iron deposition and ameliorate the toxicity that would result from such deposition. As more information becomes available on the long-term use of deferasirox, combination therapy with deferoxamine may change the way chelation is prescribed. Research continues on the development of newer oral chelators. These advances hold promise for a new era of effective diagnosis, monitoring, and treatment of transfusional iron overload.

**Jonathan P. Wallis<sup>1</sup> & Ulrich J.H. Sachs<sup>2</sup>**<sup>1</sup>Consultant Haematologist, Department of Haematology, Freeman Hospital, Newcastle upon Tyne, United Kingdom<sup>2</sup>Head, The Platelet and Granulocyte Laboratory, Institute for Clinical Immunology and Transfusion Medicine, Justus Liebig University, Giessen, Germany

Acute noncardiogenic pulmonary edema occurring immediately after transfusion of donor plasma known to contain leucoagglutinins was first clearly described by Brittingham in 1957.<sup>1</sup> Scattered case reports of “allergic pulmonary edema” or “anaphylactic pulmonary edema” followed. In 1985 Popovsky and Moore<sup>2</sup> published the first prospective study of this complication that—recognizing the similarity in pathophysiology with the syndrome of acute lung injury (ALI) seen in critically ill patients—they called transfusion-related acute lung injury (TRALI). They reported a much higher incidence of the complication than had previously been considered likely, and following their report, increasing numbers of individual cases and small case series were published. However, with the development of hemovigilance schemes in the late 1990s, it became apparent that TRALI was not only an important cause of transfusion-related morbidity but, with the reduction in infective complications of transfusion, the leading cause of transfusion-related mortality. In the first decade of this century, recognition and understanding of the condition has further increased and the first serious efforts at prevention have been made.

## Clinical Features

Clinical reports of TRALI describe a sudden deterioration in lung function closely related to blood transfusion. The changes occur rapidly and generally begin within 2 hours and nearly always within 6 hours of the subsequently implicated transfusion. A small number of reports suggest that the onset may rarely be delayed until 12 hours or more after transfusion.<sup>3</sup> The conscious patient describes a tightness in the chest, feels short of breath, develops a dry cough, and may also experience nausea, dizziness, and rigors. On examination the patient is hypoxic, is often

hypotensive, and has tachypnea and tachycardia. Widespread crepitations are heard on auscultation of the chest. Rigors and fever are commonly reported but are not always present and fever may develop only some hours after the transfusion.

On intubation, or on suction of the already ventilated patient, a typical finding is of a copious frothy tracheal exudate, much like lightly whipped egg white. The nature and quantity of this exudate are often remarked on by attending anesthetists and it may be considered one of the hallmarks of severe TRALI. Arterial blood gases show hypoxia and hypercapnia that is often severe. Chest x-rays show nodular shadowing typically in the “bat’s wing” pattern of acute respiratory distress syndrome (ARDS) (Fig 56-1). Physiologic measurements such as pulmonary artery wedge pressure or esophageal Doppler study of the left atrium show systemic hypovolemia that may be marked. Further diagnostic tests of value are described below.

These cases represent the severe end of the spectrum of the disorder. Most early published reports describe severe cases such as these, but with more knowledge of the condition many milder cases are being recognized. Milder cases are proportionately less dramatic.

Recovery of respiratory function starts as early as 6 hours after the onset in milder cases but in severe cases deterioration may continue until 24 hours or beyond.

Some authors have reported a slightly different clinical picture in which the chief signs are rigors and fever with transient respiratory dysfunction, hypertension rather than hypotension, and usually occurring within 30 minutes of transfusion. Pulmonary edema is not always demonstrated radiologically and recovery is within 1 or 2 hours. These reactions have typically been associated with cellular blood components. It has been suggested that these cases may represent a different and non-antibody-related etiology (see below) from the “classical” severe cases.<sup>4</sup> However, a similar spectrum of mild to moderate reactions of this nature has also been documented with transfusion of plasma containing antibody to a neutrophil antigen, anti-HNA-2a.<sup>5</sup>

Acute lung injury with noncardiogenic pulmonary edema is common among critically ill patients and is generally

**Figure 56-1.** Chest x-rays from a 33-year-old man with severe TRALI, taken 2 hours (A) and 24 hours (B) after onset of symptoms, following transfusion of FFP containing HLA Class II antibodies. Note the “bat’s wing” pattern of edema with sparing of the lung bases, and the air bronchograms clearly visible on the first radiograph, and the more confluent airspace shadowing but still with basal sparing in the second x-ray.

considered to have a multifactorial pathogenesis. Many sick patients receive transfusion, especially after multiple trauma. There is evidence that TRALI is a significant contributor to ALI and that plasma-rich components from female donors are particularly implicated. The relationship between ALI and TRALI is further discussed below.

**Figure 56-2.** Sections of lung from a fatal case of TRALI. Note the presence of granulocytes in the capillaries (arrow indicates neutrophils).

## Pathophysiology

### Acute Lung Injury

ALI is the result of a capillary endothelial leak that allows fluid to pass from the pulmonary vessels, initially into the interstitial space and subsequently into the alveolar space. Because this edema is distinct from hydrostatic edema caused by cardiac failure or volume overload, it is sometimes known as nonhydrostatic edema. Numerous stimuli have been suggested to contribute to the likelihood of developing nonhydrostatic pulmonary edema including sepsis, trauma, aspiration of gastric contents, disseminated intravascular coagulation, and high tidal volume ventilation. In some cases of TRALI the transfusion appears to be the only probable cause of the lung injury, whereas in other cases it may be only one of several possible factors present. Histopathology, clinical findings, and experimental work have helped elucidate the nature of the stimulus from the transfused blood and the mechanism of the lung damage.

### Histopathology

Histopathologic findings from fatal TRALI cases are consistent with those for early ARDS, showing interstitial and intraalveolar edema<sup>2,3,6-10</sup> and extravasation of neutrophils into the interstitial and air spaces (Fig 56-2).<sup>3,6,7,10</sup> Hyaline membranes and destruction of the pulmonary architecture have been reported.<sup>6,7</sup> A consistent finding in TRALI is the presence of increased numbers of neutrophils within the pulmonary capillary vasculature and small pulmonary vessels.<sup>9,10</sup> On electron microscopic pictures, neutrophils were degranulated and focally in direct contact with

denuded stretches of the capillary wall. A positive correlation has been reported between capillary leukostasis and desquamated epithelial cells and between the degree of capillary leukostasis and the amount of proteinaceous fluid within the alveolar air spaces.<sup>10</sup> From these observations it appears that the neutrophil is central to the occurrence of lung damage. After sequestration in the early stages of TRALI, neutrophils and endothelial cells of the pulmonary microvasculature establish close contact. Activation of the neutrophils leads to endothelial damage and capillary leakage. The transit of proteinaceous fluid from the vessels into the air spaces results in acute pulmonary edema. In the later stage, especially of severe TRALI, neutrophils extravasate from the capillary into the alveoli and induce further pulmonary injury.

Evidence for an Antibody-Related Etiology

The relationship between TRALI and leukocyte antibodies in donor plasma was first noted by Brittingham, who reported that leukoagglutinins present in the plasma of a multitransfused patient induced an acute pulmonary reaction when transfused to a volunteer.<sup>1</sup> Severe pulmonary edema was similarly induced in a healthy volunteer who received an experimental gamma globulin concentrate, deliberately prepared from plasma that contained leukocyte, and, in particular, monocyte-reactive antibodies.<sup>11</sup> It is likely that this preparation contained high levels of HLA Class II antibodies. In addition to these cases of TRALI resulting from experimental transfusion of plasma containing leukocyte antibodies, there are numerous case reports of TRALI in which a transfused unit has been found to contain antibodies reactive with recipient leukocytes. In two large series of TRALI, where pulmonary infiltrates were apparent in chest x-rays, leukocyte antibodies in the donor of a transfused blood component were detected in 61% to 89% of cases.<sup>2,12</sup>

Animal models have provided confirmation of this antibody-mediated mechanism of TRALI. Severe vascular leakage was reproduced in isolated rabbit lungs by application of HNA-3a antibodies in an ex-vivo rabbit lung model.<sup>13</sup> From this experiment it was concluded that leukoagglutinating antibodies and concomitant complement activation are capable of causing TRALI. Other animal experiments have confirmed that antibodies are capable of causing TRALI but suggest that complement is not a prerequisite for TRALI induced by antibodies to CD177 (HNA-2a), because the induction of TRALI was found to be dependent on the density of the cognate antigen and occurred in a complement-free environment.<sup>14</sup> Alternative mechanisms leading to TRALI have been proposed and are discussed later, but the available evidence strongly suggests that donor leukocyte antibodies reacting with recipient antigens are the predominant mechanism.

Specificities of Antibodies Identified as Causing TRALI

Antibodies to HLA Class I and II antigens and to neutrophil antigens have all been clearly implicated as causing TRALI. Evidence from hemovigilance schemes and laboratories specializing in TRALI investigation has shown that the majority of cases (75-90%) are associated with HLA antibodies, and that with

Table 56-1. Leukocyte Antibodies Implicated in Transfusion-Related Acute Lung Injury\*

\*Only antibody specificities that matched the antigens of the transfusion recipient are listed.

improved detection techniques about 50% of these are directed against Class II antigens.<sup>15</sup> Antibodies to neutrophil antigens are found in about 10% to 25% of cases. The spectrum of antibody specificities is shown in Table 56-1.

Mechanisms of Lung Damage in TRALI

Priming and Activation of Neutrophils

In TRALI the endothelial and alveolar cell damage appears to be mediated chiefly by activated neutrophils. Neutrophils activated by injurious agents will respond by the release of preformed granular enzymes and proteins and by the de-novo synthesis of a range of highly toxic reactive oxygen species (ROS). Neutrophils may be activated directly by one sufficiently strong stimulus, but the process often requires two or more stimuli. The first or “priming” stimulus will potentiate the response to a second or “activating” stimulus. A large percentage of patients who develop TRALI are sick, and there is in-vivo evidence that surgical

**Figure 56-3.** The neutrophil's passage through the pulmonary microvasculature. Approximately 50% of all pulmonary capillaries surrounding the alveoli have a smaller diameter than the spheric neutrophil. (A) In order to pass through the capillary, neutrophils are forced to pause, deform, and assume a "sausage shape" that allows transit of the capillary. (B) Neutrophil priming is associated with a decrease of deformability (called "stiffening"), which results in local trapping of the cell and a prolonged overall transit time. (C) Activation of the endothelial cells of the capillaries results in the upregulation of surface ligands, which also results in local trapping of the cell and a prolonged overall transit time.

procedures and active infections induce neutrophil priming.<sup>16-18</sup> In response to priming agents, neutrophils undergo polarization, a process that leads to "stiffening" of the cell.<sup>19</sup> This "stiffening" augments mechanical retention of neutrophils within the pulmonary capillary bed and prolongs their passage through the lungs (see below).<sup>20</sup> Prolonged, close contact between neutrophils and the endothelium provides a micro-environment in which transmembrane receptors and released mediators of each cell type can interact closely. Sequestered neutrophils, having been primed in the circulation, and endothelial cells can be activated by exogenous stimuli present in the blood bag. These transfused stimuli include antibodies, cytokines, and bioactive lipids (see below).<sup>21,22</sup>

Antibodies to neutrophil antigens involved in TRALI cases are able to prime and to activate neutrophils in some cases without additional stimuli,<sup>14,23-25</sup> explaining why even completely healthy individuals can develop TRALI if the antibody stimulus is sufficient.<sup>11</sup>

### Aspects of Neutrophil Passage through the Pulmonary Microvasculature

The alveolar capillary bed is a complex interconnecting network of short capillary segments. The path of a neutrophil from arteriole to venule crosses up to eight or more alveolar walls and encounters more than 50 capillary segments. Approximately half of these pulmonary capillaries are narrower than the diameter of a spherically shaped neutrophil (Fig 56-3). This forces neutrophils to slow and to deform before passing through the narrow capillary segment.<sup>26</sup> The transit time of neutrophils through the

pulmonary microvasculature is mainly affected by their deformation time, and slow transit accounts for significant accumulation of neutrophils in the lungs.<sup>27</sup> The pulmonary circulation normally contains about 28%, the "marginated pool," of the total blood neutrophil pool.<sup>28</sup> The stimulus-induced decrease in deformability appears to be more important than selectin-mediated rolling, a key mechanism of neutrophil adhesion within other capillary beds, but changes in surface receptors in primed neutrophils will also lead to molecular adhesion to endothelial cells.<sup>27,29,30</sup> Under physiologic conditions, primed and locally trapped neutrophils migrate from the capillaries into the alveoli as part of a local inflammatory reaction. In TRALI the primed and trapped neutrophil encounters a further activation signal in the form of transfused antibody or other transfusion stimulus, activates its microbicidal arsenal, and induces endothelial damage.

### Activation of Pulmonary Endothelial Cells

TRALI can also be triggered by activated pulmonary endothelium. In addition to constitutively expressed surface receptors, activated endothelial cells upregulate surface membrane receptors that facilitate neutrophil adhesion and priming.<sup>31-34</sup> Primary activation of endothelial cells has been suggested as the mechanism responsible for TRALI induction after infusion of bioactive lipids.<sup>35,36</sup>

### Neutrophil/Endothelial Cell Interplay

The interplay between neutrophils and endothelial cells, regardless of whether it has been started by neutrophil or endothelial cell activation, contributes largely to lung damage. Neutrophils respond to endothelial cell-derived mediators by activating and expressing integrins and by releasing proinflammatory mediators and granule contents. Released mediators activate endothelial cells, which, in turn, mobilize selectins, upregulate adhesion proteins, and produce inflammatory mediators; thereby, they enhance neutrophil adhesion and activation. It is within this interplay that the lung barrier breaks down and allows transit of proteinaceous fluid and, later, of neutrophils into the alveolar space. ROS released from neutrophils may play a relevant role in this process.<sup>7,14,37,38</sup>

### Mechanisms of Lung Injury by Different Mediators in Transfused Blood Components

The exact pathway leading to lung damage associated with transfusion depends on the nature of the antibody or other stimulus and the interplay between it and the cellular components.

### Antibodies to Human Neutrophil Antigens

Serologic work-up of TRALI patients identified antibodies to human neutrophil antigens in a number of cases.<sup>39-41</sup> In hemovigilance schemes, they are detected in approximately 10% of cases. As discussed above, the ability of these antibodies to induce TRALI has been shown in ex-vivo models of lung injury.<sup>13,14</sup> HNA antibodies, particularly those of HNA-2a, HNA-3a and HNA-4a specificity, are capable of directly activating neutrophils, which appears to be the mechanism by which they induce TRALI [Fig 56-4(A)].<sup>14,23,42,43</sup>

**Figure 56-4.** Proposed mechanisms of TRALI. The activation of neutrophils and the subsequent release of toxic agents that harm the endothelium is a key mechanism in TRALI. Epidemiological, clinical, and experimental data show that most TRALI reactions are induced by antibodies present in a transfused blood component. These antibodies may recognize epitopes on the surface of (A, B) the neutrophil, (C) the monocytes, or (D) endothelial cells. Binding of HNA or HLA Class I antibodies to neutrophils causes direct activation of the cell. Binding of antibodies, especially of HLA Class II antibodies, to monocytes has been proposed to induce the release of mediators that activate the neutrophil. Experimental data

demonstrate that neutrophils may also be activated indirectly when HLA Class I antibodies are bound to the endothelium of the lung, where they can recruit neutrophils via their Fc receptors binding to the Fc parts of these antibodies. Fc receptor cross-linking leads to neutrophil activation. (E-F) Biologically active substances other than antibodies (eg, bioactive lipids and CD40L derived from cellular blood components) are thought to cause some cases of TRALI. These substances are usually too weak to activate neutrophils directly, but may induce TRALI in concert with other factors that activate endothelial cells or neutrophils. See text for details.

### Antibodies to HLA Class I Antigens

Only a few studies have investigated the mechanisms by which major histocompatibility complex (MHC) Class I antibodies induce a TRALI reaction. An elegant study performed on mice by Looney and coworkers<sup>44</sup> presented in-vivo data on the mechanism of endothelial cell-dependent TRALI [Fig 56-4(D)]. Transfusion of an MHC Class I monoclonal antibody to mice expressing the cognate antigen induced TRALI and acute peripheral blood neutropenia. Mice lacking neutrophils and mice lacking the Fc $\gamma$ -receptor were resistant to MHC Class I antibody-induced TRALI. Transfer of wild-type neutrophils into FcR $\gamma^{-/-}$  mice restored TRALI following antibody infusion. This model is consistent with binding of the antibody directly to endothelial cells, in the first vascular bed encountered after injection, and recruitment of neutrophils through binding of the immunoglobulin Fc portion to the neutrophil Fc $\gamma$ -receptor. The protection observed in FcR $\gamma^{-/-}$  mice argues against direct neutrophil activation by the antibody. A clinical example of TRALI in keeping with such a mechanism was reported by Dykes et al<sup>45</sup> in a patient who had undergone lung transplantation several weeks earlier and who developed lung injury in the transplanted lung only following transfusion. An antibody to HLA-B44 (HLA Class I antigen) was present in the donor of one of the transfused units, and the cognate antigen was expressed on the transplanted lung but not on the patient's native tissues.

In this case direct Fab-dependent interaction between MHC Class I antibodies and the neutrophils could not have

contributed to the neutrophil recruitment and subsequent lung injury. However, proof that HLA Class I antibody may also cause TRALI by direct binding to neutrophil antigens comes from case reports of “inverse TRALI.” In one well-documented case infusion of human granulocytes caused severe lung injury in a patient who had Class I antibodies.<sup>50</sup> The antibodies cannot have reacted with the native endothelial cells but did react in vivo with the donor granulocytes, in keeping with a mechanism of TRALI by direct activation of neutrophils [Figs 56-4(A) and 4(B)].

In summary, cases of TRALI caused by HLA Class I antibody may be by specific antibody binding directly to endothelial cells with Fc-induced neutrophil aggregation, by specific antibody binding to leukocytes, or by a combination of both.

### Antibodies to HLA Class II Antigens

The biological mechanism by which HLA Class II antibodies induce TRALI remains to be fully elucidated. Corresponding Class II antigens are not expressed on resting human neutrophils, although they may be expressed upon neutrophil stimulation.<sup>46</sup> Expression of HLA Class II antigens on activated endothelium has been described, but HLA Class II antigen expression was not found on vascular endothelium of pulmonary capillaries or intravascular neutrophils in a patient who experienced fatal TRALI caused by an HLA Class II antibody.<sup>38</sup> Blood monocytes and intraalveolar macrophages normally express HLA Class II, and one possibility is that binding of antibodies to HLA Class

II causes release of cytokines from monocytes and activation of neutrophils within the pulmonary circulation [Fig 56-4(C)].<sup>47,48</sup> It is uncertain at present whether local monocytes are able to produce sufficient amounts of cytokines to significantly alter the activity of neutrophils and/or the endothelium.

It is unlikely that transfused antibodies have direct access to the alveolar space through an intact endothelium in sufficient concentration to induce release of cytokines and subsequent activation of neutrophils and/or endothelial cells, but where there is already some damage to the pulmonary endothelium, such a reaction may exacerbate ALI.

It remains possible that detection of antibodies to HNA and HLA could be surrogates for antibodies to yet unknown antigens on other cell types, eg, on monocytes. Alloantibodies to these or other cells might explain some apparently antibody-negative cases.

### Inverse TRALI: Transfusion of Neutrophils

In most cases of TRALI, antibodies or neutrophil-priming agents present in the blood component are causative for the pulmonary reaction. However TRALI, as described above, has also been reported in alloimmunized patients receiving blood components that contain neutrophils. Viable neutrophils may still be present in other blood components and Popovsky and Moore estimated that 6% of observed TRALI cases were caused by antibodies present in the recipient.<sup>2</sup> As universal leukocyte reduction is introduced in more countries, inverse TRALI caused by leukocytes in platelet concentrates (PCs) and Red Blood Cells (RBCs) will become less important, but will remain of particular relevance to patients receiving granulocyte transfusions.<sup>49,50</sup>

### Bioactive Lipids

Blood components may accumulate intermediate metabolic products, such as bioactive lipids, during storage. These substances are breakdown products of membrane lipids, including lyso-phosphatidylcholines [C16, C18 lyso-platelet activating factor (PAF)], and act on neutrophils through the cells' PAF receptors in order to prime the respiratory burst reaction.<sup>51</sup> Because these neutrophil-priming agents do not develop in stored acellular plasma, their generation is dependent on the presence of blood cells. It has been demonstrated that posttransfusion sera from these patients contained significantly more neutrophil-priming activity than the controls,<sup>7</sup> and were also reported to induce TRALI after the transfusion of stored autologous blood.<sup>52</sup> In an ex-vivo rat lung model of TRALI, addition of both lipopolysaccharide (LPS) and plasma containing neutrophil-priming lipids obtained from stored RBCs was necessary to induce TRALI,<sup>7</sup> which is in accordance with the pathophysiologic model that priming precedes efficient activation of neutrophils [Fig 56-4(E) and (F)]. Plasma from stored PCs and containing neutrophil-priming lipids can cause TRALI in an identical animal model.<sup>36</sup> In this model, rats were treated with LPS to approximate active infection. Lungs from LPS-treated animals perfused ex vivo with plasma from stored RBCs or stored PCs, but not plasma from identical fresh RBCs or PCs, evidenced

TRALI.<sup>51</sup> Lungs pretreated with vehicle instead of LPS did not evidence TRALI with any of the perfusates.

### CD40-Ligand

CD40 ligand (CD40L) is another neutrophil-priming breakdown product. It is a platelet-derived proinflammatory mediator found in cell-associated and soluble (sCD40L) forms. It may be found in PCs and accumulates during storage.<sup>53</sup> sCD40L binds to CD40, which is present on the surface of monocytes, macrophages, and neutrophils.<sup>54</sup> This CD40L/CD40 interaction induces neutrophil priming. CD40L has been identified as a possible cofactor in TRALI because its concentration in transfused PCs that were involved in TRALI cases was found to be significantly higher than in control units. In vitro, human microvascular endothelial cells preincubated with LPS experienced severe damage when sCD40L-primed neutrophils were added, whereas unprimed neutrophils did not induce such damage.<sup>54</sup>

### Immune Complexes

Incubation of neutrophils with immune complexes (ICs) results in production of tumor necrosis factor alpha (TNF- $\alpha$ ) and induced apoptosis of endothelial cells in vitro.<sup>55</sup> It remains speculative whether antibodies present in blood components might form ICs with their corresponding soluble HNA or HLA antigens in the recipient's circulation and so prime or activate neutrophils in the pulmonary circulation.

### Immunoglobulins

Normal IgG has been postulated to activate neutrophils in a patient with osteopetrosis being treated with gamma interferon and granulocyte and monocyte colony-stimulating factor.<sup>56</sup> The patient had very low levels of endogenous IgG1 and IgG2 and developed severe lung injury shortly after transfusion of platelets from an untransfused male donor. No leukocyte antibodies could be found either in donor or recipient. It is suggested that transfused IgG binding to the neutrophils, which were already primed by interferon and stimulating factor, was sufficient to cause neutrophil activation and lung injury. This case may be considered to be a good example of "multiple hit" TRALI.

Reports of lung injury following intravenous IgG infusion are rare and seem to be associated with high doses or concentrates prepared intentionally with high level of leukocyte antibodies.<sup>11,57</sup> It is possible that antibodies are both diluted and neutralized during the preparation of the pooled product as suggested for pooled viridically treated plasma.<sup>58,59</sup>

### Multiple Hit/Threshold Theory of TRALI Causation

Where the stimulus to endothelial and neutrophil activation is sufficient, lung damage can occur in an otherwise healthy individual with no other likely cause of lung injury. Evidence for this comes from reports of TRALI in transfused volunteers as described above and also from reports where plasma has been used for clinical reasons in otherwise healthy individuals. These cases are a minority and most patients receiving transfusion and

**Figure 56-5.** A TRALI threshold model. The TRALI threshold model proposes that a certain threshold must be overcome to commence a TRALI reaction. The threshold of mild TRALI, in which oxygen supply is sufficient, is lower than that of severe TRALI, in which patients require mechanical ventilation (horizontal lines). In order to overcome this threshold, numerous factors must act in concert. These factors can be summarized as strength of exogenous transfusion-related mediators (light box) and individual predisposition of the patient (grey box). The individual predisposition covers both constitutive (genetic) factors and dynamic or acute influences, ie, acute infection or trauma. A strong exogenous transfusion-related mediator, such as a strong activatory neutrophil-specific antibody, will precipitate a TRALI reaction even if the influence of the individual predisposition is low (example A, in an otherwise healthy recipient). In contrast (example B, an individual “at risk,” such as a septic patient with an activated pulmonary endothelium), a relatively mild exogenous transfusion-related mediator with low neutrophil-priming activity will be sufficient to overcome the threshold. Used with permission from Bux and Sachs.<sup>60</sup>

especially transfusion of plasma have significant comorbidities, some or many of which may also result in priming or activation of neutrophils or damage to pulmonary endothelial cells. It has been suggested that TRALI will be more common in such patients. Early reports noted that most patients with TRALI had recently undergone surgery and suggested that this in itself was a sufficient second stimulus in many cases. Some experimental evidence for the theory of “two hit” or “multiple hit” theory has been provided by studies on bioactive lipids described above.<sup>36</sup> The theory of “multiple hits” has been further developed by Bux and Sachs,<sup>60</sup> who suggest that the neutrophil is central to the pathogenesis of TRALI and that activation of the neutrophil requires sufficient stimuli from one or more sources to reach a certain threshold at which point full activation and lung damage will ensue (Fig 56-5). Depending on the magnitude of the neutrophil response, the lung damage can be mild or severe with corresponding clinical effects.

### ALI and Transfusion in Critically Ill Patients

Clinical evidence for the theory that “multiple hits” may result in TRALI has been provided by studies involving critically ill patients who are known to be susceptible to ALI. Numerous retrospective studies have suggested a relationship between the amount of blood transfused and morbidity and mortality. All these studies are beset by the difficulty in allowing for the confounding factor of how much blood the patient required also being a marker for the severity of the illness. The Transfusion Requirements in Critical Care (TRICC) trial of transfusion triggers was both prospective and randomized and found a

significantly higher incidence of pulmonary edema and a higher incidence of ALI in patients receiving more transfusion where the standard component was relatively plasma rich.<sup>61</sup> Gajic et al<sup>62</sup> studied the clinical associations with ALI developing in patients during mechanical ventilation that was required for management of critical illness. They found a strong association with transfusion of plasma, but not with red cell transfusion, age of transfused red cells, the leukocyte content of transfused red cells, or with platelet transfusion. Further studies identified transfusion of female plasma as being particularly associated with development of ALI in keeping with an antibody type of mechanism.<sup>63</sup> A prospective study in intensive care patients comparing male donor and parous female plasma found similar results.<sup>64</sup> The incidence of ALI associated with transfusion in these studies was of the order of 1 in 50 to 200 units of female plasma transfused, a far higher incidence than the reported incidence of TRALI in other circumstances. These findings are in keeping with the “multiple hits” or “threshold” model of TRALI in which highly susceptible patients subject to multiple toxic insults to neutrophils and endothelial cells develop lung damage after a relatively mild additional stimulus from transfusion.

## Diagnosis and Differential Diagnosis

### Respiratory Dysfunction

The development of new respiratory dysfunction caused by pulmonary edema in association with recent transfusion should be considered as evidence of possible TRALI. Significant respiratory dysfunction consistent with ALI can be defined as a decrease in transcutaneous oxygen saturation to less than 90% or an arterial  $pO_2$  of less than 60 mm Hg while breathing room air, or a  $PaO_2/FiO_2$  ratio of less than 300 mm Hg.

Pulmonary edema can be demonstrated by clinical examination and chest x-ray. Alternative causes of sudden respiratory dysfunction, without edema, include transfusion-related problems such as allergic reactions with bronchospasm, shock associated with a bacterially infected unit or with ABO incompatibility, and causes unrelated to the transfusion such as cardiac arrhythmias, infection, and pulmonary embolus (Fig 56-6).

### Distinguishing between Hydrostatic and Nonhydrostatic Pulmonary Edema

Once pulmonary edema is demonstrated, it is necessary to determine whether it is cardiogenic (hydrostatic) or caused by increased capillary permeability as in TRALI and other forms of ALI (nonhydrostatic). Cardiogenic pulmonary edema may be caused by transfusion-associated cardiac overload (TACO) or may be caused by factors unrelated to transfusion, such as simple overhydration, especially in renal failure.

### Radiology

Radiographic appearances of edema from increased pulmonary capillary permeability are often characteristic with patchy

**Figure 56-6.** Flow chart for diagnosis of TRALI.

or nodular shadowing, mainly peripheral but sparing both the apices and the costophrenic angles and with the appearance of air bronchograms. This pattern is sometimes likened to a bat's wing. In contrast, cardiogenic edema typically shows upper lobe venous distension and edema in the perihilar and basal areas. Edema in overhydration or renal failure is typically perihilar, and shows no air bronchograms. In severe TRALI or in later stages, the radiologic appearances may progress to a complete white-out of the lung fields.

### Physiologic Measurements

Physiologic measurements are aimed primarily at assessing the cardiac status. Measurement of the left atrial pressure or volume may be by pulmonary artery wedge pressure through a Swan-Ganz catheter, via esophageal Doppler ultrasound, or by transthoracic echocardiography. High left atrial filling pressure or volume suggest cardiogenic pulmonary edema or fluid overload.

Normal or low pressure or volume is in keeping with noncardiogenic pulmonary edema. Low levels indicate hypovolemia, a common finding in TRALI. Electrocardiography may also be helpful in detecting cardiac strain patterns or evidence of infarction.

Prior or new cardiac failure does not exclude the possibility of TRALI, because both may be present in the same patient. However, cardiac failure does indicate that the use of diuretics, which are otherwise contraindicated in TRALI, may be beneficial.

### Laboratory Tests

A serum level of B-type natriuretic peptide (BNP) of less than 250 pg/mL is consistent with ALI rather than cardiac failure, while a level of greater than 250 pg/mL or a twofold increase from a previous level is consistent with cardiac failure.<sup>65</sup> A low level is not completely specific for ALI nor very sensitive, as many patients with ALI also have cardiac dysfunction. A high level may also be seen in renal failure.

| D. No temporal relationship to an alternative risk factor for ALI      |
| II. Possible TRALI                                                     |
| A. ALI                                                                 |
| B. No preexisting ALI before transfusion                               |
| C. During or within 6 hours of transfusion                             |
| D. A clear temporal relationship to an alternative risk factor for ALI |

A protein concentration in the pulmonary edema of greater than 70% of the serum protein is strong evidence in favor of a capillary to alveolar leak as seen in ALI from any cause.

### Implicating Transfusion as a Cause of Nonhydrostatic Edema

#### Consensus Definition of TRALI

A consensus definition of TRALI was agreed upon in 2004.<sup>66</sup> A clinical diagnosis of TRALI is considered where a new episode of ALI has occurred within 6 hours of a blood component or derivative transfusion. Where no other cause of ALI is found, the diagnosis of TRALI is considered probable whatever further tests show. Where another possible cause of ALI is present, the diagnosis of TRALI can only be considered possible (Table 56-2). These criteria are useful but do not include laboratory tests. Many cases of TRALI will be in patients with competing etiologies for ALI. Further recipient and donor investigation can help determine, often in retrospect, the probability that the lung injury was wholly or partly due to transfusion.

#### Laboratory Tests

##### *Changes in Circulating Leukocytes*

Leukopenia and, in particular, neutropenia and monocytopenia occurring within the first hour after the transfusion and possibly present before the development of clinical lung injury, are supportive of transfusion as opposed to other causes of ALI. The neutropenia is often followed by neutrophilia 5 to 6 hours later.<sup>1,67</sup> Monocytopenia is common, may be absolute, and may be more persistent than the neutropenia.<sup>67,68</sup> Neither change is completely specific or sensitive. The degree of neutropenia is likely to be greater with neutrophil-specific antibodies such as

anti-HNA-2a, and with neutrophil agglutinating antibodies such as anti-HNA-3a and anti-HLA-A2, whereas monocytopenia alone is most likely to be seen with HLA Class II antibodies.<sup>68</sup> Neutropenia is seen without evidence of lung damage with some neutrophil-specific antibodies.<sup>5,69</sup>

#### Donor Tests

To implicate a particular donation as a cause of antibody-related TRALI requires leukocyte typing of the recipient and antibody testing of the donors (see below). Samples for neutrophil and HLA typing should be taken early from the patient in case death ensues. The finding of a donor/recipient antibody/antigen match is of value in donor management and will make the diagnosis of TRALI more likely than a negative investigation, especially where only a small number of units have been transfused. Such matches also occur in patients without TRALI, and are of increasing statistical likelihood where a large number of units have been transfused. A positive match does not prove that TRALI has occurred.

### Management and Outcome

#### Management of the Patient

The mainstay of treatment is respiratory support, either with oxygen alone, or with oxygen and continuous positive airway pressure by mask or mechanical ventilation. In severe cases with systemic hypovolemia, there must be adequate fluid replacement in addition to positive pressure ventilation. This will often require central venous pressure or left atrial volume monitoring. Additional strategies such as high-frequency ventilation and prone ventilation can be of value. Diuretics are contraindicated, because they have been clearly reported to worsen the hypovolemia and hypotension in several cases.<sup>49,70</sup> Only where there is concomitant fluid overload from cardiac failure or other causes are diuretics indicated. The use of corticosteroids after the insult is of uncertain value. Where the diagnosis is made within 6 hours and the lung damage is severe, use of high-dose steroids might in theory limit further damage by inhibition of neutrophil activation. Prednisolone, methylprednisolone, and dexamethasone have all been used, but there is no useful clinical evidence regarding efficacy. Where the diagnosis is made later, they are unlikely to be of value. In intractable cases for which maximal ventilation is insufficient, extracorporeal membrane oxygenation has been used to support the patient until recovery.<sup>71</sup> The use of plasmapheresis with the intent of removing the causative antibody has been reported.<sup>11</sup> Further transfusions should be given if clinically indicated, but plasma-rich products from female donors should be avoided.

#### Clinical Course and Outcome

Most patients begin to improve by 24 hours after the initial injury. Milder cases improve as early as 6 hours. Chest x-rays usually show clearance of edema by 48 to 96 hours. Nearly all patients who recover do so without any long-term lung damage. Other organ damage such as acute renal failure is seen in more

**Figure 56-7.** Flow chart for investigation and management of donors.

severe cases, although it is not clear whether this is all due to hypoxia and hypovolemia or whether there is damage to capillary beds in organs other than the lungs.<sup>67</sup> Mortality in different published series varies between 5% and 30%. This depends in part on how cases are ascertained. Where patients receiving transfusion were assessed prospectively for the complication, the incidence was higher, presumably because of recognition of milder cases, but the mortality was low (6%). Where reports depend on a physician recognizing and reporting the condition, the incidence is lower but mortality higher. As an example, the hemovigilance scheme in the United Kingdom (UK) reported seven deaths out of 28 possible, probable, or likely cases reported in 2002, a mortality of 25%.<sup>72</sup> Mortality is more likely in patients receiving larger volumes of single donor plasma [including Fresh Frozen Plasma (FFP)] rather than RBCs and more likely in patients with more comorbidities.

### TRALI in Neonates and Children

TRALI has been reported in children with the same features as noted in adults, including leukopenia, nonhydrostatic pulmonary edema, and hypovolemia. Of 12 published reports, four ascribed death of the child partly or wholly due to the transfusion reaction.<sup>56,73,74</sup> Age range of cases is from 0 months to 16 years but only two neonatal cases have been reported,<sup>49,75</sup> and no neonatal cases have been reported to the UK hemovigilance scheme over 10 years. Use of blood components is more common in neonates than older children, and neonates also receive larger volumes of single donor plasma relative to their weight. It is possible that neonates are in some way less susceptible to TRALI.

### Directed Donations and TRALI

A particular feature of pediatric TRALI is its occurrence after the use of directed donations from the mother. This practice

has been documented to cause TRALI and can be expected to be high risk by virtue of the high probability of the mother having leukocyte antibodies that will match her child's antigen specificity.<sup>76</sup> By the same rationale, directed donations from a wife to a husband, or of a leukocyte-containing component from a child to a mother or a husband to a wife, will be particularly likely to cause TRALI.

### Donor Investigation

Strategies of donor investigation vary among blood centers. The dual aim of investigation is to help establish the diagnosis and to allow appropriate management of implicated donors. A typical scheme adapted from Su and Kamel<sup>77</sup> is shown in Fig 56-7. Investigation of donors is undertaken only when a diagnosis of TRALI is considered probable or possible. Donations transfused within the 6 hours before the development of lung injury are considered to be under suspicion. Where the number of possibly implicated donors is small (four or fewer) all donors should be investigated. Where the number of possibly implicated donors is greater, the high-risk donors with a history of pregnancy or transfusion are initially investigated. If a donor or donors are found with an antibody that matches a cognate antigen, investigations of the lower risk donors are not undertaken. If no donor is implicated in the initial investigation, further lower risk donors can be tested in those cases that are considered to be probable TRALI. A further selection policy is to initially investigate only those donors of plasma-rich components. Investigations are undertaken at a qualified laboratory with adequate sensitivity for HLA Class I and II antibodies, and HNA antibodies. Recipient HLA and HNA typing may be performed prospectively or only when a donor antibody is found. Tests for recipient antibodies may be undertaken when the lung injury followed transfusion of granulocyte concentrate, or following non-leukocyte-reduced

component transfusion in which no donor/recipient antibody/antigen match can be identified. When a nonantibody mechanism is suspected, or if an antibody-related etiology has been largely excluded, tests on the residual donation for abnormal lipids or other bioactive substances may be carried out at a research or reference center.

### Management of Implicated Donors

Management of implicated donors varies among countries and centers. It is possible to permanently defer all donors who are implicated in a case of TRALI by virtue of having leukocyte antibodies of any specificity. This would undoubtedly exclude many donors unnecessarily and the logical extension of such a policy is that all donors with leukocyte antibodies should be deferred whether or not they have been possibly implicated in a case of TRALI. Alternatively, only those donors with antibody matching a recipient antigen are excluded from future donation. This policy assumes that some feature of the antibody in that donor makes them more likely to have caused TRALI in the index case, and thus to cause TRALI with further donations. Finally, it is possible to defer donors who are either possibly or definitely implicated only from donation of plasma-rich components. In addition, some centers automatically defer permanently any donor found to have anti-HNA-3a because of the high frequency of the antigen in the recipient pool (95%) and the common association with severe TRALI. As more countries restrict the manufacture, of plasma-rich components to male or nulliparous untransfused females, the policy of donor management will become less contentious.

## Incidence and Epidemiology

### Variables Affecting the Incidence of TRALI

The frequency of reported TRALI depends upon variables affecting the donors, the recipients, and the physicians. Antibody-associated TRALI, which is the common and severe form, is nearly always associated with blood donations from female donors with a history of pregnancy and is both more common and more severe with transfusion of plasma-rich products, such as FFP or apheresis platelets. HLA antibodies have been found in approximately 15% of all female donors but are more common in those who have had more pregnancies and more recent pregnancies,<sup>78,79</sup> and are even more common with more sensitive tests.<sup>80</sup> Human neutrophil antibodies are less common. Therefore, incidence of TRALI will depend in part on the donors used by the local blood center. Policies to reduce the number of components containing antibodies are discussed below.

Look-back studies for regular donors of blood whose antibody-containing plasma has been implicated in a case of TRALI show that many cases of TRALI are either overlooked or unreported. In addition, infusion of an antibody to a recipient with a matching antigen does not necessarily result in TRALI.<sup>81,82</sup> Both inherited and acquired recipient variables and details of

the transfusion will affect the likelihood of developing clinically apparent TRALI. Inherited variables have not been defined but will almost certainly include polymorphisms in the immune response pathways. The presence of high levels of soluble HLA antigens in the recipient's plasma may be protective.<sup>83</sup> Acquired recipient variables include the presence of other lung insults, and other forms of comorbidity as discussed earlier. Transfusion variables include the titer and specificity of antibody, the volume of plasma infused, and the speed of infusion. Plasma-reduced RBCs transfused over 90 minutes rarely cause TRALI, whereas FFP given over 15 minutes—a more than 50-fold higher rate of plasma transfusion—is not uncommonly implicated.

Finally, the likelihood of diagnosing and reporting TRALI depends heavily on the physician's knowledge of the condition.

### Reported Frequency of TRALI

One single hospital prospective study estimated frequency for all blood components transfused without any donor selection as 1 in 5000 units.<sup>2</sup> A retrospective single hospital study estimated the incidence as 1 in 7900 units of FFP only.<sup>67</sup> Hemovigilance data from voluntary reports in the UK found a reported incidence of approximately 1 in 30,000 units of FFP transfused.<sup>72</sup> Retrospective studies of ALI/TRALI in critically ill patients and a single prospective trial of TRALI after FFP infusion found that as many as 1 in 50 to 200 units of plasma from parous female donors could cause some respiratory dysfunction when compared to plasma from male donors.<sup>64,65</sup>

It is not possible to give a single figure for incidence, but the chance of female donor plasma containing an antibody matching a recipient antigen is greater than 1 in 50. Severe and clinically distinct TRALI probably occurs about 1 in 2500 to 4000 units of female donor plasma transfused. ALI in which transfusion is a contributory factor in a critically ill patient may be much more common.

## Prevention

The majority of severe TRALI cases have an antibody-related etiology. Therefore, prevention is largely aimed at reducing the likelihood of transfusion of the causative antibodies. There are several strategies to be considered.

### Avoidance of Unnecessary Transfusion of Plasma

This includes unjustified transfusion of plasma components such as FFP and of unnecessary transfusion of plasma associated with RBCs. Use of FFP varies considerably among countries and it has been demonstrated that use to correct minor coagulopathies is both ineffective and unnecessary.<sup>84,85</sup> Avoidance of unnecessary transfusion of FFP will reduce the potential for transfusion of units containing antibody. RBCs in additive solution containing less than 20 mL residual plasma are uncommon causes of TRALI, and in those recorded cases there have usually been multiple antibodies in the donor plasma matching cognate antigens in the recipient. Whole blood donations, particularly

**Figure 56-8.** Cases of TRALI reported to the UK hemovigilance scheme from 1996 to 2006. After 1998 all cases were considered by an expert panel and classified as highly likely, probable, possible, or unlikely. From 1996 to 2003 case ascertainment rose steadily with increasing knowledge of the condition among physicians. From October 2003 a policy to procure FFP from male donors only was introduced. Following the change there was a decrease in reports, and a marked decline in highly likely or probable TRALI and in deaths from TRALI (note that cases were recorded by the year that the report was made, and that many cases documented for 2004 occurred in 2003). Data kindly provided by Dr. C Chapman on behalf of SHOT UK.

from high-risk donors (parous female or previously transfused donors), can be processed into RBCs in additive solution with minimal remaining plasma. Similarly, use of platelet additive solutions will reduce the volume of plasma with platelets.

### High-Risk Donor Exclusion

The most straightforward form of this policy is to exclude donations from all female donors from production of plasma-rich components. Some individual blood centers have followed such policies locally for some years.<sup>86</sup> The effectiveness of this intervention was demonstrated in the UK, where such a policy was instituted nationally in 2003. An active hemovigilance scheme clearly showed a 66% decrease both in the incidence of probable TRALI and in associated deaths over the next 3 years (Fig 56-8).<sup>87</sup> Further developments of this policy include excluding only females with a history of pregnancy and excluding any donor with a history of transfusion or organ grafting.

### Antibody Testing

By testing donors for HLA and HNA antibodies it is possible to exclude all donors with detectable antibodies, or those with antibodies of certain specificities or titer, either from all blood donation or just from donation of apheresis plasma-rich components. This strategy is attractive in that unnecessary exclusion of valuable donors is avoided but it also depends on the sensitivity and specificity of the antibody tests. It has been used with apparent success in some centers.<sup>88</sup>

### Use of Pooled Plasma

Pooled solvent/detergent-treated plasma does not appear to cause TRALI. It is hypothesized that this is because of dilution of antibodies, neutralization of HLA antibodies by soluble HLA antigens in the plasma of other donors, and subsequent removal of the immune

complexes in the processing.<sup>58,59</sup> Extensive use of solvent/detergent-treated plasma in Europe has not been associated with TRALI.<sup>89,90</sup>

### Nonantibody TRALI and Inverse TRALI

Leukocyte reduction reduces the production of cellular activation or breakdown products that have been implicated in TRALI. It also will prevent the rare but distinct cases of inverse TRALI related to bystander granulocyte transfusion.

## Conclusion

It has taken over 50 years for the full extent of TRALI to be appreciated. It is now recognized as one of the major adverse outcomes of transfusion. Preventive strategies are effective but risk loss of donors. These strategies will be refined over the next decade as more about the condition is learned.

# V Cell and Tissue Therapy

**Thomas M. Williams**

Professor and Chair, Department of Pathology, University of New Mexico School of Medicine, and Director, HLA and Molecular Diagnostics, TriCore Reference Laboratories, Albuquerque, New Mexico, USA

The human major histocompatibility complex (MHC) resides on the short arm of chromosome 6. The complete genomic sequence of this region contains more than 200 genes and spans 4 to 8 megabases, depending on where the telomeric boundary is drawn.<sup>1</sup> Many of the genes in the MHC encode proteins involved in immune responses, including the Class I and Class II antigenic molecules of the HLA system; the Class III molecules comprising complement components C2 and C4, and tumor necrosis factor; and the peptide transporter proteins TAP1 and TAP2. This chapter focuses on the genetic structure of the MHC, current HLA nomenclature, tests for detecting HLA, and the biomedical significance of HLA antigens.

The existence of white cell antigens independent of red cell genetic systems was suggested as early as 1952. In 1958, Jan Dausset<sup>2,3</sup> detected, in a patient who had undergone multiple transfusions, the first leukocyte antibody [called Mac (HLA-A2)]. This discovery was followed in 1958 by independent studies on similar antibodies in postpartum serum, reported by van Rood et al<sup>4</sup> and Payne and Rolfs.<sup>5</sup> These antibodies originally were thought to be autoimmune in nature or to be isoantibodies responsible for febrile (nonhemolytic) transfusion reactions. Early in 1960, Brunning et al<sup>6</sup> found that these antibodies could be used to detect several diallelic genetic systems present on the cells of most tissues. Until 1964, advances in HLA typing were hampered by inconsistent and nonspecific leukoagglutination testing methods. This status changed with the development of the microlymphocytotoxicity assay by Terasaki and McClelland.<sup>7,8</sup> In a slightly modified form, this test continued to be the standard for clinical HLA typing until the widespread adoption of nucleic-acid-based methods in the 1990s.

In 1964, the first International Histocompatibility Workshop was held. Since then, 13 workshops have been held at 2- to 4-year intervals. These workshops are designed to confirm scientific

findings, to develop unifying concepts regarding the MHC, and to upgrade existing HLA nomenclature. Table 57-1 presents an overview of the workshops, the year and their major themes. In the third workshop (1967), it was established that the HLA antigens belonged to the same genetic system,<sup>9</sup> and the term HL-A, coined from the Hu leukocyte system of Dausset et al<sup>10</sup> and the LA system of Payne et al,<sup>11</sup> was assigned to identify this system. By 1970, it was established through skin grafting studies with human subjects, particularly families with HLA-identical siblings, that these antigens were important in organ transplantation.<sup>12</sup> In 1973, it became clear from results of one-way mixed leukocyte cultures with homozygous testing cells that other genetic polymorphisms existed within the MHC.<sup>13</sup> Also by 1973, the remarkable association of HLA with certain diseases became apparent.<sup>14,15</sup> In the late 1970s, HLA-D (defined by mixed leukocyte culture) antigens were established,<sup>16</sup> serologically detected antigens on B lymphocytes [HLA-DR (D-related)] were found to be closely related to the HLA-D antigenic products,<sup>17,18</sup> and the existence of the HLA-C locus was confirmed.<sup>19</sup>

From 1980 to 1987, advances in biochemistry, molecular biology, and the development of monoclonal antibodies to the MHC antigenic product markedly expanded knowledge about the MHC. Workshops during this time confirmed the existence of the DQ and DP loci<sup>20,21</sup> and focused on increasingly refined methods for identifying the burgeoning number of HLA alleles and correlation of the serologic, biochemical, and molecular biologic findings related to the MHC. In the 1996 and subsequent two workshops, a primary focus was the use of powerful genomic technology to identify the more than 2000 MHC alleles now known to exist in human populations around the world.

**Major Histocompatibility Complex**

The Class I, II, and III genes of the MHC lie in a 4-megabase region of chromosome 6 (8 megabases if one includes the more telomeric Class I-related gene HFE and the butyrophilin family of genes.)<sup>22</sup>

**Table 57-1** Historical Overview of International Histocompatibility Workshops

| International Workshops | Year | Major Theme                                                                                                                       |
|-------------------------|------|-----------------------------------------------------------------------------------------------------------------------------------|
| I                       | 1964 | Comparison of serologic techniques                                                                                                |
| II                      | 1965 | Standardized techniques and nomenclature                                                                                          |
| III                     | 1967 | One major genetic system named HL-A                                                                                               |
| IV                      | 1970 | International anti-sera analysis                                                                                                  |
| V                       | 1972 | Population differences for HLA                                                                                                    |
| VI                      | 1975 | Identification of D(DR) locus by cellular techniques; HLA-C locus confirmed                                                       |
| VII                     | 1977 | Serologic detection of DR antigens                                                                                                |
| VIII                    | 1980 | Compendium of HLA antigen frequencies                                                                                             |
| IX                      | 1984 | Introduction of RFLP molecular techniques; DQ/DP loci confirmed                                                                   |
| X                       | 1987 | Standardization and application of RFLP; introduction of PCR/SSOPH typing                                                         |
| XI                      | 1991 | Standardization and application of PCR/SSOPH HLA Class II typing to transplantation, disease association, and population genetics |
| XII                     | 1996 | Analysis of Class I and Class II alleles by means of DNA sequencing                                                               |
| XIII                    | 2002 | Definition of extent of Class I and II gene variation and application to typing of volunteer donors                               |
| XIV                     | 2005 | Genomics and immune responses                                                                                                     |

RFLP = restriction fragment length polymorphism; PCR = polymerase chain reaction; SSOPH = sequence-specific oligonucleotide probe hybridization.

**Figure 57-1.** Selected genes in the major histocompatibility region on human chromosome 6 in the Class I, II, and III regions. Distances between loci are not drawn to scale. For exact gene locations, see <http://www.sanger.ac.uk/HGP/Chr6/MHC.shtml>.

The telomeric 2000kb of the MHC contains a number of genes, including those encoding the Class I antigens (Fig 57-1). The Class I HLA-A, -B, and -C genes reside in this region, as do the nonclassical MHC-Ib genes HLA-E, -F, and -G. HLA-E, -F, and -G are expressed at lower levels than are the classical genes, do not have the extensive polymorphism of the HLA-A, -B, and -C genes, and appear to have more limited functions in the immune system. Between the HLA-B locus and the tumor necrosis factor loci described later resides the MHC Class I chain-related

genes that encode variants of Class I proteins. Loci within this family display extensive polymorphism and encode proteins that interact with T cells and participate in natural killer cell activation.<sup>23</sup> Finally, the HFE gene responsible for genetic hemochromatosis lies approximately 4.3 megabases telomeric to HLA-A.<sup>24</sup> Centromeric of the HLA-B locus of the Class I region is a 1-megabase segment traditionally called the Class III region (Fig 57-1).<sup>22</sup> This region has a dense and diverse array of genes, many with as yet unknown functions. Some of these Class III

**Figure 57-2.** Simplified illustration shows the biochemical structure of Class I and II antigens. Modified with permission from Strominger.<sup>27</sup>

genes encode proteins with functions in innate immunity and inflammation. This region includes the complement components C2, Bf (factor B protein of the alternate pathway of complement activation), and C4. In most persons, the C4 locus is duplicated as C4A and C4B, each encoding a functional, somewhat biochemically different, molecule. Members of the tumor necrosis family also lie within the Class III region. Other genes within the Class III region, such as those encoding 21-hydroxylase enzymes involved in steroid metabolism, have no direct link to immunity. Although linkage to specific HLA alleles may be helpful in assessing 21-hydroxylase deficiency associated with congenital adrenal hyperplasia, direct genotyping is now possible.

The Class II gene loci occupy approximately 1 megabase of DNA centromeric to the Class III region (Fig 57-1).<sup>22</sup> Within this region are 18 closely linked loci that code for the  $\alpha$  and  $\beta$  chains of the Class II antigenic proteins. Proceeding from the telomeric to the centromeric boundaries of the region, the first gene cluster is composed of several  $\beta$ -chain loci and one  $\alpha$ -chain locus that encode the HLA-DR antigens. The DRB1 locus is responsible for the DR1 to DR18 specificities, whereas the DRB3, DRB4, and DRB5 loci are responsible for the DR52, DR53, and DR51 specificities, respectively. Each DR specificity is formed by a heterodimer encoded by the DRB1, 3, 4, or 5 locus and the DRA locus. Centromeric to the DRB genes are the DQ genes (Fig 57-1). The DQA1 and DQB1 loci encode the HLA-DQ specificities. Near the centromeric end of the MHC, the genes DPA1 and DPB1 encode the HLA-DPw1 to DPw6 specificities. The Class II region also contains several pseudogenes related to the genes encoding the DR, DQ, and DP antigens with errors preventing successful transcription and translation. Other genes with important accessory functions to Class I and II antigen presentation are present in the Class II region. The LMP2 and LMP7 genes, the TAP1 and TAP2 genes, and the tapasin gene encode proteins that participate in protein degradation and peptide transport and loading in the Class I system.<sup>25</sup> The HLA-DM and HLA-DO loci encode proteins involved in peptide loading in the Class II system.

**Figure 57-3.** (A) Side view of Class I antigen molecule. (B) View of the antigen-binding pocket looking down toward the cell membrane. Modified with permission from Bjorkman et al.<sup>28</sup>

## Class I and II Antigens and Their Function

The structure, tissue distribution, and function of the glycoprotein antigenic products of the Class I and Class II genes of the MHC differ considerably. Both Class I and Class II antigens are heterodimeric, having three to four extracellular domains in addition to transmembrane and intracytoplasmic regions (Fig 57-2).<sup>26</sup> Class I antigens are composed of a 45,000-D  $\alpha$  heavy chain encoded by the HLA-A, -B, and -C gene loci non-covalently bound to a 12,000-D light chain,  $\beta_2$ -microglobulin, encoded by a gene locus on chromosome 12. The  $\alpha$  chain is a transmembrane protein, whereas  $\beta_2$ -microglobulin is extracellular. Domains  $\alpha_1$  and  $\alpha_2$  contain variable amino acid sequences and thus represent the antigenic sites. The  $\alpha_3$  domain has constant sequences homologous to the constant regions of immunoglobulin proteins. The  $\alpha_3$  domain of the heavy chain and  $\beta_2$ -microglobulin are noncovalently associated with each other near the cell membrane. The  $\alpha_1$  and  $\alpha_2$  domains sit on top of them to form peptide antigen-binding cleft with a floor of eight flat  $\beta$  sheets bound on the sides by two long  $\alpha$  helices, as illustrated in Fig 57-3. Most of the polymorphic amino acid changes

of the Class I histocompatibility antigen differences are associated with the floor or sides of this pocket, although some map to other domains.<sup>28,29</sup>

Class II antigens are composed of a 33,000-D  $\alpha$  chain non-covalently associated with a 28,000-D  $\beta$  chain (Fig 57-2). The  $\alpha$  chain is encoded by the A gene loci and the  $\beta$  chain by the B gene loci in the HLA-D region of the MHC. For example, the DQ antigen  $\alpha$  and  $\beta$  chains are encoded by the DQA1 and DQB1 genes, respectively. The  $\alpha_1$  and  $\beta_1$  domains are variable and form an antigen-binding groove similar to that described earlier.<sup>30</sup> The  $\alpha_2$  and  $\beta_2$  domains are relatively constant with immunoglobulin-like homology.

Class I antigens have a universal tissue distribution as plasma membrane proteins of all nucleated cells and platelets. Class II antigens have a limited tissue distribution primarily on antigen-presenting cells such as B lymphocytes and macrophages, although they can be induced in several cell types, including endothelial cells.

Class I and II molecules acquire self and nonself peptides in their binding cleft and display them on the plasma membrane of cells for recognition by the T-cell antigen receptor.<sup>25</sup> In the normal state, T cells that bind with high affinity to self peptides in the context of an individual's Class I and II molecules are either deleted or suppressed by a variety of mechanisms to prevent autoimmune disorders. However, peptides derived from viruses, bacteria, and some parasites presented by the Class I and Class II molecules to T-cell antigen receptors evoke an immune response. Class I molecules primarily acquire 8- to 10-amino-acid peptides generated by means of degradation of cytoplasmic proteins in the proteosome system. Class I antigens function as MHC restriction elements in the destruction of virus-infected target cells and present peptides to CD8 cytotoxic T cells. Class II molecules bind 13- to 25-amino-acid peptides of exogenous and endogenous origin degraded within the endosomal system. Class II antigens are MHC restriction elements that augment the sensitizing limb of the immune response and present peptides to CD4

helper T cells. Activation of CD8 and CD4 T cells then results in a program of cell division and differentiation resulting in cellular and humoral immune responses.<sup>25</sup>

Nomenclature and Polymorphism of the HLA System

Table 57-2 illustrates the HLA gene loci, the variable polypeptide chains, the number of related serologic specificities, and the number of alleles within each specificity. In the Class I region, the HLA-A, -B, and -C loci are all highly polymorphic with 300 to 1000 known alleles.<sup>31</sup> Multiple alleles are present within most of the known serotypes. For example, the A2 serotype has more than 160 alleles. In the Class II region, the HLA-DRA locus is almost monomorphic, whereas the DRB genes are polymorphic, with hundreds of known alleles. The DQA1 and DQB1 genes and the DPA1 and DPB1 loci demonstrate similar but less extensive polymorphism. The DQA1, DPA1, and DPB1 allelic variation can be detected with DNA typing but not with serologic testing.<sup>32</sup> The HLA system is the most polymorphic genetic system known to exist in humans. The number of different phenotypes possible from all combinations of these HLA alleles is greater than the global population. Fortunately, linkage disequilibrium in all human populations results in great overrepresentation of certain haplotypes, which makes finding HLA-identical individuals within a population for purposes such as unrelated marrow transplantation possible.

Exons in which most of the polymorphism in the Class I (exons 2 and 3) and Class II (exon 2) genes occurs encode the  $\alpha_1$  and  $\alpha_2$  and the  $\alpha_1$  and  $\beta_1$  domains, respectively, which interact with bound peptides.<sup>31</sup> New alleles appear to emerge at a fairly high rate and become fixed in populations, in theory, if they provide a selective advantage in presenting peptides from infectious organisms. New alleles are generated by means of point mutation, recombination, and gene conversion-like events.<sup>31,32</sup>

Table 57-2. HLA Nomenclature

| Genetic Locus | Encoded Polypeptide | Antigen or Associated Specificity | Allelic Equivalent | Number of Known Alleles/ Polypeptides |
|---------------|---------------------|-----------------------------------|--------------------|---------------------------------------|
| HLA-A         | $\alpha$            | A1 to A80                         | A*0101 to *8001    | 630/495                               |
| HLA-B         | $\alpha$            | B7 to B81                         | B*0702 to *8301    | 979/833                               |
| HLA-C         | $\alpha$            | Cw1 to Cw10                       | Cw*0102 to *1803   | 338/264                               |
| DRA           | $\alpha$            |                                   | DRA*0101 to *0102  | 3/2                                   |
| DRB1          | $\beta_1$           |                                   | DRB1*0101 to *1612 | 549/462                               |
| DQA1          | $\alpha$            | DQ1 to DQ9                        | DQA1*0101 to *0602 | 34/25                                 |
| DQB1          | $\beta_1$           |                                   | DQB1*0501 to *0634 | 90/66                                 |
| DPA1          | $\alpha_1$          | DPw1 to DPw6                      | DPA1*0103 to *0401 | 24/15                                 |
| DPB1          | $\beta_1$           |                                   | DPB1*0101 to *9901 | 128/114                               |

The number of polypeptides known for each locus reflects unique amino acid sequences encoded by a larger number of alleles that may differ only by silent polymorphisms.

The nomenclature of the HLA system is established by an international committee sponsored by the World Health Organization and is updated frequently.<sup>33,34</sup> Table 57-2 shows the general scheme for designating HLA antigens and alleles. Each serologic specificity is prefixed by the genetic system designation HLA-, followed by a letter denoting the encoded antigen (eg, A, B, C, DR). This letter is followed by a digit indicating specificity.<sup>33</sup> For example the A locus encodes the specificities HLA-A1 through A80; the B locus, HLA-B7 through B81; the C locus, HLA-Cw1 through Cw10; the DRA and DRB1 loci, HLA-DR1 through DR18; and the DQB1 and DQA1 loci, HLA-DQ1 through DQ9.

The nomenclature of the HLA system was first established with serologic data. Molecular data were introduced later according to the precise DNA sequences of each allele. The existing nomenclature had to be modified to accommodate this information. This modification is shown in Table 57-2. For Class I alleles, because only the  $\beta$  chain is variable, the molecular designation is the system (HLA-), the locus (A, B, or C), an asterisk (\*), and a four-digit number. The first two digits of this number correspond to the serologic specificity; for example, *HLA-A\*0301* is the first molecular allele of the HLA-A3 serologic specificity, and *HLA-A\*0302* is the second. In the Class II region, because both the  $\alpha$  and  $\beta$  chains can be variable, the locus designation must include the polypeptide chain responsible for the allele. For example, Class II, *HLA-DRB1\*1501* is interpreted as HLA system, DR locus,  $\beta$ -1 polypeptide chain (B1), DR15 serologic specificity (15 after the asterisk), first molecular allele (01). For molecular alleles that have no serologic equivalents, alleles are sequentially numbered; for example, *HLA-DQA1\*0101* is the first molecular allele of the  $\alpha_1$  polypeptide chain of the DQ. Fifth, sixth, and seventh digits are employed to designate alleles with silent polymorphisms or with variation occurring outside exons.

## Identification of HLA Antigens and Alleles

The detection of HLA antigens and alleles is generally accomplished with three basic methods (Table 57-3). The microlymphocytotoxicity assay developed by Terasaki and McClelland<sup>7</sup> of peripheral blood lymphocytes isolated from whole blood has been the standard test for the serologic detection of HLA-A, -B, and -C antigens. This is a complement-dependent test in which the addition of rabbit serum to HLA antibodies fixed to the lymphocyte membrane causes cell death. The endpoint is leakage or retention of fluorescent dyes from lymphocytes with damaged or intact cell membranes, respectively. Modifications of this test, primarily an increase in incubation time and isolation of B lymphocytes from peripheral blood, allow typing for the HLA-DR and -DQ antigens.<sup>17</sup>

Variations of the mixed leukocyte reaction (Table 57-3) with homozygous testing cells, primed lymphocytes, or T-cell clones are the primary methods for detecting HLA-D, -DQ, and -DP antigens.<sup>35-37</sup> The mixed leukocyte reaction methods have been

largely replaced by nucleic-acid-based techniques for the detection of Class II alleles.

The application of molecular genetic technology to the field of histocompatibility has led to an unprecedented expansion in knowledge of the MHC at the molecular level. DNA sequences have been obtained for the HLA genes and alleles in a variety of populations worldwide.<sup>33</sup> These sequence data have been useful for several reasons.

1. They have revealed the underlying DNA sequence variations among individuals (and therefore, amino acid variations) responsible for the antigenic differences in HLA molecules detectable with traditional serologic and cellular HLA testing.
2. They have made apparent the fact that results of serologic HLA tests define only broad groups of Class I and Class II alleles. Numerous subgroups of alleles distinguishable by sequence differences are present within these broad serologic groups. The result is a very large number of known alleles.<sup>38</sup>
3. Sequence data have allowed detailed definition of the genetic basis of the HLA-mediated disease associations described later.
4. Knowledge of the DNA sequences of HLA alleles has facilitated the substitution of nucleic-acid-based methods for serologic and cellular methods for clinical HLA typing.

Several methods have been developed to identify Class I and II alleles. These range from restriction fragment length polymorphism assays to direct DNA sequencing (Table 57-3). Most laboratories have replaced or complemented serologic typing with DNA-based typing methods for several reasons. Precise identification of alleles not possible by serologic means is clinically important in unrelated bone transplantation, as discussed later. Second, nucleic-acid-based typing can help resolve serologic typings compromised by cross-reactivity or complicated by clinical states resulting in pancytopenia or poor expression of HLA antigens on lymphocyte membranes. Third, even in the best circumstances, serologic typing may not be accurate, especially in ethnic groups with great diversity at loci such as HLA-B.<sup>39</sup>

**Table 57-3.** Detection of HLA Antigens and Alleles

### Serologic methods

- HLA-A, -B, and -C: microlymphocytotoxicity test
- HLA-DR and DO: modified microlymphocytotoxicity test, B-cell-enriched lymphocytes

### Cellular methods

- HLA-D(DR) and DQ: one-way mixed lymphocyte reaction (MLR) with
  - Homozygous testing cells
  - Primed lymphocytes (PLT)
  - Cloned T cells
- HLA-DP: MLR in PLT or with T-cell clones

### Nucleic-acid-based methods for Class I and II allele identification

- Sequence-specific primer polymerase chain reaction
- Sequence-specific oligonucleotide probe hybridization analysis
- Automated DNA sequencing
- Emerging DNA sequencing techniques

### Sequence-Specific Oligonucleotide Probe Hybridization

Relevant regions of the Class I and Class II genes are amplified from genomic DNA by means of the polymerase chain reaction (PCR) with two oligonucleotide primers that anneal to 5' and 3' flanking regions that are conserved (are identical) among individuals. Care must be taken in choosing primers to find ones that are locus-specific (amplify HLA-A but not the related HLA-B locus, for example), that amplify all known alleles at a locus, and that result in roughly equal amplification of the two alleles in a heterozygous individual. After the PCR, the amplified DNA is generally interrogated with allele-specific DNA probes attached to solid supports. Identification of the individual alleles is accomplished by means of hybridization of the PCR products with a series of fluorescently labeled sequence-specific oligonucleotide probes.<sup>40,41</sup> Probes are chosen to anneal to amplified regions of the Class I and II genes that vary from allele to allele. Probes with nucleotide sequences perfectly complementary to the amplified DNA hybridize specifically to the PCR product target and can be detected via fluorescence. With careful control of stringency conditions of hybridization and washing, these probes can detect single-base-pair differences, which result in single-amino-acid substitutions in the expressed proteins. Alleles are assigned on the basis of panels of positive and negative hybridization reactions with oligonucleotides specific for a particular allele or sequence. Sequence-specific oligonucleotide probe hybridization (SSOPH) typing is complex because it requires a substantial number of oligonucleotide probes to detect and differentiate among the large number of known Class I and II alleles. However, the development of multiplexed methods for SSOPH employing fluorescent microspheres with attached allele-specific probes has greatly improved the ease of use and efficiency of this method and made it a leading means for HLA typing in many laboratories.<sup>42</sup>

### Sequence-Specific Primer Polymerase Chain Reaction

Polymerase chain reaction primers are designed so that their 3'-most one or two nucleotides are complementary to base positions within Class I and II genes that differ for different alleles.<sup>43</sup> Sequence-specific primers with 3' ends that anneal perfectly to sequences present in a particular allele or allele subgroup result in productive DNA amplification. Other alleles or allele subgroups are not amplified. Gel electrophoresis can then be used to detect the presence or absence of PCR products of the appropriate size, and hybridization assays are avoided. Sequence-specific PCR is most useful for medium-resolution HLA typing and for initial quick identification of broad antigen groups, such as DR52. Then, SSOPH or DNA sequencing can be used to define microvariants of these specificities, if necessary. Sequence-specific PCR requires 100 or more simultaneously performed PCR assays per patient to identify HLA-A, -B, and -DRB allele groups at serologically equivalent resolution. The method requires optimization to avoid failed amplification reactions in each run.

### Sequence-Based Typing

Sequence-based typing has the advantage of requiring only a limited number of primers for the PCR for each HLA locus.

There is no need for a series of detecting oligonucleotide probes for each allele. Polymerase chain reaction products are prepared that will encompass the relevant polymorphic positions within the Class I or II gene to be sequenced. Sequencing primers are annealed to the PCR products to generate sequencing ladders that are separated on a high-resolution gel. Any known or previously unknown allele in the population can be identified by means of inspection of the DNA sequence or electropherogram. Electropherograms must be of high quality for accurate detection of heterozygous positions in the sequenced PCR products. The development of high-throughput automated fluorescent DNA-sequencing machines, analysis software, and capillary electrophoresis systems has made this method less cumbersome. Direct sequencing for HLA typing yields unparalleled precision in allele identification. As the number of known Class I and II alleles continues to escalate, the SSOPH and sequence-specific PCR methods have become increasingly complex, making direct sequencing an increasingly attractive method for laboratories.<sup>44-46</sup>

### Choice of HLA Typing Method

Several factors influence a decision to use one HLA typing method over another. Sequence-specific PCR and reverse SSOPH can be performed in a time (4 to 5 hours) appropriate for clinical situations such as cadaveric renal transplantation. DNA sequencing is a reasonable approach for situations such as unrelated marrow transplantation in which allele-level HLA matching of donors and recipients is desired and turnaround times of a few days to a week are acceptable.

---

## Genotypes, Phenotypes, and Haplotypes

HLA antigens are expressed codominantly. The phenotype of expressed antigens for any given person is not equivalent to the genotype. Because HLA genes are closely linked on chromosome 6, they are inherited in units known as haplotypes. Each sibling of a family inherits one of two HLA haplotypes from each parent.

Figure 57-4 illustrates the segregation of haplotypes in a family of seven, focusing on the A, B, Cw, and DR serologic specificities. Analysis of the data for a single individual does not allow assignment of the serologic types present to a specific paternally or maternally derived chromosome; that is, the typing data are unphased. Thus, one cannot be certain whether the DR7 in sibling 3 is present on a chromosome carrying B8 or B13. However, analysis of the typing data for the entire family and the transmission of specificities to the children make it possible to phase each of the pairs of parental chromosomes and to determine haplotypes. For example, one of the paternal chromosome-6 pairs, haplotype [a], contains HLA-A1, Cw4, B35, and DR1; the other paternal chromosome, haplotype [b], includes HLA-A3, Cw7, B8, and DR7. Similarly, the maternal chromosome-6 pairs can be separated as haplotypes [c] and [d]. Each child in this family inherits [a] or [b] from the father and [c] or [d] from

**Figure 57-4.** HLA-A, -B, -C, and -DR antigens segregating as haplotypes in a family. The data reflect the genotypes of each family member as well as the parental haplotypes.

the mother. Each child differs from each parent by one HLA haplotype. Because there can be only four parental haplotypes, the chances are 1 in 4 that the siblings will have same paternal-maternal haplotypes (are HLA-identical), 1 in 2 that siblings will differ by one haplotype, and 1 in 4 that they will differ by two haplotypes. For example, siblings 4 and 5 are HLA-identical, and sibling 4 shares one haplotype with siblings 2 and 3 but no haplotypes with sibling 1. Because siblings 4 and 5 are genetically identical with regard to the MHC, their lymphocytes will not react in mixed leukocyte culture.

The difference between phenotypes and genotypes can be clarified even further with sibling 4 (Fig 57-4) as an example. If family data were not available, this sibling's phenotype would be written as HLA-A3, A24; Cw2, Cw7; B8, B27; DR4, DR7. This implies lack of family data that would allow assignment of the A, C, B, and DR combinations to the appropriate haplotypes. With family data available, however, the genotype is written HLA-A3, Cw7, B8, DR7/A24, Cw2, B27, DR4. The slash in this statement clearly defines the two haplotypes inherited by this child.

Although HLA gene loci are closely linked, there is a low frequency of recombination during meiosis. The crossover rate is approximately 0.8% between the A and B loci and approximately 0.5% between the B and DR loci. For example, 1 of every 200 families exhibits recombination between the B and DR genes.

HLA allele and haplotype frequencies exhibit ethnic variation. Some alleles and haplotypes are widely distributed around the globe, and others are almost exclusively within a particular ethnic group. In population studies, the phenomenon of linkage disequilibrium is apparent in all groups. This term indicates that in randomly mating populations, the haplotype frequency for

two or more linked gene loci is significantly higher than would be expected by chance alone. The expected frequency is obtained from the product of the gene frequencies of the involved genes. For example, among persons of European ancestry, the observed A1, B8 haplotype frequency (7.0%) is approximately 4.4 times greater than the expected haplotype frequency (1.6%). These excess haplotype frequencies may exist for a variety of reasons, including high prevalence in the founders of a population and selective pressure from infectious organisms.<sup>47</sup>

## Medical and Biologic Significance of HLA

The HLA system plays a role in several areas of biomedical significance including the following:

- Antigen presentation
- Association with certain diseases
- Organ and stem cell transplantation
- Platelet transfusion
- Population genetics and anthropology.

Tracing the appearance of novel HLA alleles in populations and comparing the frequencies of alleles among populations to gain information about human origins and migration in anthropologic and evolutionary studies is a fascinating field of inquiry but beyond the scope of this chapter.<sup>48</sup> The extensive polymorphism of the HLA loci has been exploited for many years in identity testing; however, the use of microsatellite loci for this purpose has supplanted the use of HLA loci. The role of HLA Class I typing to support platelet transfusion is described in Chapter 11.

## Transplantation

Transplantation poses a special problem in medicine because the extreme polymorphism of the HLA loci make it unlikely that an unrelated donor of cells, tissues, or organs will be matched at an allele level or at a serologic level with a recipient without a concerted effort to identify matched donors and recipients. One solution is to identify an HLA-identical sibling, but many potential transplant recipients do not have access to these donors. For organ transplantation, powerful immunosuppressant drugs have made transplantation feasible with mismatched living and cadaveric donors and recipients. However, better HLA-A, -B, and -DR matching at a serologic level generally increases the half-life of the transplanted organ and decreases overall morbidity.<sup>49</sup> Thus cadaveric donor kidneys are shared on a national basis with waiting recipients who have end-stage renal failure and no mismatches.<sup>50</sup>

Finding well-matched donors of hematopoietic stem cells if there are no HLA-identical siblings is facilitated by resources such as the National Marrow Donor Program, which has enrolled several million potential donors with known HLA types.<sup>51</sup> The goal for unrelated stem cell donation is increasingly allele-level matches for HLA-A, -B, -C, and -DRB1, although the level of mismatching permissible is incompletely understood. Subtle allelic mismatches between stem cell donors and recipients appear to increase the risk of severe graft-vs-host disease and decrease overall survival.<sup>52,53</sup> The use of umbilical cord blood stem cells and the depletion of T cells from transplanted cells may allow greater donor-recipient mismatches.<sup>54,55</sup> Retrospective studies are continuing to assess in a definitive manner the level of matching necessary for successful stem cell transplantation.<sup>56</sup> Hematopoietic stem cell transplantation is discussed in Chapters 33 through 36.

There are two major mechanisms by which Class I and II donor-recipient mismatches may adversely affect transplantation—production of HLA antibodies and cell-mediated rejection. Transplant recipients become sensitized or produce antibodies directed against Class I and Class II specificities through several routes. Exposure to fetal HLA molecules encoded by paternal haplotypes during pregnancy, especially multiple pregnancies, can lead to the presence of long-lasting, high-titer HLA antibodies. Similarly, mismatched HLA antigens from previous organ donors and donors of transfused blood components can lead to sensitization. The presence of recipient preformed HLA antibodies may lead to hyperacute rejection of a donor organ bearing the relevant HLA specificities.<sup>26</sup> Therefore, laboratories maintain serum screening programs to detect and identify HLA antibodies in waiting recipients so that inappropriate donors can be avoided. Immediately before transplantation, crossmatches to detect donor-directed HLA antibodies are performed between donor lymphocytes and recipient serum by means of the microcytotoxicity assays described earlier or more sensitive flow cytometric technology.<sup>57</sup>

Donor HLA antigens mismatched with recipient HLA antigens can elicit a strong cell-mediated immune response. As many as 10% of a recipient's T cells are able to recognize and respond to donor-mismatched HLA antigen.<sup>58</sup> These responses

contribute to acute rejection in organ transplantation and graft-vs-host disease in stem cell transplantation. HLA matching and immunosuppressive therapy help to mitigate this problem.

## Disease Association

The association of certain HLA alleles and their encoded antigens with particular diseases, especially autoimmune disorders, has been known for some time. In more than 40 disorders, there is significant deviation in the frequency of HLA antigens from that of healthy controls (Table 57-4).<sup>59</sup> In general, HLA-associated diseases have certain common features. They are known or suspected to have an inherited component, usually have autoimmune features, and display a clinical course often featuring repeated acute relapses followed by remission. For most HLA-associated diseases, the etiologic factor is unknown and the pathophysiologic mechanism is incompletely understood. One hypothesis for the link between HLA antigens and disease suggests that a necessary but not sufficient requirement for disease development is the differential ability of a Class I or II heterodimer encoded by a specific allele to present autoantigens to the T-cell receptor.

Two of the strongest HLA associations are the *DQB1\*0602* allele with narcolepsy<sup>60</sup> and *B\*27* alleles with ankylosing spondylitis.<sup>59</sup> Almost all patients with narcolepsy have the associated alleles; approximately 90% of patients with ankylosing spondylitis have the associated alleles. In populations without these disorders, the frequencies of *DQB1\*0602* (25% to 30%) and of the *B\*27* group (5% to 10%) are substantial but do not approach the frequencies among persons with these disorders. Thus the antigens involved are not unique to narcolepsy and ankylosing spondylitis but are overrepresented among affected persons. Approximately 3% of persons with a *B\*27* allele have ankylosing spondylitis, a risk approximately 100-fold greater than that among persons without *B\*27*. Results of HLA testing that show the absence of *DQB1\*0602* or *B\*27* alleles is useful to help rule out a diagnosis of narcolepsy or ankylosing spondylitis for a patient. Results that show the presence of these alleles are less useful because of the prevalence of these alleles in the general population.

The association of HLA antigens with most other autoimmune disorders usually does not carry the high relative risk that narcolepsy and ankylosing spondylitis do. Although these HLA associations are generally less useful in diagnosis, they provide important insights into the pathophysiologic mechanism of these diseases and may help assess prognosis. For example, approximately 95% of patients with type 1 diabetes mellitus (formerly known as insulin-dependent diabetes mellitus) have either the *DRB1\*03* or the *DRB1\*04* allele or both.<sup>61</sup> Patients heterozygous for *DRB1\*03\*04* have a relative risk for type 1 diabetes mellitus three to six times greater than that of patients with *DRB1\*03* or *DRB1\*04* alone or in combination with another *DRB1* allele. Susceptibility to type 1 diabetes mellitus appears to be linked to haplotypes containing *DRB1\*03* or *DRB1\*04* with *DQB1\*02* and *DQB1\*03* alleles.

Many persons with rheumatoid arthritis have inherited *DRB1\*04* alleles encoding a common epitope. Heterozygosity

**Table 57-4.** Selected Diseases Associated with HLA Alleles

| Disorder                                                   | HLA Linkage                                                    | Comments                                                                                                             |

| Hemochromatosis                                            | Diagnosis by direct <i>HFE</i> genotyping                      | <i>HFE</i> is a Class-I-related gene at the telomeric end of the MHC                                                 |

and homozygosity for alleles encoding this epitope may be predictive of a more severe course of arthritis. Thus allele identification may be helpful in assessing prognosis.<sup>62</sup>

A number of studies have been performed in an attempt to define specific HLA alleles that confer susceptibility or resistance to AIDS (Table 57-4).<sup>63,64</sup> There appear to be HLA alleles that interact with other genetic and environmental factors to influence the outcome of this multifactorial disease. However, results may vary somewhat among studies given the complexity of AIDS, differences in the ethnicity of the populations studied, and the subtypes of the human immunodeficiency virus type 1 involved. Recently, hypersensitivity to the antiretroviral drug abacavir was linked to the presence of *HLA-B\*5701* in treated patients.<sup>65,66</sup> Near complete elimination of hypersensitivity morbidity was achieved by first screening patients to exclude the 5% to 10% with *B\*5701* from exposure to this agent. In this example, HLA allele identification serves as a pharmacogenomic test to stratify a patient population for targeted therapy.

Because the MHC contains genes with no obvious role in immune system function, some diseases caused by point mutation or deletion of genes in this region cause disorders not directly related to immunity. However, because of linkage disequilibrium, overrepresentation of specific Class I or Class II antigens may occur in these disorders. Congenital adrenal hyperplasia is caused by mutations in the MHC Class III region genes encoding 21-hydroxylase.<sup>67</sup> Although linkage to specific HLA alleles is present in persons with congenital adrenal hyperplasia, direct genotyping is generally preferable for diagnostic purposes. Similarly, genetic hemochromatosis is caused by mutations in the *HFE* gene telomeric to the *HLA-A* locus.<sup>24</sup> Although the presence of *A\*03* confers several-fold excess risk of hemochromatosis, the most direct route to genetic diagnosis is *HFE* genotyping.

## Summary

The HLA loci on chromosome 6 are composed of a series of Class I and II genes that display a degree of naturally occurring polymorphism unmatched within the rest of the human genome. This polymorphism appears to be maintained to ensure appropriate responses to the infectious organisms encountered by global human populations. The crucial role of the Class I and II molecules is to bind to the degradation products of proteins and present them to T-cell antigen receptors for recognition as endogenous or foreign peptides. MHC polymorphism has several consequences in medicine and biology beyond the normal immune response: 1) MHC genetic variation can be exploited as a tool for anthropologic study of human migration and development. 2) Specific HLA alleles are associated with a propensity to development of particular disease entities, especially autoimmune disorders. 3) The challenge of finding HLA-matched donors and recipients presents special problems in stem cell and organ transplantation.

In the United States, organ and tissue procurement has been organized in such a way so as to maximize availability in an efficient fashion that is fair to both donor and recipient. Most of the organ procurement efforts have become systematized and organized under federal mandate; there is, however, a growing cooperation between organ procurement organizations (OPOs) and tissue recovery organizations to facilitate meeting the requirements of both organ and tissue procurement. Successful tissue preservation has encouraged the use of bone and soft tissue grafts, cardiovascular tissue, and skin in the clinical setting. Semen cryobanking has been practiced for many years, and the demand for embryo banking services has greatly increased recently as assisted reproductive procedures have become more diverse and much more widely available. As technology in this area continues to expand, blood banks may play an increasingly important role in coordinating, supporting, and directing transplantation and transplant-related interventions.

### Growth of Tissue Banking

Each year, hundreds of thousands of patients benefit from donated bone, cartilage, and tendon used to reconstruct and rehabilitate joints and other bony structures, corneas to restore sight, skin to treat burns, veins and great vessels to restore blood flow, heart valves to restore cardiac function, and reproductive tissue to treat infertility. In addition to whole grafts and sections, bone, in particular, can be machined into specialized products to conform with manufactured support constructs. It can also be ground into demineralized bone matrix (DBM), which is available as a ground powder or as combination forms such as gels, pastes, strips, and even moldable grafts designed to avoid migration in specific applications. Myriad types of tissues are transplanted in a variety of medical and dental specialties for

diverse clinical applications (Table 58-1).<sup>1</sup> The most commonly transplanted allografts are bone and cornea (Table 58-2).

The total number and range of tissues collected, processed, and transplanted in the United States are difficult to determine, because there is no national reporting system. In 1999, tissue banks accredited by the American Association of Tissue Banks (AATB) distributed approximately 750,000 allografts for transplantation. By 2003, the figure had more than doubled. The American Orthopaedic Society for Sports Medicine reported that its members used more than 60,000 allografts in knee surgery alone, in 2005.<sup>2</sup> The quantity of musculoskeletal tissue allografts used annually is approximately 1,500,000. Cornea transplants numbered >45,000 in 2006.<sup>2</sup> Skin is distributed at the rate of about 17,000 square feet annually. Transplantation of heart valves is now estimated at >2500 annually. These procedures require annual donation of cardiovascular tissue, musculoskeletal tissue, and skin from >40,000 deceased donors (New York State Department of Health, unpublished data, 2005), and donation of eyes from >38,500 deceased donors.<sup>3</sup>

In addition to such tissues from deceased donors, many tissues for clinical use are derived from living donors, including semen and oocytes for use in artificial insemination and assisted reproductive technology procedures. In 2005, New York State-licensed semen banks located throughout the United States processed 27,118 ejaculates from 962 semen donors. In addition, semen from 16,347 client depositors was collected and cryopreserved for later use by the client depositor's wife or other "intimate partner" (New York State Department of Health, unpublished data, 2005). Donor oocytes were used in approximately 12% of all assisted reproductive technology cycles carried out in the United States in 2005.<sup>4</sup> Tissue from living donors is also considered by some to include human milk to nourish low-birthweight, premature infants. The Human Milk Banking Association of North America reports the existence of 11 active member banks.<sup>5</sup> The Food and Drug Administration (FDA), however, does not consider human milk to be subject to regulations that apply to human allograft tissue.

Because no comprehensive national usage figures are available, it is difficult to determine the rate of increase in the demand for

**Table 58-1.** Some Common Human Allograft Applications, by Specialty<sup>1</sup>

| Specialty                  | Procedure/Application                                                                                                                                                                                                                                                   | Allograft Types Used                                                                                                                                                                                                                                                                                                               |

tissues. However, novel uses for tissue in transplantation have emerged that had not been envisioned even a few years ago. Amniotic membrane is transplanted to correct epithelial eye defects; bioengineered skin products are used for wound healing; and nerve tissue is transplanted to serve as a conduit for nerve regeneration in damaged limbs. In late 1998, the medical world was fascinated by the first hand transplant surgery; there have been at least 18 worldwide since, and the world's first face transplant procedure was performed in November 2005. In the future, human pluripotent progenitor cells from embryos may be used in the treatment of Parkinson disease, diabetes, and spinal cord injuries.

## Tissue Donation

### Living Donors

The tissue most commonly donated by living donors is blood, the primary subject of this book, but living donors also provide other tissues. Tissue donation by a living person generally is limited to renewable tissue, such as gametes, extraembryonic tissue, and milk. Except for autografts, which can be expanded by culturing for use on burned patients, skin is usually recovered from deceased donors. However, some tissue banks have

developed processes to promote living donor skin donation following extensive weight loss (>300 such donations per year in the United States). Cartilage can also be cultured for autologous transplant in knee repair. Bone can be obtained from living donors in the form of femoral heads and tibial plateaus that are removed and would otherwise be discarded during surgical procedures (total hip and knee replacements with prostheses). Outside the United States, such surgical bone banking remains a significant source of bone grafts in many countries.

**Deceased Donors**

In contrast to organ donors, tissue donors (excluding living donors, of course) do not need to have functioning circulation. Tissues such as bone, eyes, and skin can generally be collected up to 24 hours after cessation of the donor’s cardiac and respiratory functions, depending on the temperature and environment in which the donor body is stored. Tissues such as bone and skin can be donated by deceased organ donors (a standard criterion for organ donors in the United States is brain death), but more commonly, tissues are donated by other hospitalized patients who have been judged deceased by both cardiorespiratory and neurologic criteria. Recently, tissue procurement practices have become more effective as a result of increased cooperation between tissue banks and OPOs, through routine referral requirements<sup>6</sup> and statutes (eg, New York State Public Health

Law §4351). Referrals for eye banks are also made through OPOs. However, many tissue banks, especially eye banks, obtain a significant portion of their referrals from medical examiners or coroners who have access to large numbers of young, healthy individuals who died suddenly and never reached a hospital.<sup>3</sup>

**Routine Referral for Donation**

The availability of tissues for transplantation depends on strong public support, the presence of laws that clear legal barriers to donation and that authorize consent before death (through such means as driver’s licenses, donor registries, and advance directives), and the availability of health professionals trained in how to approach the next of kin on the subject of donation. (The next of kin is/are a deceased person’s closest relative(s), as determined by a hierarchy specified in state law.) Key to donation in the United States is a spirit of altruism and volunteerism, coupled with autonomous choice being valued. Consent to donate is informed and voluntary with few exceptions. About one-third of eye banks are located in states with medical examiner laws that allow removal of corneas for transplantation under the following circumstances: 1) the body is under the medical examiner’s jurisdiction; 2) autopsy is required by law; 3) there is no known objection by the next of kin; and 4) the removal will not disturb the body’s appearance.<sup>3,7,8</sup> These state laws presume consent and permit removal of eyes without an interview of the next of kin concerning the deceased’s medical and social history, including human immunodeficiency virus (HIV) and hepatitis risk behaviors. Maryland expanded the law to cover non-medical-examiner cases when a next of kin cannot be found.<sup>9</sup> In 2006, >34,000 corneas were provided for transplantation; about 10% of these were obtained through use of a state’s medical examiner law. Nationwide the number of corneas obtained under medical examiner laws has been declining, mainly because of ethical concerns, but also because of increased FDA regulation that requires specific screening for relevant communicable diseases, which must include a donor medical and social history interview with a knowledgeable historian.<sup>3,7</sup>

In the late 1980s, most states enacted “required request” laws that sought to increase the supply of organs and tissues by requiring that hospital personnel request permission of the next of kin for organ and tissue donation at the time of a patient’s death (if the prospective donor was medically eligible). Following findings that families were more likely to consent to donation if approached by requesters who had received training in the most effective ways to present donation opportunities, some states amended these laws to require referral of all deaths to an OPO or designated tissue bank, whose specially trained requesters would then ask for consent. Federal routine referral requirements were implemented by the Health Care Financing Administration (now the Centers for Medicare and Medicaid Services) in Hospital Conditions of Participation for Organ, Tissues, and Eye Donation, which became effective August 21, 1998.<sup>6</sup> These rules mandate, as a condition of Medicaid and Medicare reimbursement, that all hospitals establish formal relationships with an

OPO in the service area, with a tissue bank, and with an eye bank. Further, the rules require that hospital personnel notify OPOs of all deaths and imminent deaths so that potential donors are identified, and so that the next of kin will be approached about donation, when appropriate. The effect of these routine referral laws is not clear. In New York, where such a law went into effect on January 1, 1998, mixed results have been reported. Although a small increase in tissue donation has been realized statewide, certain metropolitan areas have actually reported a decline in eye donation. It is also not clear whether the increase in tissue donation in recent years is the result of required referral or of enhanced advertising campaigns and increased public awareness of the need for organ and tissue donation. Under routine referral, the costs associated with around-the-clock reporting of deaths and imminent deaths are proving to be high in certain areas, although the cost to OPOs is shared by Medicare and the transplanting hospitals through “standard acquisition charges” applied to individual organs transplanted. Uniform Anatomical Gift Laws were developed to standardize state requirements for first party consent, requesting personnel, and recovery. A 2006 revised version, which expanded definitions, clarified roles, and enhanced a focus on personal autonomy, had been enacted in 20 states and had been introduced in 15 more by early 2008 (see <http://www.anatomicalgiftact.org>).

## Organization of Tissue Banking in the United States

Unlike the organ procurement and sharing system, tissue banking is not formally organized based on geography. There are approximately 15 independent tissue banks that process conventional musculoskeletal tissue, four that process cardiovascular tissue, and 13 that process skin. Although most are not for profit, a few for-profit companies process human tissue for transplantation. These processors usually independently perform donor eligibility assessment, including laboratory testing, even if the tissue bank that recovered the tissue had already performed such an assessment. An unpublished AATB survey of 2003 activity found that donor eligibility had been determined by a tissue bank accredited by AATB for about 95% of the bone grafts distributed (Scott Brubaker, personal communication, August 17, 2007). There are approximately 89 not-for-profit eye banks accredited by the Eye Bank Association of America (EBAA; see <http://www.restore-sight.org>). Almost all cornea allografts are provided by these eye banks. Blood centers with expertise in donor recruitment, donor eligibility determination, cell cryopreservation, and compliance with standards and regulations are good candidates to undertake tissue banking services. Some blood centers have already taken on the challenge of providing comprehensive tissue bank services, and they recover, process, store, and distribute tissues.

Procedures to achieve allograft safety and efficacy are guided by national professional standards set by such organizations as AATB,<sup>10</sup> EBAA,<sup>11</sup> and the American Society for Reproductive

Medicine.<sup>12</sup> The FDA and some states, including New York, Florida, and California, have regulatory and licensure requirements (see section on oversight of tissue banks below).

## Public Attitudes

Public altruism and the willingness of people to be organ and tissue donors form the foundation of the transplant system. A 1986 Gallup survey assessing the public’s attitudes found that people were more willing to consent to donation if they were provided with relevant information. Effective public education is thus a key component of successful organ and tissue donation programs. A major impediment to the procurement of greater numbers of transplantable organs and tissues has been the failure of health-care professionals to adequately present the next of kin the option of organ and tissue donation.<sup>9</sup> Grieving relatives of a potential donor may not spontaneously consider donation, but they should gently be offered the opportunity by persons trained to make organ and/or tissue donation presentations (“donation approach”). The donation approach is much more effective when “decoupled” from the care of the dying or deceased by having a person separate from the patient care team make the approach. This decoupling also reduces the risk of or the perception of a conflict of interest between patient care and organ and tissue recovery. The situation has improved gradually through professional education and encouragement by federal and state legislation and initiatives.

The Department of Health and Human Services Office of the Inspector General (OIG) conducted an investigation of some tissue bank practices. In a 2001 report, the OIG recommended that tissue banks make their finances public and enhance consent processes by describing potential uses of donated tissue and disclosing the bank’s relationships with other companies.<sup>13</sup> The OIG also recommended that the FDA expedite the publication of its proposed regulatory agenda for tissue banks.

Media attention to organ and tissue transplantation has increased the recognition and credibility of OPOs, as well as the public and professional support for donation. Some media inquiries, such as the *Orange County Register’s* April 2000 report entitled “The Body Brokers,” and a number of 2006 reports regarding alleged theft and forgery in tissue donation consent and recovery, may have served to shake the public’s confidence that donated tissues are handled with respect and do not result in excessive corporate profits. Such articles triggered a national debate on the ethics of procuring and processing tissue for profit. Questions were raised about the propriety of financial gain from tissue donation, possible diversion of tissue needed for lifesaving purposes to cosmetic uses, weaknesses of the consent process, and the extent to which tissue banks were monitored.

There is evidence that the industry responded to such concerns. For example, one criticism voiced was that skin needed for medically necessary reconstruction was sometimes diverted for cosmetic surgical uses, potentially creating shortages of fresh

**Table 58-3.** Infectious Diseases Reported to Have Been Transmitted by Deceased Donor Allografts

| Allografts       | Infectious Disease                       |
|------------------|------------------------------------------|
| Bone             | Hepatitis C                              |
|                  | Hepatitis, unspecified type              |
|                  | Human immunodeficiency virus, type 1     |

skin for burn patients. Today donated human skin is routinely recovered using a thin and thick method (thin for burn patients and thick to provide collagen), which is balanced to ensure that availability of skin for burn patients is not compromised. Additionally, research has resulted in development of clinically useful synthetic products that fill most of the needs for dermal components of products for use in cosmetic procedures.

**Tissue Transplant-Transmissible Diseases and Prevention**

**Transmissible Diseases**

Despite a careful donor selection process, the risk of donor-to-recipient transmission of viral, bacterial, fungal, and prion diseases cannot be eliminated (Table 58-3).<sup>14-16</sup> In one well-publicized case, 48 organ or tissue recipients received an organ or tissue from a single donor who, although he had no risk for HIV infection found by history, proved to have been recently infected with HIV and in the window period before HIV-1 antibody could be detected by the assays in use at the time (October 1985).<sup>17</sup> All four organ recipients became infected with HIV, but the majority of tissue recipients did not. Whole unprocessed frozen bone did transmit HIV to three recipients, while bone from which the marrow had been removed did not; transplanted

corneas, lyophilized soft tissue, and  $\gamma$ -irradiated dura mater also did not transmit the virus. This case additionally served to highlight vulnerabilities associated with inadequate disposition records, given that six recipients could not be identified from hospital records. In 2002, before routine implementation of hepatitis C virus (HCV) nucleic acid testing (NAT) for tissue donors, tissue from a man with no identifiable infectious disease risk by history or physical examination, and a negative test for anti-HCV, was found to have transmitted HCV to recipients.<sup>18</sup> All organ recipients who could subsequently be tested were found to be infected with HCV. Among 32 tissue recipients, five probable cases occurred: one of two saphenous vein recipients, one of three tendon recipients, and one of three recipients of tendon with bone allografts. All eight recipients whose infection was linked to the transplant were determined to be infected with the same HCV genotype. The current risk of viral transmission is thought to be exceedingly low.<sup>19,20</sup> In addition to donor selection and testing strategies, processing methods now in use further reduce the risk for tissues not requiring viable cells.

West Nile virus transmission linked to breastfeeding of a woman's own infant, to organ transplantation, and to blood transfusion have been reported,<sup>21</sup> but transmission through donor tissue has not been documented. Chagas' disease has been linked to transplantation of organs but transmission of parasitic diseases through vascular tissue allografts (considered likely to be possible) has not been reported.<sup>22,23</sup> Although vessel grafts associated with organ transplantation, in which arteries or veins from a different donor may be used if the donor and/or recipient vessels are damaged or insufficient, are not considered tissue by the FDA, such grafts caused documented transmission of rabies to two recipients in 2004.<sup>24</sup> Transmission of malignancy via tissue transplantation has not been reported, but is thought to be possible. Infectious diseases can also be transmitted through transplantation of tissue from living donors. Cases are well documented in the semen banking arena (Table 58-4),<sup>25</sup> as well as in the use of surgical discard bone, such as a femoral head collected during hip arthroplasty.<sup>15</sup>

Transmission of bacteria is a known risk of tissue transplantation. Bacteria can be present in the donor, either as a normal occurrence or as the result of a disease process or medical intervention.<sup>16</sup> Resuscitation efforts can increase the dispersion of such organisms. In addition, agonal bacteremia is a well-known process whereby endogenous bacteria, such as normal intestinal flora, begin to disperse throughout the body after cessation of cardiopulmonary functions, as the putrefaction process begins. This process is accelerated in persons with sepsis, rhabdomyolysis, or a cocaine overdose before death.<sup>39</sup> Bacteria can be introduced during tissue recovery; during processing, whether through cross contamination, insufficient aseptic technique, or contaminated chemicals or solutions; or even during packaging. Some tissues, including ocular tissue, skin, and semen, are inherently not sterile even if collected aseptically; fortunately, the contaminants are primarily skin contaminants with low virulence in most recipients, and are susceptible to standard antibiotics.

HIV-1 = human immunodeficiency virus, type 1; HSV-2 = herpes simplex virus, type 2; HTLV-I = human T-cell lymphotropic virus, type I.

At particular risk for transmission of bacteria are the articular cartilage allografts used in knee surgery, because these cannot be subjected to extensive processing if their mechanical properties and chondrocyte viability are to be preserved (note, however, that the latter has not been proven to be essential). In 2001, a 23-year-old man was found to have died from *Clostridium sordellii* sepsis following receipt of a femoral condyle allograft. An extensive investigation identified 14 patients who had received allografts between 1998 and 2002 and who developed postoperative infections with *Clostridium* species.<sup>40</sup> The tissues were derived from nine donors, but all were prepared by the same processor, and investigation identified several factors that could have contributed to the infections. Although the tissues were cultured, they had already been suspended in antimicrobial solutions, likely leading to false-negative results. Additionally, for two of the donors, including the donor of the tissue that was implicated in the fatal case, the interval between death and refrigeration of the body (19 hours for the donor in the fatal case) exceeded the industry's voluntary standards at the time, likely permitting excessive bacterial proliferation. Tissue was processed aseptically without the use of disinfection or terminal sterilization, and the processing methods used had not been validated. Human error can also lead to release of contaminated tissues. In one case, a technician failed to follow standard procedures, resulting in release of tissue labeled as

having been subjected to irradiation when, in fact, no irradiation had occurred.<sup>41</sup> However, a wound infection in a tissue recipient, or even disseminated bacteremia, does not necessarily implicate the donor tissue. Site infections are a well-known risk of many surgical procedures and can result from the use of contaminated solutions or equipment insufficiently sterilized between procedures.<sup>42</sup>

### Risk Reduction Procedures

After death has been declared and consent for donation has been given, the process of determining the suitability of the potential deceased donor begins. The risk of disease transmission is minimized by collection and careful review of 1) information obtained during interviews with family member(s) or other knowledgeable historian(s) and health-care providers; 2) available medical records; 3) findings of a physical assessment; 4) results of an autopsy, if performed; and 5) results of blood tests for infectious disease markers. Procedures for processing and, in some cases, sterilizing tissues also contribute to tissue safety.

### Donor History Screening

Evaluation of the health and behavioral risk history of the prospective donor is an important step in establishing the suitability

of tissues for transplantation and preventing the transmission of infectious diseases. Family members may be able to provide reliable medical and behavior information, but friends and associates may provide relevant information not known to family members, especially the legal next of kin. Medical personnel may also be aware of significant medical and risk information. General donor eligibility criteria include the absence of systemic infection or any infectious or malignant disease transmissible by tissues and of behavioral risks for HIV infection or viral hepatitis. Malignancy generally disqualifies the donor, unless the malignancy is nonmetastatic or not known to metastasize to the tissue to be recovered (eg, virtually no cancer is known to metastasize to the eye or skin), and there is no suspicion of direct regional spread. The donor history review is specifically designed to reject those at high risk for viral hepatitis or HIV (eg, nonmedical injected drug users; men who have had sex with other men; persons who exchanged sex for money or drugs; persons with hemophilia or related clotting disorders; and persons with recent significant incarceration or with symptoms suggestive of a current viral infection).<sup>10</sup>

Beyond the general selection criteria for donors, there are specific eligibility criteria for each tissue type, to facilitate selection of tissues that will function adequately, as well as those that will not transmit disease. For bone and soft tissue, these include such factors as: donor age, for bone that is intended to be used for weight-bearing functions; no evidence of significant metabolic bone disease or a connective tissue disorder; and no exposure to toxic substances that could accumulate in the tissue to be recovered. Donors of cardiac tissues are screened for a history of significant valvular disease or cardiac infection, and vascular donors may be determined ineligible if there is a history of diabetes, vasculitis, varicose veins, or significant atherosclerosis. Cardiac and vascular tissue donations are also limited by age restrictions per AATB standards and individual tissue bank policy. When skin is recovered, areas of skin exhibiting signs of a skin infection, or where a rash, nevus, or tattoo is present, are avoided. Cornea donors cannot have a history of refractive corneal procedures, such as radial keratotomy. Also per EBAA and AATB standards, tissue recovery sites in deceased donors are evaluated for trauma and tissue is not recovered from sites found to be damaged. Donors of reproductive cells or tissues are screened for evidence or risk of inheritable diseases, and there are age restrictions. Extraembryonic tissue such as amnion and umbilical vein require the delivery to be full term; meconium staining of amniotic fluid is not acceptable, and there can be no current pelvic or vaginal infection in the mother. Consent is obtained from both parents.

In an effort to improve the efficacy and uniformity of the donor history acquisition process, a multiorganizational project team was established to develop a standardized donor history questionnaire and materials, modeled after the acceptable full-length donor history questionnaire and accompanying materials for blood donors. The project team includes members from the AATB, AABB, Association of Organ Procurement

Organizations, EBAA, NATCO (formerly the North American Transplant Coordinators Organization), Centers for Disease Control and Prevention (CDC), FDA, Health Resources Services Administration (HRSA), United Network for Organ Sharing (UNOS), and Health Canada. The goal is to eliminate questions that do not contribute significant information, and to develop simple and concise questions that employ terminology easily understood by the lay public. The ongoing effort is intended to produce a standardized form, with an accompanying standard operating procedure, to serve as a guide for donor history information collection by tissue banks. Use of the form is not intended to be mandatory, but it will be designed to facilitate effective history collection, in compliance with regulatory and professional standards requirements.

### Donor Physical Assessment

The physical assessment seeks evidence that is consistent with risk for infectious diseases that would disqualify the donor. Such findings include unexplained jaundice or icterus; enlarged lymph nodes; unexplained white lesions in the oral cavity; blue or purple spots on the skin (possible Kaposi sarcoma); signs of non-medical injected drug use; unexplained hepatomegaly; genital lesions consistent with a sexually transmissible disease; signs of systemic infection (generalized rash or petechiae); tattoos, piercing, or other body art that appears recent; trauma to intended retrieval sites; corneal scarring; and a rash, a scab, or a lesion that is suspicious for vaccinia. The physical assessment is fully documented so that it can be reviewed, along with medical/social/behavioral history, medical records, and records of an autopsy (if performed). AATB offers a sample tissue donor physical assessment form and instructions for its use (see <http://www.aatb.timberlakepublishing.com/files/guidancedocument1v2.pdf>), to facilitate the performance and documentation of this assessment in a thorough manner by tissue banks.

### Tissue Recovery

Tissues are collected aseptically in an operating room, in an autopsy room, or other suitable location where aseptic procedures can be performed. AATB standards require control of recovery site parameters including size/space, location, traffic, lighting, plumbing/drainage, ventilation, cleanliness of the room and furniture surfaces, presence or absence of pests, absence of other activities occurring simultaneously, sources of contamination, and capacity to permit proper handling of contaminated equipment and disposal of biohazardous waste. In addition, all working surfaces must be disinfected. Following a surgical scrub, the person performing the recovery dons proper attire (gown and gloves). Body preparation, including shaving body hair; cleansing the skin with antimicrobial agent(s); and surgical draping of the body is performed, consistent with aseptic technique. Using aseptic technique, recovery of tissue is sequenced, and well-defined zone recovery methods are employed. These recovery methods are described in AATB's Guidance Document 2, "Prevention of

Contamination and Cross-contamination at Recovery: Practices and Culture Results” (see <http://www.aatb.timberlakepublishing.com/files/bulletin46attachment1.pdf>). Generally, recovered tissues are not processed at the time of recovery. Tissues are often cultured at recovery, then individually packaged in sterile wraps, labeled with a unique donor identifier, placed on wet ice, and sent without delay to tissue banks that will process them. Following donation, the donor body is usually reconstructed to permit normal funeral arrangements and viewing. The organ/tissue donor coordinator’s responsibilities continue after the transplant procedure, in that a letter of appreciation may be sent to the next of kin, giving general information about the use of the donated organs and tissues. This communication serves as a liaison between the donor’s family and the organ/tissue procurement agency. Later, contact may be reestablished to assist in the amelioration of grief and bereavement. However, some donor families specifically request that there be no postdonation communication. AATB standards require formal establishment of donor family services. AATB has published a guidance document, “Providing Service to Tissue Donor Families,” which describes support that should be considered (see <http://www.aatb.timberlakepublishing.com/files/2007bulletin34attachment.pdf>).

### Infectious Disease Testing

Infectious disease marker testing includes HIV-1 and HIV-2 antibodies and nucleic acid, HCV antibody and nucleic acid, hepatitis B surface antigen (HBsAg), human T-cell lymphotropic virus, types I and II (HTLV-I/II) antibody, and syphilis. Tissue banks also screen donors for antibodies to hepatitis B core antigen (anti-HBc), which, although a confirmatory test is not available, may indicate HBV infection even when HBsAg is not detectable. Whenever possible, infectious disease marker testing should be performed on pretransfusion/preinfusion blood samples to avoid false-negative results caused by dilution in the event that transfusions and/or infusions had been given shortly before the time of death.<sup>43</sup> In the case of posttransfusion/infusion specimens, algorithms for determining the extent of plasma dilution are available.<sup>10</sup> Testing of postmortem (postasystole) blood specimens may be complicated by hemolysis or the presence of sediment, which can cause false-positive results in some HBsAg enzyme immunoassays (EIAs) and false-negative results in some HIV, HBV, and HCV NAT assays.<sup>19</sup> There are tests on the market for HIV and hepatitis that have been validated for use with postmortem specimens and approved by the FDA for use in tissue donor screening (see <http://www.fda.gov/cber/tissue/prod.htm>). When practical, tissue from living donors is preserved and quarantined before the donor is retested for HIV and hepatitis viruses in order to rule out seroconversion during the period of storage. Specific regulatory requirements for quarantine apply to donor semen. Additionally, both semen and oocyte donors must be found negative for *Neisseria gonorrhea* and *Chlamydia trachomatis* and are usually tested for carriage of at least one genetic disorder, as indicated by donor racial and ethnic

background. Donors may also undergo specific testing for rare genetic disorders if the recipient couple seeks a donor known to be negative for a particular gene mutation.

### Tissue Sterilization

Tissue sterilization is defined as the killing or elimination of all microorganisms, whereas disinfection refers to the removal of microbial contamination, from allograft tissue. The Association for the Advancement of Medical Instrumentation (AAMI), a standard-setting organization for the medical manufacturing industry, defines Sterility Assurance Level (SAL) as the probability that an individual device, dose, or unit is nonsterile (ie, one or more viable microorganisms being present) after it has been exposed to a validated sterilization process. While absolute sterility theoretically would represent an absence of any pathogen, SAL is generally applied only to the level of possible contamination with bacteria or parasites. In contrast to log reduction of viruses determined in assessments of virus reduction methods, SAL is an absolute determined by the ability of the method to eradicate or reduce microorganisms, the susceptibility of organisms that may be present to the sterilization method applied, and the maximal bioburden that could occur in the initial material. Thus, a process validated to achieve a specific SAL must include a step to assess the initial bioburden present and its susceptibility in order to qualify a specific level of assurance. For example, an SAL of  $10^{-6}$  means that there is less than a 1 in 1,000,000 chance of a viable microorganism remaining after the sterilization procedure. The FDA requires that medical devices be sterilized using a method validated to achieve an SAL of  $10^{-6}$ . A medical device derived from or that includes a biological product component must also meet an SAL of  $10^{-6}$  if it is to be labeled sterile. An SAL of  $10^{-3}$ , or a 1 in 1000 chance of a viable microorganism being present, is a more achievable goal selected by some processors for aseptically processed tissues unable to withstand the harsh treatment needed to achieve a more restrictive SAL without an impairment of tissue function. Such tissues may not then be labeled as sterile.

The complex physical structures and density of musculoskeletal tissues pose challenges for adequate penetration of antimicrobial agents and eradication of microorganisms. Allografts will not tolerate methods usually applied to metal and plastic medical devices because such treatment would impair the mechanical and biologic properties necessary for clinical utility. As an alternative, sterilization of tissues has been accomplished by several methods, including heat, chemicals, ethylene oxide gas, and irradiation. However, not all sterilants have adequate tissue penetration. This is particularly the case for gases and liquids. The initial bioburden, which may be high in some tissues, must be considered. Some tissues are treated with antibiotics in vitro before storage, but this treatment decontaminates only the surface and may be effective against bacteria only.

A variety of methods, including chemical treatments and irradiation, have been used to reduce or eliminate pathogens in

tissue intended for transplantation. The introduction of bone sterilization by ethylene oxide gas simplified bone processing and facilitated the widespread use of sterilized air-dried and lyophilized bone products.<sup>44</sup> The effects of ethylene oxide treatment on the biomechanical and osteoinductive capacity of bone allografts have been questioned, although animal studies have yielded inconsistent results.<sup>45-47</sup> These concerns, combined with those regarding the carcinogenic potential of ethylene oxide and its breakdown products, have largely led to abandonment of this method in the United States and the United Kingdom.

First introduced over 30 years ago,  $\gamma$ -irradiation of bone is still used widely, usually employing a cobalt-60 source. The  $\gamma$ -rays penetrate bone effectively and work by generating free radicals, which have adverse effects on collagen and limit utility in soft tissues unless performed in a controlled dose fashion at ultra low temperature. The minimal bacteriocidal level of  $\gamma$ -irradiation is 10 to 20 kGy (1 kGy = 100,000 rad). Uncontrolled human studies have shown irradiated, calcified, and demineralized bone grafts to be clinically effective.<sup>48,49</sup> Numerous studies have shown that mineralized bone allografts irradiated at 25 to 30 kGy are also clinically effective, with success rates of 85% to 91% reported.<sup>50,51</sup> In controlled studies, the clinical effectiveness of bone allografts subjected to 25 kGy irradiation was comparable to that of nonirradiated bone grafts,<sup>52</sup> although doses exceeding 25 kGy for cortical bone and 60 kGy for cancellous bone have been found to induce cross-linking of collagen and to impair mechanical function in a dose-dependent fashion.<sup>53</sup> There is in-vitro evidence that irradiation reduces osteoclast activity and increases osteoblast apoptosis, and that residual bacterial products induce inflammatory bone resorption following macrophage inactivation.<sup>53</sup> However, the clinical significance of these findings has not been established. Newer processes employing radioprotectants have preserved bone allograft integrity when doses >25 kGy are applied and controlled-dose methods permit successful irradiation at lower doses (see proprietary chemical sterilization methods to follow). Irradiated demineralized bone has active osteoinductive activity and has been effective in non-structural clinical applications.

Concerns about pathogen transmission and the limitations of irradiation, especially for soft tissues, have prompted improvements in sterilization methods and in the validation of these methods. A number of proprietary chemical-based processing methods have been developed with aims of effectively penetrating tissues and reducing, killing, or inactivating microorganisms and viruses without unacceptable adverse effects on the tissue's biomechanical properties. Additionally, for use in transplantation, the agents must either be able to be effectively removed or be nontoxic. All methods in current use are applied only to tissue from donors who have met stringent criteria for medical history and behavioral risk assessment as well as negative results on infectious disease marker testing. Some popular methods used are described below.

The Tutoplast process (Tutogen Medical, Gainesville, FL) was the first comprehensive method to sterilize and preserve

tissue without compromising its biological or mechanical properties. The process has been in use for over 30 years, for a variety of hard and soft tissues, including bone, fascia lata, pericardium, dermis, amniotic membrane, and sclera. Initially, lipids are removed in an ultrasonic acetone bath that also inactivates enveloped viruses and reduces prion activity. Bacteria are destroyed using alternating hyperosmotic saline and purified waterbaths that also wash out cellular debris. Soluble proteins, nonenveloped viruses, and bacterial spores are destroyed in multiple hydrogen peroxide baths, and a 1N sodium hydroxide treatment further reduces prion infectivity by 6 logs. A final acetone wash removes any residual prions and inactivates any remaining enveloped viruses. Vacuum extraction dehydrates the tissue before the grafts are shaped and then double-barrier packaged. Terminal sterilization using low-dose  $\gamma$ -irradiation yields an SAL of  $10^{-6}$ .

The Allowash XG process (LifeNet Health, Virginia Beach, VA) employs six steps, including bioburden control and assessment; minimization of contamination during processing; rigorous cleaning and disinfection steps, which employ detergents, antibiotics, alcohols, and hydrogen peroxide; and a final step of low-temperature, controlled-dose  $\gamma$ -irradiation. The process has been validated to achieve an SAL of  $10^{-6}$ .

The BioCleanse process (Regeneration Technologies, Alachua, FL) employs low-temperature addition of chemical sterilants, such as hydrogen peroxide and isopropyl alcohol, which permeate the tissue's inner matrix, followed by pressure variations intended to drive the sterilants into and out of the tissue. Regeneration Technologies reports an SAL of  $10^{-6}$  for soft tissues without adverse effects on the initial allograft mechanical properties.

The Clearant process (Clearant, Los Angeles, CA) avoids the negative effects of  $\gamma$ -irradiation through addition of free radical scavengers, employing dimethylsulfoxide (DMSO) and propylene glycol as pretreatment radioprotectants. Although the process subjects tissue to 50 kGy of radiation and achieves an SAL of  $10^{-6}$  for bacteria, fungi, yeast, and spores, the tissue's biomechanical properties are retained.

The Musculoskeletal Transplant Foundation (Edison, NJ) uses a series of chemicals, including nonionic detergents, hydrogen peroxide, and alcohol, to treat cortical and cancellous bone grafts. For soft tissues, such as bone-patellar tendon allografts, an antibiotic mixture containing gentamicin, amphotericin B, and primaxin is added, and then washed out to a nondetectable concentration. The Musculoskeletal Transplant Foundation claims an SAL of  $10^{-3}$  for its products. Incoming tissues whose bioburden exceeds prescribed parameters are pretreated with low-dose  $\gamma$ -irradiation.

NovaSterilis (Lansing, NY) has developed a sterilization technique that uses supercritical carbon dioxide at low temperatures and relatively low pressures, resulting in transient acidification, which is lethal to bacteria and viruses, with good penetration reported. However, this technique is still in development, and data on retention of allograft mechanical properties are limited.

## General Principles of Tissue Preservation and Clinical Use

Except for bone, which is usually lyophilized (freeze dried), the most common method of storing recovered tissues is at cold temperatures, either by refrigeration or by freezing (Table 58-5). For short-term storage, refrigeration at about 4°C often suffices, whereas long-term storage usually requires a frozen state. Several types of tissues can be preserved by multiple methods. Bone, dura mater, and amnion can be effectively cryopreserved or lyophilized. Much of the lyophilized and cryopreserved human tissue used in transplantation is intended to serve a structural purpose and maintenance of cell viability is not necessary. Tissues of this type, which include dermis, are composed of an extracellular matrix (such as collagen) with few or no viable cells present to support the matrix after transplantation, although they can contribute growth factors to facilitate remodeling. Even when the processing method used is intended to preserve cell viability, the donor cells will die following transplantation. The extracellular matrix, whether transplanted containing viable cells or devoid of them, is repopulated through the ingrowth of metabolically active recipient cells. More gradually, depending in part on the size and type of the allograft implanted, remodeling occurs, and the transplanted structure may eventually be entirely replaced by host cells.<sup>55</sup> The transplantation of allograft heart valves and cardiac conduit tissues provided in an acellular matrix form is being studied to determine the rate and extent of repopulation with recipient cells.<sup>56</sup>

In some tissues, such as cornea, a single layer of viable donor cells is important, and this requirement necessitates maintenance of the tissue in culture medium at refrigerated temperature.<sup>57</sup>

Other human tissues, such as marrow, skin, and gametes, are stored by either refrigeration or cryopreservation. In the latter, a controlled-rate freezing process and a cryoprotectant remove water from the cells while maintaining viability. The usefulness of tissues requiring posttransplantation cell viability depends on their maintenance of not only metabolic activity, but also capacity to synthesize protein, proliferate, or differentiate.

### Bone

Bone allografts have many uses, including provision of acetabular and proximal femoral support for replacement of failed prosthetic hip joints, packing of benign bone cysts, fusion of the cervical or lumbar spine to correct disk disease or scoliosis, restoration of alveolar bone in periodontal pockets, reconstruction of maxillofacial deficits, and replacement of bone that has been resected because of a bone malignancy, such as osteosarcoma (see Table 58-1). The last procedure is accomplished with large osteochondral allografts that permit tumor resection and achievement of a cure without limb amputation.

Historically, bone allografts were prepared by cutting a larger graft using simple techniques. Today's technology allows the cutting, machining, and piecing together of allografts via precision instrumentation, and has resulted in stronger and more versatile grafts that can withstand the challenges of new surgical techniques. Linear grooves, notches, or crosshatchings may be incised into bone surfaces to make the bone graft less likely to slip or become dislodged after placement. Many bone allografts, especially those used in neurosurgical applications, are now placed using precision instrumentation that not only ensures exact placement, but also enhances stability. Allografts can be cut or shaped

**Table 58-5.** Recommended Human Tissue Storage Conditions and Durations

| Tissue                   | Storage Condition                | Maximal Storage Duration |
|--------------------------|----------------------------------|--------------------------|
| Bone                     | −40°C or colder                  | 5 years*                 |
|                          | −40 to −20°C                     | 6 months                 |
|                          | 1–10°C                           | 5 days                   |
| Tendon                   | −40°C or colder                  | 5 years*                 |
| Fascia lata              | Lyophilized, ambient temperature | 5 years*                 |
|                          | −40°C or colder                  | 5 years*                 |
| Articular cartilage      | −40°C or colder                  | 5 years*                 |
|                          | 1–10°C                           | 5 days                   |
| Skin                     | −40°C or colder                  | Not defined              |
|                          | Lyophilized, ambient temperature | Not defined              |
| Cornea                   | 2–8°C                            | 14 days                  |
| Semen                    | Liquid nitrogen, immersed        | Not defined              |
|                          | Liquid nitrogen, vapor phase     | Not defined              |
| Cardiac, vascular tissue | −100°C or colder                 | Not defined              |
| Dura mater               | Lyophilized, ambient temperature | Not defined              |

\*Or as validated by the processor.

to precise angles that accommodate, for instance, lordosis of the cervical and lumbar spine. Advanced processing methods have resulted in improvements in availability and also in graft biocompatibility and functioning, in such processes as osteoinduction, osteoconduction, bioresorption, and tissue regeneration.<sup>1</sup>

Fresh autograft can be taken from the patient's own iliac crest during surgery, but this practice is becoming less common.<sup>55</sup> Fresh bone autograft is preferred by some surgeons, but preserved allografts are practical and accepted alternatives that approximate the results obtained with fresh bone autograft.<sup>58</sup> In some patients, an autograft is not an option because sufficient bone is not available. In addition, the use of bone allografts reduces operating room time and the number of operative sites, leading to reduced morbidity and lower cost. The use of bone allograft does carry the risk of donor-to-recipient transmission of infectious disease,<sup>15</sup> although this risk is minimized through careful donor selection and testing, and disinfection and sterilization of tissue during processing.

### Frozen Bone

Frozen bone, collected under aseptic conditions and then frozen or cryopreserved, is available in a wide variety of shapes and sizes from deceased donors, or as femoral heads or tibial plateaus obtained from living donors undergoing total joint replacement in an operating room (now an uncommon practice in the United States, but continuing in Canada, Australia, and Europe). This frozen bone is largely free of bacteria, but it does carry the risk of viral transmission. Diseases known to have been transmitted by unprocessed bone include AIDS, tuberculosis, and hepatitis.<sup>15</sup>

Frozen bone can cause alloimmunization from exposure to antigens on the attached connective tissues, marrow, and blood, although such alloimmunization apparently does not affect the graft's efficacy. Detailed reviews addressing the role of histocompatibility and the immune response in bone allograft transplantation have been published.<sup>59,60</sup> Antibodies to histocompatibility antigens,<sup>59,60</sup> blood group antigens,<sup>61,62</sup> and bone matrix proteins have been induced by transplanted frozen bone. In order to avoid Rh alloimmunization, bone from an Rh-negative donor is usually selected when using bone that has not been processed to remove red cells and the recipient is an Rh-negative female of childbearing potential.

Bone that otherwise would be discarded can be collected from living donors during surgical procedures (total hip or knee replacements with prostheses). The eligibility of a volunteer living donor is determined by a careful health history review, a directed physical examination if indicated, and donor testing for anti-HIV-1 and -2, HIV-1 NAT, HBsAg, anti-HBc (total), anti-HTLV-I/II, anti-HCV, HCV NAT, and syphilis.<sup>10</sup> In some countries, if NAT assays are not performed, the donated tissue is quarantined, and the living donor is retested 6 months later for infectious disease markers. This quarantine and retesting process is intended to eliminate donors who were in the early stage of viral infection but were antibody negative at the time of donation (in the window period). A follow-up anti-HBc test may

detect donors who had been infected with HBV shortly before donating but who no longer have detectable HBsAg.

Generally, culturing for bacteria is performed on each bone to be fresh frozen or on each batch/lot of cryopreserved bone. Allograft bone is further prepared by removal of extraneous tissue; it is then packaged, and immediately either shipped to the processing tissue bank on wet ice or sent to temporary freezer storage at  $-40^{\circ}\text{C}$  or colder. Frozen bone allografts are available as whole bones or cut into usable shapes and sizes. Frozen bone can generally be stored up to 5 years at  $-40^{\circ}\text{C}$  or colder, but the maximal storage duration and expiration date may vary based on processing and storage methods, as validated by the tissue bank. There is no evidence that the biomechanical or osteoinductive properties decline during frozen storage. However, in the absence of cryopreservation, frozen bone does not maintain cellular viability. Thus, frozen bone is used for structural support that depends on an intact calcified extracellular matrix or is used as filler to promote new bone formation.

### Lyophilized Bone

Following aseptic recovery, deceased donor bone can be placed on ice for transport to temporary storage in a freezer and maintained frozen at  $-40^{\circ}\text{C}$  or colder, and then can later be sent to a tissue processor with dry ice as a refrigerant. Alternatively, immediately after recovery, the tissue can be placed on wet ice and expedited directly to the processing tissue bank where, within 72 hours of recovery, it is frozen at  $-40^{\circ}\text{C}$  or colder until processing. Such processing includes removal of surface tissues and internal fat, blood, and marrow by means of mechanical agitation, high-pressure water jets, and alcohol soaks. It can also include detergents and other solutions as part of a proprietary process. Then the bone is milled into clinically useful shapes and sizes. This may include computer-guided milling and use of assemblies that result in complex mechanical structures. Conventional allografts include corticocancellous strips, wedges, and dowels; cortical struts and rings; and cancellous and corticocancellous cubes and chips. Bone can also be ground into a powder and be available as DBM and products that include it. DBM, which is also known as demineralized freeze-dried bone allograft, is derived from cortical bone and is available in combination products in the form of gels, pastes, putties, and flexible strips or sheets. DBM itself may be obtained in specific granule or particle sizes, as a powder, or in entangled, twisted fiber configurations. DBM primarily provides growth factors, but accompanying collagen can help play a structural role as a scaffold for future bone growth. The combining of DBM with approved polymer carriers results in moldable grafts that are user friendly for the surgeon, do not migrate after placement, and whose bone content does not dissolve following transplantation. Such grafts can readily be applied to completely fill bony defects and to act as a scaffold for ingrowth of the recipient's own cells, or they can be used to enhance other structural repair devices, such as dental implants, vertebral body spacers and cages, or support devices such as rods, screws, and plates.<sup>1</sup>

The bone allografts are lyophilized to a residual moisture content of <6% or 8% (depending on measurement method) and packaged into peel packs or “boat” packaging. Routine quality control testing of bone is designed to monitor safety, rather than potency or efficacy. Sterility is assessed by the testing of samples of each batch, or by another acceptable method. If a robust validated sterilization process is used, sterility may need to be assessed only at established intervals, such as quarterly. Potency can be evaluated by using assays for osteoinductive capacity and biomechanical properties, but these analyses usually are conducted only when there is a change in the production process. Lyophilized bone is brittle unless fully rehydrated before use. Lyophilized bone can usually be stored at ambient temperature for up to 5 years if the graft’s package integrity and its vacuum are maintained, depending on validation performed by the tissue processor.

Bone collected aseptically in an operating room and processed aseptically can be lyophilized without use of a sterilant. Because the bone, theoretically, is bacteria-free, final sterilization with  $\gamma$ -irradiation may not be necessary. Although the bone should be free of bacteria, it still has the potential to transmit disease. Despite this risk, some physicians have preferred aseptically processed, nonsterilized lyophilized bone because it was thought to have better osteoinductive capacity than sterilized bone. However, controlled-dose low-temperature radiation has been found to have no significant effect on osteoinductive capacity.<sup>63</sup>

### Ear Ossicles

Ear ossicles are used as a special kind of bone graft to correct selected cases of deafness in which the patient’s own ossicles have suffered congenital, traumatic, or postinfectious damage.<sup>64</sup> Ear ossicles are procured by removal of the temporal bone en bloc or as a core with a bone-plug cutter. The temporal bone can be stored temporarily, for months if frozen, or up to 2 weeks if preserved in formalin; the tympanic membrane and ossicular chain are then dissected. Ossicles have been stored for up to 2 months in cialit (an organomercuric compound), and for up to 1 year at room temperature in buffered formaldehyde. Alternatively, ossicles are dissected at the time of collection, lyophilized, and then sterilized by  $\gamma$ -irradiation. Lyophilized ossicles can be stored at ambient temperature for up to 5 years.

### Connective Tissue

#### Cartilage and Meniscus

Human cartilage can be transplanted at weight-bearing or non-weight-bearing sites. For non-weight-bearing uses such as nasal reconstruction and mandibular or orbital rim augmentation, the graft provides structural support and need not be viable. Costal cartilage can be recovered for this use. The cartilage can be sterilized by  $\gamma$ -irradiation and stored in saline at refrigerated temperatures, or it can be lyophilized and stored at ambient temperature.

Articular cartilage can be transplanted to weight-bearing articular surfaces to replace focal cartilage defects caused by

trauma or degenerative disease, particularly in the knee. Cartilage in an osteochondral or osteoarticular allograft can be obtained as a femoral hemicondyle, a tibial plateau or fragment, or a measured segment removed with a template cutter that can be press-fitted into a similarly cut area in the recipient. Osteochondral allografts avoid autograft harvest site morbidity and are advantageous when the focal articular cartilage defects being repaired are large (>2.5 cm).<sup>65</sup> It has been assumed that, in weight-bearing applications, chondrocytes must survive the collection and preservation process and remain viable, producing normal cartilage matrix to maintain mechanical properties. It appears that chondrocytes deep within the cartilage matrix resist cell-mediated immune responses by the recipient and, if kept viable during storage, are able to survive after transplantation. Cartilage grafts from histoincompatible donors, stored <24 hours at 4°C, have survived for as long as 7 years after transplantation, if the grafts developed a sound union and if conditions for correct biomechanical functioning were present.<sup>66</sup> Articular cartilage collected in a sterile manner can be stored at 4°C in saline or electrolyte solutions with or without 10% fetal calf serum and antibiotics.<sup>67</sup> An FDA rule proposed in January 2007 would prohibit the use of certain cattle materials. This rule indicates that the FDA considers cow-to-calf transmission of bovine spongiform encephalopathy unproven by current evidence, and the agency believes that procedures could provide assurance that contamination has been prevented.<sup>68</sup> Osteoarticular and osteochondral allografts can be stored refrigerated for up to 28 days with successful clinical outcomes. If they have been cryopreserved, expiry for these allografts may be extended to 1 year. Cartilage cryopreserved with or without DMSO maintains viability with variable degrees of success.<sup>69</sup>

The use of a large osteochondral allograft, such as the femur with the articular cartilage attached, is thought to require preservation of cartilage viability in order to maintain biomechanical properties. To accomplish this, grafts have been stored at refrigerated temperatures in electrolyte solutions for up to 1 month, or have been frozen in 10% glycerol or 15% DMSO and stored at  $-70^{\circ}\text{C}$  or colder.<sup>70</sup> Following transplantation in humans and animals, the surface of the articular cartilage allograft undergoes degenerative changes within a few years. These grafts have the same risk of disease transmission as other fresh tissue allografts.

Menisci are C-shaped disks of fibrocartilage interposed between the femoral condyle and tibia. The presence and integrity of the meniscus are essential for knee mechanics and biochemical functions. Loss or disruption of the meniscus is associated with pain, joint laxity, and degenerative arthritis. Meniscal transplantation has been proposed as a method of providing a biologically and biomechanically acceptable structure to replace a damaged or removed meniscus, with a goal of relieving pain, decreasing stress on the anterior cruciate ligament, and preventing late arthritis, although evidence of allograft tissue being chondroprotective is lacking. Although there have been unpublished reports of successful transplantation of menisci stored <24 hours at 4°C, fresh menisci are not usually

available. Cryopreserved menisci are used successfully, with good outcomes (including reduced pain and increased knee function) reported.<sup>71,72</sup>

### **Tendon and Ligament**

The knee is the joint most frequently involved in sports-related injury. Arthroscopic methods for replacing the anterior or posterior cruciate ligaments with autografts, allografts, or artificial tendons and ligaments are frequently used. Despite the attendant need for sacrifice or weakening of normal structures, the use of autografts appears to have the highest success rate and the lowest incidence of complications. However, allografts may be indicated for multiple ligament knee injuries, anterior cruciate ligament revisions, or posterior cruciate ligament reconstruction, and when extensor mechanisms are impaired (as with previous tendon tears). It is sometimes preferable to avoid the morbidity associated with autograft harvesting. In addition, there are occasions when sources of adequate autograft tissue are not available.<sup>73</sup> Allografts used to replace the injured anterior cruciate ligament are usually derived from deceased donor patellar ligaments, tendons of the leg (eg, tibialis, semitendinosus, gracilis, and peroneus longus), or Achilles tendons. Ligament and tendon allografts are usually stored frozen, but some are stored lyophilized. In-vitro biomechanical properties of tendons do not seem to be greatly affected by freezing, lyophilizing, or ethylene oxide sterilization.<sup>74</sup> However, many surgeons eschew lyophilized tendon allografts because of experiences with clinical failure. Frozen tendon allografts are commonly sterilized by  $\gamma$ -irradiation, although this can reduce their mechanical strength, particularly if the dose exceeds 20 kGy.<sup>75</sup> There is no evidence that maintenance of cellular viability during processing and storage is important to clinical effectiveness. The effect of irradiation on the biomechanical properties of human tissue has been explored extensively, with inconsistent results. This is probably because the studies failed to use uniform irradiation methods and comparable study designs. A key study found a difference in average stress at failure between nonirradiated and  $\gamma$ -irradiated tendons; that difference is likely a consequence of the free radicals generated, which can cause minor crosslinking of collagen fibers and alteration of the tendon's material properties.<sup>76</sup> In order to eliminate the potential for elongation of irradiated grafts after implantation, the authors encouraged pretensioning of grafts before insertion.

### **Fascia Lata**

The fascia lata is a broad fibrous membrane surrounding the thigh muscles. The thick lateral portion acts as a flattened tendon, and its muscular insertions helping to maintain the trunk in an erect posture. Fascia lata can be removed and transplanted as an autograft or allograft. As an allograft, fascia lata has been used to suspend the upper eyelid to correct ptosis, to replace injured anterior cruciate ligaments, to provide support for bladder suspension, and to repair ankle, hip, and shoulder suspensions (ie, repair of a ruptured shoulder rotator cuff). Fascia lata usually is preserved by lyophilization, resulting in a residual moisture of <6% or 8% (depending on measurement method), the graft

is then sterilized by  $\gamma$ -irradiation and stored for up to 5 years at ambient temperature. After rehydration, the graft's biomechanical properties equal those of fresh frozen fascia lata. The use of fascia lata has become less popular because of the availability of alternative products, such as decellularized skin.

### **Dura Mater**

Dura mater is the outermost, toughest, and most fibrous of the three meningeal membranes covering the brain and spinal cord. The intracranial portion is collected, processed, stored, and distributed for several clinical applications; the most common use is the closure of dural defects caused by resection of tumor or the repair of traumatic injury. Human dura allograft most commonly is preserved by lyophilization. Ethylene oxide and  $\gamma$ -irradiation are effective in preventing transmission of viruses and bacteria; however, Creutzfeldt-Jakob disease (CJD) has been transmitted by dura mater treated by these methods. Following findings by Brown and coworkers,<sup>77,78</sup> in 1986 The Committee on Health Care Issues of the American Neurological Association recommended using 1N NaOH for 1 hour or steam autoclaving for 1 hour at 132°C as standard sterilization procedures for CJD-infected tissue or contaminated materials. Donors with a history of clinical dementia or other central nervous system disorders are not accepted as dura mater donors. Lyophilization and sterilization treatments do not lessen the effectiveness of dura mater allografts. Reconstituted freeze-dried dura mater is thick and strong, holds suture well, and is incorporated into normal surrounding tissue without rejection. Because of the risks and resulting decreased demand, dura mater is currently processed in the US by only one tissue bank.

### **Skin**

Human skin allograft is the dressing of choice for temporary grafting onto deep burn wounds whenever sufficient amounts of autograft skin are unavailable. Early excision of burned tissue and covering of the wound with deceased donor skin allograft has shortened hospitalization and decreased mortality more than has any other treatment.<sup>79</sup> A skin allograft provides temporary coverage and acts as a barrier against loss of water, electrolytes, protein, and heat. It reduces opportunities for the invasion of bacteria and speeds re-epithelialization. Skin allografts are replaced periodically until the patient's vascular bed is reestablished. Skin allografts also are used for unhealed skin defects (decubitus ulcers, autograft skin donor sites, pedicle flap donor sites, and traumatically denuded areas). While skin has historically been used only as a covering, decellularized (mechanically and chemically treated) skin offers the opportunities for use of a collagen matrix that can be implanted and be remodeled within the site with the recipient's own cells. It is used for such applications as bladder suspension surgery and repair of large defects, such as postoperative hernias and dehiscence wounds. In an analogous fashion, Taylor and colleagues<sup>56</sup> have used perfusion-decellularized cardiac tissue matrix in an attempt to develop a bioartificial heart.

After collection, fresh skin can be stored in medium at 1 to 10°C for up to 14 days,<sup>10</sup> but fresh skin is seldom used today. Skin also can be frozen using a method that retains cell viability, in order to improve availability. Because cell viability declines during refrigerated storage, results are best when cryopreservation is performed within 2 to 3 days after recovery. Cryopreserved skin can be prepared as strips (often 3-inch by 8-inch sections), either unmeshed or meshed (most commonly with a 1:1.5 expansion ratio, which triples the area that can be covered). The skin then covered in fine-mesh gauze and laid flat, is packaged, and is then cryopreserved, with glycerol or DMSO at a concentration of 10% or 15% as a cryoprotectant. Cryogenic damage is minimized by controlling the rate of freezing to between  $-1$  and  $-5^{\circ}\text{C}/\text{minute}$ . Many tissue banks use a “heat sink” freezing method, rather than one that employs computer-controlled freezing chambers. Heat sinks involve aluminum plates combined with styrofoam-insulated boxes; these are placed directly into a  $-70^{\circ}\text{C}$  mechanical freezer. This simple process provides a slow, controlled freezing rate that is acceptable for skin and that also maintains cellular viability.<sup>80</sup> AATB standards permit frozen storage in a mechanical freezer at  $-40^{\circ}\text{C}$  or colder, in the vapor phase of liquid nitrogen, or submerged in liquid nitrogen.<sup>10</sup> The maximal allowable storage period in the frozen state during which viability and structural integrity are maintained has not been determined. Cryopreserved skin allograft usually is transported from the tissue bank to the hospital with dry ice in order to maintain a frozen environment until use.

Skin for use in burn applications generally is not preserved by lyophilization because this method decreases clinical efficacy. However, lyophilized skin is sometimes used by oral surgeons to cover oral mucous membrane defects and to speed re-epithelialization. Lyophilized acellular dermal matrix is also available, in two thicknesses for different applications, and can serve as a natural biological matrix for soft tissue augmentation in soft tissue defects and in periodontal peri-implant soft tissue management. Following hydration, lyophilized skin has multidirectional strength and can adapt to surface contours, and it then is resorbed over 4 to 6 months, depending on the site, defect size, patient age and health status, and the biomechanical load on the graft. Depending on processing method and packaging configuration, lyophilized skin can be stored as long as 5 years at ambient temperature or it may require refrigeration.

### Ocular Tissue

Cornea is one of the most frequently transplanted tissues; >34,000 corneas were transplanted in the United States in 2006. Corneal transplantation has become highly effective because of improvements in suture materials, surgical instruments, and topical antiinflammatory medications to control rejection. It is now considered a standard therapy for a variety of conditions. However, early in this century demand decreased because of improvements in cataract surgery techniques compared with those in use in the 1990s, during which time use for complications of cataract surgery had supplanted keratoconus as the

leading indication. More recently, development of a new technique that uses an air bubble to hold the allograft in place, obviating the need for sutures and retaining the normal topography, has resulted in faster recovery and improved visual acuity, as well as a reduction in the occurrence of adverse effects. As a consequence, corneal transplantation for Fuchs epithelial dystrophy is becoming an accepted therapy at much earlier stages of the disease, resulting in a resurgence of demand for cornea allografts. Currently the most common indications for corneal transplantation are postcataract surgery corneal edema, keratoconus, Fuchs dystrophy, and corneal regrafting. Donor cells in the avascular full-thickness cornea graft enjoy long-term survival without the aid of histocompatibility matching because the recipient site is also almost completely avascular. Some experts believe that the failure rate of 5% to 10% might be improved by HLA matching; recipients known to be sensitized to HLA antigens have rejection rates higher than nonsensitized recipients.<sup>81</sup> The possibility of alloimmunization is of particular concern in patients who are undergoing repeat grafting procedures because of graft failure or who have ocular infections, as the corneal rim may become quite vascularized. Systemic immunosuppressants are not used, but topical corticosteroids are used routinely. Sclera may be used in the repair of ocular deficits, in orbital reconstruction following enucleation, and in some dental applications.<sup>82</sup>

Ocular tissue can be recovered by enucleation or by in situ excision of the cornea, with a rim of sclera. It is preferable that recovery be performed within 6 hours after death. The oldest method of storage for whole globes was at  $4^{\circ}\text{C}$  in a moist chamber; this method appeared to maintain viable endothelial cells sufficient for graft efficacy for as long as 48 hours after recovery. Because it yields improved viability, a more common method today is storage of the cornea, with attached rim of sclera, at  $4^{\circ}\text{C}$  in a modified tissue culture medium, based on that developed in 1974 by McCarey and Kaufman.<sup>83</sup> One example commonly used is Optisol-GS (Bausch & Lomb, Irvine, CA), which contains dextran (as an osmotic agent), chondroitin sulfate, gentamicin, and streptomycin. Storage of corneas in the medium, at 2 to  $8^{\circ}\text{C}$ , can maintain endothelial viability for as long as 14 days, and can maintain functional integrity for eutopic graft applications not requiring visual acuity for even longer storage periods.<sup>84</sup> Grafts are usually used within 7 days. Although they have been treated with antibiotics, allograft corneas are not considered sterile. An alternative culture technique, used at a few eye banks, has maintained viable corneas for as long as 5 weeks in tissue culture medium at  $34^{\circ}\text{C}$ .<sup>85</sup> Rarely, corneas are frozen with cryoprotectants. Sclera is usually preserved in  $\geq 70\%$  ethyl alcohol; such a method yields a shelf-life as long as 2 years.

### Cardiovascular Tissue

Cardiovascular tissue includes cardiac tissues (heart valves) and vessels that can be used as conduits. Donor medical history requirements differ, so AATB has established separate standards for cardiac tissues and for vascular tissues.<sup>10</sup> Since their introduction 4 decades ago, human heart valve allografts have been

shown to be a superior alternative for patients needing heart valve replacement and for whom mechanical and porcine valves are contraindicated. Human heart valve allografts do not require recipient anticoagulation, have a lower incidence of thromboembolism, and appear relatively resistant to infection. After valve allograft transplantation, donor endothelium is not maintained, but donor fibroblasts remain for an undetermined period. Because anticoagulation is unnecessary, human valve allografts are the graft of choice for children, females of childbearing potential, and patients with infection in the aortic root. The use of allograft valves has been slowed, however, because implantation is more difficult technically and because their availability is limited. Additionally, clinical results with transplantation of xenograft tissue valves have improved, although these are not available in the small sizes required by many pediatric patients.

Technical impediments have made it impossible to successfully produce man-made (either completely artificial or modified porcine) replacement heart valves for use in neonates and other pediatric patients who require very small grafts. Only donated human heart valves from newborns or small children offer unobstructed blood flow through such a small annulus. Also, the tissue's pliability renders human allografts adaptable to the ingenuity of cardiothoracic surgeons who repair congenital defects by using allografts to replace underdeveloped or otherwise defective valves or outflow tracts, or to construct valves and tracts that may be absent.<sup>86</sup> Complex repairs may need to be staged over many years or may be only palliative. Clinical use of nonvalved conduit sections of cardiac allografts, mostly from the main pulmonary artery and/or its branches, has reached a level equivalent to that of the two semilunar valve allografts. On a global scale, availability of cryopreserved pediatric allograft heart valves has historically been low and unable to meet demands.

To obtain valve allografts, hearts are recovered aseptically, immersed in a sterile isotonic solution within a sterile container, placed on wet ice, and transported expeditiously to a tissue processing facility. The pulmonic and aortic valves, along with their intact outflow tracts and/or small pieces of these conduits, are dissected free of the heart within 48 hours of donor asystole, and then placed in tissue culture medium amended with a low-dose antibiotic cocktail. Initially, human heart valves were stored up until use at 5°C in tissue culture medium containing antibiotics. However, although their cell viability was lost under these conditions after 48 hours, such grafts could be used successfully after a few weeks in such refrigerated storage. Subsequently, studies demonstrated that cryopreservation of heart valves allowed successful banking of valves of various sizes and types. Additionally, such allograft valves were found to be superior, based on their retaining the cellular matrix and having a low clinical incidence of valve degeneration, rupture, leaflet perforation, and valve-related death. For these reasons, human heart valves generally are cryopreserved,<sup>87</sup> with a method that includes an initial exposure to antibiotic solutions for 12 to 24 hours. Cryopreservation then follows, using a 10% DMSO solution tissue culture medium that often is amended with 10% fetal

calf serum. Freezing is accomplished using a computer-assisted controlled rate of  $-1^{\circ}\text{C}/\text{minute}$  to  $-40^{\circ}\text{C}$ . Valves generally are stored in the vapor phase of liquid nitrogen. Heart valves can be stored indefinitely in liquid nitrogen, although the nature of any deterioration during storage is not well characterized. The viability of cryopreserved connective tissue matrix cells is maintained, but at a lower level than that of fresh valves,<sup>88</sup> and endothelial viability is lost.<sup>89</sup>

The aorta and iliac arteries can be preserved using the same methods applied to heart valves. Frequently, the aortic arch is preserved with the aortic valve intact; such grafts are intended for transplantation as a valved conduit. Preservation and storage methods are similar to those for valves. Synthetic grafts are the primary graft of choice, but such grafts may be less effective in an infected field. Aortoiliac arteries are used successfully as conduits in mycotic aneurysm repairs, when synthetic grafts have become infected, and for aortoenteric fistulas in an infected field.<sup>90</sup>

Arterial or venous segments of vascular organs may be recovered in order to provide a source of vascular "conduits" for use in organ transplants when the organ's attached vessels are damaged or inadequate. Vascular "conduits" that have been recovered and transplanted under these conditions are not considered tissues under the FDA's human cells, tissues, or cellular or tissue-based products (HCT/Ps) rules, but they are regulated as organs under 42 CFR Part 121. Donor screening and testing, as well as labeling and storage requirements, are identical to those for donor organs specified in a federal contract with the Organ Procurement and Transplantation Network.

Autograft veins are used in cardiac and peripheral vascular bypass graft procedures whenever it is possible, but veins from deceased donors that have been recovered under aseptic conditions may be used for revascularization when autologous mammary or saphenous vein grafts are not available. These veins are more fragile than are the great vessels, and they are more easily damaged during recovery and during thawing and preparation for implantation. Cryopreservation of veins is similar to that of cardiac allografts. Arterial grafts are seldom used for this purpose because their layers tend to separate during thawing. Well-established tissue bank procedures are designed to retain venous endothelial cells during recovery, processing, and preservation, but these cells are rapidly sloughed off the lumen after the vein is transplanted into the high-pressure arterial system. Retention of endothelial cells during recovery and processing does aid, however, in reduction of the risk of thrombosis or failure after implantation through protection of the integrity of the vessel's basement membrane.<sup>86</sup>

Although not proven to be necessary for successful clinical outcome or to prevent alloimmunization, ABO- and Rh-compatible allograft valves and vessel conduits are usually requested. Cryopreservation is known to alter the expression of antigens on donated cardiovascular tissue, but the mechanism of this effect is not well understood. Some studies have shown that the use of these tissue allografts may carry a risk of HLA antigen sensitization.<sup>91</sup>

## Peripheral Nerve

Fresh autografts of peripheral sensory nerves are used in nerve repair, but this practice is hampered by donor site morbidity and resulting limitations on the amount of autologous nerve tissue that can be made available. Although allografts ideally might repair peripheral nerve defects without requiring the sacrifice of the patient's own nerve, frozen, irradiated, and lyophilized allografts have not functioned well. New animal studies using nerve allografts cold-preserved for 7 weeks have shown promising results, as have cultured Schwann cells added into synthetic conduits.<sup>92</sup> Axogen, Inc. (Alachua, FL) has developed a thermally acellularized nerve allograft scaffold called Avance that is treated with chondroitinase in order to degrade chondroitin sulfate proteoglycan. Such grafts have been shown to inhibit both aberrant growth and retrograde regeneration in the absence of any immunosuppressive therapy. Animal studies employing such an approach demonstrated enhancement of nerve regeneration. The first human Avance nerve allograft was implanted in July 2007 into a 38-year-old man who had suffered a traumatic facial injury; a single nerve allograft was used to connect the severed nerve root to three nerve branches. The surgeons informally reported that the graft's handling characteristics were superior to those of autograft tissue, but it is too early to assess the extent and character of nerve regeneration.

## Parathyroid

Hypercalcemia, kidney stones, and other complications associated with hyperparathyroidism can be treated by surgical removal of the parathyroids. Hyperparathyroidism often is caused by a single parathyroid adenoma, but in 10% of cases, generalized parathyroid hyperplasia is found, rendering the removal of all four parathyroids necessary. Postoperatively, the lack of parathyroid hormone can result in permanent hypocalcemia in 5% of patients. To prevent this outcome, autotransplantation of a small amount of parathyroid tissue is performed during total parathyroidectomy in order to provide a controlled source of parathyroid hormone.<sup>93</sup> The parathyroid tissue is placed in the sternocleidomastoid muscle, flexor muscle groups, or subcutaneous tissue of the forearm. The remaining parathyroid tissue can be divided, placed in vials containing chilled tissue culture medium, and then cryopreserved using 10% autologous serum and 10% DMSO. The excess tissue then can be frozen under controlled conditions and stored in liquid nitrogen at  $-196^{\circ}\text{C}$ .<sup>94</sup> Frozen parathyroid autograft can be retrieved for subsequent use if the tissue implanted at time that the parathyroid was removed proves to be insufficient, fails to function, or becomes infected. Cryopreservation of parathyroid tissue with DMSO maintains cell viability and graft function. This is illustrated by postimplant amelioration of hypocalcemia and sustained elevation of parathyroid hormone in the venous effluent of the grafted forearm compared with that of the nongrafted forearm.<sup>95</sup> Postthaw viability can also be demonstrated in vitro by the suppression of parathyroid hormone secretion by the addition of increasing calcium concentrations.<sup>96</sup> The maximal duration of cryopreserved parathyroid tissue storage has not been determined.

## Reproductive Tissue

### Semen

Assisted reproductive technology procedures and artificial insemination of a female with her partner's previously stored semen or with donor semen are established therapies for the clinical management of infertility or when a woman does not have a male partner. Cryopreserved semen is used in both forms of artificial insemination. Cryopreserved semen can be stored by a man, termed a "client depositor," who may become sterile as a consequence of therapy for testicular malignancy or for another reason, for later use with his wife or other "intimate partner," or even with a surrogate mother. Sperm can even be collected postmortem, but such a practice poses ethical issues regarding the lack of consent. According to the FDA, there are approximately 110 semen banks in the United States. In 2005, semen banks licensed by New York State processed 27,118 ejaculates from 962 donors into 145,751 vials/straws in inventory. These banks distributed 74,366 vials/straws of semen for clinical use (New York State Department of Health, unpublished data, 2005).

Semen banks usually offer a library of donors from whom donated frozen semen specimens are available. The offering of a selection of donors facilitates the matching of donor's hair and eye color, race, and other genetically determined characteristics with those of the intended father or co-parent or with those of both parents. These donors are usually "anonymous"; such a donor's identity is known only to a few of the semen bank staff. However, some semen banks offer a program through which some donors have agreed to disclose their identities when offspring reach the age of 18 or, sometimes, even before use of the semen. Sexually transmitted diseases, including HIV infection, can be transmitted by donor semen to women undergoing artificial insemination.<sup>25,97,98</sup> Cryopreservation permits extended storage and the retesting of donors at least 6 months after the donation of specimens to be released. This process is intended to prevent use of semen donated by a recently infected man, before development of detectable antibody or viral nucleic acid (during the "window period"). Other diseases and organisms transmissible by donor semen include hepatitis B, gonorrhea, *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Trichomonas vaginalis*, and *Chlamydia trachomatis*. Transmission of HTLV-I, syphilis, HCV, and human papillomavirus may also be possible (see Table 58-4).<sup>25</sup>

The basic practices and techniques of semen cryopreservation have changed little since the cryopreservative glycerol was discovered accidentally by Polge and coworkers<sup>99</sup> in 1949. Glycerol remains the standard cryoprotectant, and liquid nitrogen remains in use for storage. Freezing methods in use have been designed to control the rate of temperature decline, and to prevent thermal shock initially by cooling the semen slowly in air or in a waterbath to  $5^{\circ}\text{C}$  before initiation of the actual freezing process, which takes place in the vapor phase of liquid nitrogen, or in a programmable controlled-rate freezing device. After freezing, semen can be stored in the liquid phase of liquid nitrogen indefinitely.

While a defective pregnancy as the result of sperm injury during the freezing-thawing process is a theoretic concern, such an effect has not been demonstrated. Cryopreservation of semen does not influence the frequency of abortions or multiple births, or the infant's gender, body size, or intelligence.<sup>100</sup> In fact, there is some evidence that indicates that the safety of cryopreserved semen actually might exceed that of fresh semen. One study reported finding birth defects in 0.7% of offspring and spontaneous abortion of 7.7% of pregnancies achieved using cryopreserved semen,<sup>101</sup> whereas in the general population the frequency of birth defects is 6% and the frequency of spontaneous abortion is 10% to 18% of pregnancies.

### Oocytes and Embryos

Since the birth of Louise Brown, the world's first "test tube baby," on July 25, 1978, there has been an explosion in the use of assisted reproductive technologies, such that several techniques have been accepted as standard medical therapy. There are at least 422 assisted reproductive technology programs in the United States.<sup>4</sup> While the technology to freeze unfertilized oocytes reliably is still in development, embryos are routinely cryopreserved. In 2005, >32,000 embryos, 13% of which were created using donor oocytes and/or donor semen, were transferred into patients in New York. In addition, >46,000 embryos were in storage in New York alone (New York State Department of Health, unpublished data, 2005). Many of those embryos were created using donor semen and/or donor oocytes. Donor oocytes were used in approximately 12% of all assisted reproductive technology cycles carried out in the United States in 2005.<sup>4</sup> Many of these were embryos created for recipients >35 years of age, using an oocyte donor who was much younger than the recipient. Embryo transfer success rates have been shown to be influenced far more by the age of the oocyte source than by the age of the uterus into which embryos are transferred. Medical history and infectious disease testing requirements similar to those for semen donors apply, although a quarantine period and retesting are not required.

### Extraembryonic Tissue Preservation and Transplantation

Extraembryonic tissues that have been used occasionally for transplantation include the amnion and the umbilical vein. Fetal amnion, which is the smooth, slippery, glistening membrane lining the fluid-filled space surrounding the fetus, has been used as a covering for nonhealing chronic leg ulcers, burns, and raw surfaces following mastectomy, and in major oral cavity reconstruction and vaginoplasty. Amnion also has been used as a pelvic peritoneum substitute following pelvic exenteration and as a source of replacement enzymes for infants with inborn errors of metabolism.<sup>102</sup> Most of the fetal amnion is covered on the maternal side by the chorion, a slightly roughened membrane. Amnion is sterilely collected during cesarean section. The amnion's epithelium and basement membrane can be separated by blunt dissection from the underlying chorion immediately after collection or after temporary storage. The amnion is then cryopreserved or lyophilized. Human umbilical vein allografts previously were used occasionally

as vascular substitutes to provide venous access for hemodialysis or as an arterial bypass graft, but such allografts proved to be inferior to saphenous vein autografts. Such umbilical vein grafts are no longer available, following application of FDA device manufacturing requirements to their recovery and processing.

---

## Donor-Recipient Matching

For most tissues, donor-recipient HLA matching is not necessary and is rarely done. Tissues such as bone, fascia, tendon, cartilage, and dura mater are not preserved or transplanted in a viable state; rather, they serve as a support or matrix that the recipient's own cells can enter and gradually replace. Immunologic rejection, therefore, is not a significant concern, and matching of blood group or HLA antigens is considered unnecessary. There are exceptions, however. Immunologic rejection can occur in patients who have received a repeat cornea graft; therefore, efforts are made to use HLA-matched corneas in these patients.<sup>103</sup> HLA sensitization has also been reported in recipients of vascular allografts or allograft heart valves.<sup>104</sup>

The ABO antigens are a significant consideration in transplantation because they constitute very strong histocompatibility antigens. Because they are expressed on vascular endothelium, major ABO mismatching can cause rapid graft rejection resulting from endothelial damage by ABO antibodies and subsequent widespread thrombosis within the graft. Therefore, ABO matching is important to the success of vascularized organ grafts (ie, kidney, heart, liver, and pancreas). ABO matching is not important for a successful outcome when using most tissue grafts (ie, fascia, bone, heart valves, skin, and cornea). However, hypersensitivity to antigens expressed by fresh or cryopreserved donor tissue is a rare occurrence and appears to be dependent on an undetermined unusual immune response by the recipient.

Alloimmunization to Rh(D), Fy(a), and Jk(b) red cell antigens following transplantation of frozen unprocessed bone has been reported.<sup>61,62</sup> Consequently, frozen unprocessed bone allografts usually are matched with the donor for the D antigen if the recipient is a female of childbearing potential, in addition to being matched for ABO group.

---

## Transfusion Service Support of Tissue Transplantation

Hospital transfusion services have been greatly affected by transplantation, and have encountered new and increased demands for services. They are involved in transplantation in several ways, including: 1) providing traditional blood components, 2) providing new or special blood components, 3) taking responsibility for tissue acquisition, storage, distribution, and tracking, and 4) providing specialized services. For organ transplants, the major demand is for traditional blood components, although special preparation may be required (see Chapter 40).

FDA regulations for tissue (see below) cover donor selection and testing, tissue recovery, processing, storage, labeling, and distribution to the “consignee” (21 CFR Part 1271). The consignee can be a distributor, a surgeon in a hospital operating room, a dentist in his or her office, or a designated individual or department in a hospital or other health-care institution. Tissue “banks” that are located in hospitals are not regulated by the FDA if they serve only to store and dispense tissues provided by comprehensive tissue banks or distributors. A hospital tissue service can be centralized in a support area for the operating rooms, hospital central supply services, or the hospital transfusion service. Alternatively, tissues can be handled using a decentralized system and be ordered, received, and stored by each functional area of the hospital in which they are used.

Currently, most human deceased donor tissue (bone, skin, heart valves, veins, and tendons) is recovered by an organ and tissue procurement agency or regional tissue bank, sent for graft processing and packaging, and then distributed directly to the operating room or to other hospital sections in which tissue transplantation occurs. However, in the absence of centralization, records of storage and recipient identification may be inadequate. In one case involving an HIV-infected donor, the recipients of six of the tissues could not be identified from hospital records.<sup>16</sup> The Joint Commission standard on record-keeping and traceability of tissues (PC 17.20), College of American Pathologists transfusion medicine checklist (TRM.45250, Phase II), and AABB *Standards*<sup>105</sup> (Standards 5.1.6.2, 5.19.6.1, and 6.2.3) require that the organization’s records permit tracing of any tissue from the donor or source facility to all recipients or other final tissue disposition. However, New York State is the only government regulatory agency that requires centralized tracking of tissues to the recipients.

The hospital transfusion service has the capacity, experience, and skills to act as a central depot and distribution point for all human tissue and to ensure that storage, issuance, and disposition records are maintained. Functions include allograft selection; vendor qualification and price negotiation; receipt of tissues, including inspection and accessioning; proper storage; inventory control; issuance; and record-keeping, which must ensure traceability to recipient or other final disposition.<sup>106</sup> Record-keeping, especially if barcodes are used in the laboratory, is complicated by the fact that barcodes are not yet standardized among tissue banks, although adoption of ISBT code 128 labeling standards has been suggested.<sup>107</sup> An additional challenge is that some tissues are produced in lots or batches, so each individual unit may not carry a unique identifier as is the case with blood components. Effective development of such tissue storage and distribution services takes time and relies on good relationships and communications with both operating room staff who will handle tissues and the surgeons who use them.<sup>106</sup>

A transfusion service operating as a central tissue repository and dispensing service may also be called upon to manage autologous tissues, such as calvaria (skull bone flaps), bone, skin, and parathyroid gland. Such tissues may require preparation and packaging before storage. Testing is not required, but careful

labeling and record-keeping are essential. Such tissues may ultimately be reimplanted in the original location (such as calvaria) or in a heterotopic location (such as limbs for parathyroid gland). It is prudent to establish time limits for storage either on an individual basis as specified by the surgeon or on a generalized basis, because stored tissues may not be claimed if the tissue was not needed because the patient died or for other reasons. The tissue dispensing service may also be called upon to package tissues in an appropriate, qualified, properly labeled transport container for transport to another institution.<sup>106</sup>

---

## Reimbursement

Reimbursement for tissue transplantation is similar to that for blood transfusion. The tissue bank recovers expenses through a service fee (per tissue) billed to the hospital. This service fee includes such costs as services rendered by the organ/tissue recovery agency; recovery supplies and logistical support of the recovery agent that may be provided by the tissue processor; the tissue processor’s operating costs associated with processing, storage, and distribution, as well as research and development; and overhead costs incurred with support of all operations. Health-care insurance carriers reimburse hospitals for most tissue service fees. Current procedural terminology codes specific to allograft transplantation procedures are available and used routinely.

---

## Oversight

With the rapid growth of all areas of tissue banking, there has been an increasing need for accountability and for measures that ensure that safe, quality tissues are available for clinical use. Quality improvement can be effected through voluntary standards, and most tissue banks have incorporated the achievement of high standards into their goals. The AATB has established comprehensive standards for donor screening, recovery and processing of musculoskeletal, cardiac, vascular, and skin tissues, and reproductive cells.<sup>10</sup> Additionally, the standards contain: institutional requirements; descriptions of required functional components of a tissue bank; requirements for construction and management of records and development of procedures; requirements for informed consent, tissue labeling, storage, and release; expectations for handling adverse outcomes, investigations, and tissue recalls; requirements for establishment of a quality program; specifications for equipment and facilities; and guidelines for tissue dispensing services and tissue distribution intermediaries. AATB’s *Standards for Tissue Banking* are referenced not only by tissue bankers, but also by end-user health-care facilities, other standard-setting organizations, and regulators worldwide. In 2008, 104 tissue banks in North America held AATB accreditation.

AABB *Standards for Blood Banks and Transfusion Services*<sup>105</sup> address tissue inspection (Standards 4.3 and 5.10), handling (Standard 5.1.5), storage (Standard 5.1.8), preparation and

dispensing (Standard 5.15.3), handling adverse events (Standard 7.4.4), and record-keeping, which must provide traceability to each recipient or other disposition (Standards 5.19.6.1, 5.1.6.2, and 6.2.3). The Joint Commission implemented standards for storage and issuance of tissue for hospitals, ambulatory surgery centers, effective July 1, 2005 (Standards PC.17.10, PC.17.20, PC.17.30). These standards apply to bone, tendon, fascia, and cartilage, as well as other cellular tissues of both human and animal (xenograft) origin. The standards address key functions, including the need to develop procedures for tissue acquisition and storage, record-keeping and tracking, and follow-up of adverse events and suspected allograft-caused infections, which must be reported to the tissue bank from which the tissue was obtained. Similar to federal regulations and AATB *Standards*, the minimal record retention period is specified to be 10 years from the date of transplantation, distribution, other disposition, or expiration, whichever is latest. The College of American Pathologists' laboratory accreditation program's transfusion medicine checklist includes several questions on storage and issuance of tissues, including accountability; procedures for proper storage, handling, in accordance with the source facility's directions; procedures for investigating recipient infections and adverse events, and handling look-back notifications from a supplier; and record-keeping, which allow for tracking from donor to recipient and vice versa (TRM.45050 - TRM.45250).

Until recently, large segments of the tissue banking industry have been unregulated by government agencies. A few states, specifically New York, Florida, and California, adopted licensure requirements in the early 1990s. The New York State Department of Health has the most comprehensive oversight program. Beginning in 1991, New York established administrative, licensure, and technical requirements for all entities that collect, process, store, and/or distribute tissue in New York. Currently, 817 tissue banks, including 79 banks that recover and/or process cardiovascular, musculoskeletal, and/or skin tissue from deceased donors; 18 eye banks; 64 semen banks; 39 oocyte-embryo banks; 63 hematopoietic progenitor cell banks; and 84 nontransplant anatomic banks (banks providing bodies, body parts, and tissues for health professional education and medical research), are licensed to operate in New York. New York State regulations extend to the clinical use of tissue, such as physicians' offices where semen is used in artificial insemination and hospitals and ambulatory surgery centers that transplant tissue. Such transplantation services constitute the remainder of licensed tissue banks. A 2001 federal report found, however, that 44% of tissue banks held neither accreditation by a professional organization nor licensure by a state agency.<sup>13</sup>

FDA authority to create and "enforce regulations necessary to prevent the introduction, transmission, or spread of communicable diseases between the States or from foreign countries into the States" under section 361(a) of the US Public Health Service Act (42 USC 264) applies to human tissue intended for transplantation. Formal enforcement policy and regulations did not exist until December 14, 1993 (codified in 21 CFR Parts 16

and 1270), when the "Interim Rule: Human Tissue Intended for Transplantation," which required donor screening, infectious disease testing and record-keeping "to prevent transmission of infectious diseases through human tissue used in transplantation," was adopted in response to reports of HIV transmission by human tissue and of potentially unsafe bone imported into the United States.<sup>108</sup> Reproductive tissue, human milk, and marrow were specifically excluded.

These regulations were supplanted by a series of federal regulations, published in stages, first announced in the Proposed Approach to the Regulation of Cellular and Tissue-Based Products in March 1997.<sup>109</sup> A final rule, "Human Cells, Tissues, and Cellular and Tissue-Based Products: Establishment Registration and Listing," published in January 2001, required organizations that are engaged in tissue recovery, donor qualification, tissue processing, and/or tissue-related laboratory testing to register as a tissue establishment with the FDA. The rule (21 CFR Part 1271) became effective for all tissue banks on March 29, 2004.

A final rule, "Eligibility Determination for Donors of Human Cells, Tissues, and Cellular and Tissue-Based Products," published May 25, 2004, set forth donor eligibility requirements, including health history screening and laboratory testing. Another final rule, "Current Good Tissue Practice for Human Cell, Tissue and Cellular and Tissue-Based Product Establishments; Inspection and Enforcement," published on November 24, 2004, established elements of good tissue practice, analogous to good manufacturing practice for blood banks. Both rules became effective May 25, 2005 (see 21 CFR Parts 1270 and 1271). An interim final rule, published on May 25, 2005 for immediate implementation, made a few technical corrections regarding donor screening and testing and product labeling. Following consideration of comments regarding the interim final rule, the final rule was published on June 19, 2007, but was unchanged from the May 25, 2005 rule (see 21 CFR Parts 1270 and 1271).

In addition to requirements for establishment registration, donor eligibility screening and testing, and good tissue practice, the regulations set forth requirements for adverse reaction reporting and also define inspection and recall authority. To improve tissue safety and surveillance, the FDA Current Good Tissue Practice Rule, effective May 25, 2005, requires that tissue establishments report infectious adverse events after allograft transplantation to the FDA through its MedWatch adverse event reporting system. In fiscal year 2006, the first full year of the requirement, 70 reports were filed by tissue banks; 44 of these reports were flagged to indicate possible recall of tissue(s). Of these flagged reports, the majority (26) pertained to acceptance of ineligible donors for whom one or more components of the donor qualification process was not performed or was insufficiently documented. The FDA also encourages health-care professionals, patients, and consumers to voluntarily report tissue adverse reactions through the MedWatch system (see <http://69.20.19.211/CBER/tissue/hctadverse.htm>). The CDC is currently funding efforts to develop the Transplantation Transmission Sentinel Network, which is intended to facilitate

recognition of adverse events associated with transplanted allografts. The system is being developed by UNOS, in collaboration with several stakeholders, including the AATB, EBAA, Association of Organ Procurement Organizations, American Academy of Orthopaedic Surgeons, American Orthopaedic Society for Sports Medicine, Society of Thoracic Surgeons, HRSA, and FDA.

Adoptive immunotherapy can be defined as the transfer of cellular products with the goal of increasing immunity against cancer or infections. A number of populations have been evaluated in clinical trials including donor leukocyte infusions (DLI) from allogeneic hematopoietic stem cell transplantation (HSCT) donors, activated T-cell population cells, natural killer (NK) cells, and antigen-specific T cells. At present, there is a defined role for adoptive immunotherapy using T-cell approaches in treating relapse of certain malignancies and some types of infection after allogeneic HSCT.<sup>1-5</sup> Extending this modality of treatment to patients with malignancies outside the HSCT setting is theoretically attractive, but successful applications are currently limited to settings where the tumors express immunogenic antigens such as viral antigens. This chapter reviews the current status of adoptive immunotherapy strategies for malignant and infectious diseases in the clinic and current areas of research to improve and extend the applicability of this approach.

### Targets for Immunotherapy for Cancer

A necessary prerequisite for T-cell immunotherapy approaches for cancer is identification of target antigens on the tumor cells. Advances in genomics have facilitated the identification of putative tumor antigens through the use of technologies such as serologic analysis of recombinant cDNA expression libraries and bioinformatics tools to deduce epitopes from candidate genes. However, for a tumor to be susceptible to immunotherapy approaches it must not only contain unique proteins to provide epitopes for targeting by specific immune responses, but must also present these peptides frequently enough and for sufficient duration to engage responder T cells. In addition, either the tumor cell or a specialized antigen-presenting cell through the

process of cross-priming must express major histocompatibility complex (MHC) antigens and express costimulatory molecules such as CD28 to induce T-cell activation.

Potential antigens for targeting tumor cells fall into several major categories (Table 59-1).

#### Alloantigens

In the setting of allogeneic HSCT, alloantigens that differ between donor and recipient are targets for T-cell recognition. Alloantigens include human MHC molecules (in HLA-mismatched transplants) and minor histocompatibility antigens, which are naturally processed peptides derived from normal cellular proteins where different polymorphisms are present in donor and recipient.<sup>18,19</sup> A number of minor histocompatibility antigens have been identified, and recent data showing that responses to donor lymphocyte infusions correlate with increase in immune responses directed against these antigens confirm their importance.<sup>20,21</sup> In some of these cases, alloreactivity also results in graft-vs-host disease (GVHD), but in cases where the minor antigen targeted is selectively expressed on hematopoietic cells, a graft-vs-leukemia (GVL) effect can occur in the absence of GVHD.

#### Virus-Associated Tumor Antigens

Some cancers (eg, subsets of lymphomas and nasopharyngeal carcinomas) are associated with viruses that present unique epitopes that are usually highly immunogenic as targets for a T-cell response. Latent Epstein-Barr virus (EBV) infection is associated with a heterogeneous group of malignant diseases (Fig 59-1) including posttransplant lymphoproliferative disease (PTLD), Hodgkin disease, nasopharyngeal carcinoma, and gastric carcinoma.<sup>4,22,23</sup> The role of EBV in tumorigenesis is well established in the EBV-LPDs that arise in immunosuppressed individuals but is less clear in other EBV-associated malignancies. Nevertheless, the presence of EBV in tumor cells offers a target for immunotherapy approaches. Human herpesvirus-8 (HHV-8) is primarily associated with Kaposi's sarcoma and primary effusion lymphoma in patients with AIDS, but is also found in some solid tumors.<sup>24</sup> Unlike most malignant cells, which

**Table 59-1.** Potential Targets for Immunotherapy of Cancer

**Figure 59-1.** Type of Epstein-Barr-virus (EBV) latency. The three types of EBV latency are defined by the number and type of latent protein expressed on EBV-infected B cells and EBV-positive tumor cells.

probably express small quantities of a single modified peptide as a cytotoxic T lymphocyte (CTL) target, virus-transformed cells may express a range of viral antigens in high copy number. These cells are, therefore, potentially much more susceptible to T-lymphocyte-mediated immunotherapy than tumor cells transformed by other mechanisms.

### Lineage-Specific Antigens

Differentiation antigens selectively expressed in tumor cells provide another potential target. In the context of hematologic malignancies, antigens such as CD19 and CD20 (B-lineage), CD33 (myeloid), and CD30 (expressed on Hodgkin's Reed Sternberg cells) have been successfully targeted with antibody therapy, and preclinical studies have identified peptides that may be targets for T-cell recognition.<sup>25,26</sup>

### Universal Antigens

Several antigens have been identified that are overexpressed in a number of different tumor cells including telomerase and

cytochrome P450 1B1.<sup>15,27</sup> Antigens that are crucial for tumor cell function such as cyclin or other cell cycle genes are other potential targets.<sup>28</sup>

### Cancer Testis Antigens

The cancer testis antigens (CTAs) comprise, to date, 44 families of genes or isoforms. Among these, 19 families are purely testis-restricted, while others are expressed in one or more somatic tissues.<sup>11</sup> The physiologic expression of CTAs within the testis prevents their effective presentation to the immune system; hence, for those expressed only in testis, T-cell tolerance does not appear to be established. Expression of the MAGE-1 CTA was first shown in melanoma, but subsequently, expression of multiple CTAs was demonstrated in a variety of tumors.<sup>11-13</sup> The mechanisms underlying the expression of CTAs are only partially resolved. Epigenetic regulation seems critical and demethylation of CTA promoter sequences has been observed in malignant cells.<sup>11</sup> CTA-specific T cells able to destroy tumor cells were first identified in patients with melanoma, but subsequently were

isolated from patients with a range of tumors<sup>29,30</sup> and have the potential to be used as a target for many cancer immunotherapies.<sup>31,32</sup> For example, NY-ESO-1 is frequently expressed in melanoma and poor prognosis B-cell malignancies and is capable of eliciting spontaneous humoral and T-cell immunity.<sup>30</sup> However, it remains a challenge to expand CTLs specific for such tumor antigens in vitro to the numbers required for clinical use.

## Targets for T-Cell Immunotherapy for Infections

In the setting of immunotherapy for viral or fungal infection, it is also crucial to know which antigens are most important for viral/fungal persistence and thus the best targets for immunotherapy strategies. The viral antigens expressed at different stages of viral infection have been well characterized for some viruses such as cytomegalovirus (CMV) and more recently adenovirus, but are less well defined for other viruses that cause morbidity such as BK virus.<sup>33,34</sup> Most published studies designed to assess the immune response to fungal antigens (eg, *Aspergillus fumigatus*) use crude extracts from mycelia and spores. Numerous recombinant *A. fumigatus* allergens associated with allergic bronchopulmonary aspergillosis have been characterized but most elicit humoral immune responses and others are toxic to peripheral blood mononuclear cells (PBMCs), are strongly homologous to human proteins, or only prime a Th2 T cell response.<sup>35</sup> Therefore it is critical to identify allergens (eg, Asp f2 and Asp f16) that have been shown to stimulate both T- and B-cell responses from patients. Over the past few years, however, antigen identification has been simplified by the availability of tools that have enabled peptide mapping of specific viral and fungal epitopes recognized by CD4+ and CD8+ T cells.<sup>34,36,37</sup>

## Types of Adoptive Immunotherapy

Immunotherapeutic approaches that have been evaluated in the clinic can be broadly divided into studies using 1) nonspecific T cells, 2) antigen-specific T cells, 3) genetically modified T cells, and 4) NK cells.

### Nonspecific T Cells

#### Unmanipulated Allogeneic T Cells (Donor Lymphocyte Infusion)

Perhaps the most successful T-cell immunotherapy to date has been the use of unmanipulated allogeneic DLI following allogeneic HSCT. DLI has been most successful in patients with chronic myeloid leukemia who relapse after transplantation (70%-80% cytogenetic remission rate)<sup>5</sup> or with BBV-LPD (up to 90%).<sup>4,38</sup> Moderate success has been seen when DLI was used after relapse in other malignancies such as: acute myeloid leukemia (15%-40%), low-grade lymphomas (~60%), and metastatic multiple myeloma (40%-60%).<sup>39-42</sup> Less than 5% of patients with relapsed acute lymphoblastic leukemia (ALL) respond to

DLI alone. Although the etiology is unclear, this could be caused by lack of antigenic expression, downregulation of T-cell recognition molecules, and/or overall tumor burden at the time of treatment.

Although treatment with DLI can induce remissions in patients with disease after HSCT, unmanipulated cells also contain alloreactive T cells and can induce GVHD. The incidence of GVHD ranges from 55% to 90% and is associated with a 20% treatment-related mortality rate.<sup>5</sup> Nevertheless, studies evaluating chronic myelogenous leukemia (CML) responses to DLI have found that up to 55% of patients who do not experience GVHD may have a disease response,<sup>43,44</sup> demonstrating that GVL effect can be separated from GVHD. Therefore, one strategy to reduce the risk of GVHD is to infuse escalating doses of T cells in an attempt to obtain the GVL effect without GVHD. Peggs et al<sup>45</sup> conducted a dose escalation study using DLI after HSCT for patients with hematologic malignancies and showed that in sibling transplantation, higher DLI doses were associated with a significantly increased risk of GVHD. In addition GVHD was more common, occurred at lower T-cell doses, and was more severe in the unrelated donor cohort, likely reflecting the increased alloreactivity between donor and recipient.

As another approach to separate GVHD and GVL effect with DLI, investigators have evaluated specific subsets of lymphocytes, such as CD4-selected cells,<sup>46</sup> CD8-depleted cells,<sup>47</sup> or functionally defined subsets such as Th2 cells.<sup>48</sup> In animal models, the culture of functionally defined T-cell subsets, such as Tc2 or Th2 cells, has allowed antitumor effects to be produced in the absence of alloreactivity. A recent Phase I clinical trial<sup>49</sup> at the National Institute of Health (NIH) evaluated the feasibility of infusing donor CD4 Th2 cells generated ex vivo using CD3/CD28 costimulation in the presence of interleukin (IL)-4 and IL-2. The patients had hematologic malignancies and underwent reduced-intensity conditioning regimens before HSCT. The cells were from a matched sibling donor who had undergone granulocyte colony-stimulating factor (G-CSF) mobilization. Nineteen patients received no additional cells, and the remaining 28 received these Th2-like cells in a dose-escalation fashion (5, 25, or 125 × 10<sup>6</sup> cells/kg). The Th2 cohort had accelerated lymphocyte reconstitution with acute GVHD and overall survival similar in both the Th2 and non-Th2 cohorts.<sup>49</sup>

### Allodepleted T Cells

Another approach to overcome the problem of alloreactivity is to selectively deplete the T-cell product of alloreactive cells expressing activation markers in response to alloantigen. Alloreactive cells express activation markers after exposure to alloantigen, including CD69, CD147, and the IL-2 receptor CD25, which is expressed within the first 24 hours of T-cell activation. This approach has been evaluated in three clinical trials using a CD25 immunotoxin to selectively deplete alloreactivity, two involving haploidentical CD34 selected grafts in predominantly pediatric patients and one involving HLA-identical sibling transplants in adults.<sup>50-52</sup> In all studies the approach was feasible and safe

and was able to promote immune reconstitution and recovery of virus-specific immunity without significant GVHD. Further studies to evaluate if there is an antitumor effect are continuing.

### Regulatory T Cells

An alternative option to prevent GvHD is to actively downregulate alloreactive T cells by recruiting regulatory T cells (Treg cells). Treg cells suppress the proliferation of CD4+ and CD8+ T cells after polyclonal or antigenic stimulation in a cell contact-dependent and cytokine-independent manner.<sup>53</sup> If CD4+, CD25+, FoxP3+, Treg cells, which are naturally present in the transplant product, are depleted before infusion into irradiated allogeneic recipient mice, then GVHD is significantly accelerated. Conversely, GVHD can be prevented by the addition of freshly isolated Treg cells to the donor product and of note the GVL effect is spared.<sup>54</sup> Supporting the importance of this effect, studies in humans have shown that a higher frequency of Treg cells in donor cells correlates with a lower risk for developing GVHD. Several groups are now investigating the value of infusing ex-vivo expanded donor Treg cells following HSCT. Many obstacles to the effective implementation of this approach remain, such as the difficulty of using cell sorting to obtain a pure Treg-cell population for infusion, given that FoxP3, the best Treg-cell marker to date, is intracellular.

Ongoing clinical trials using Tregs include the transfer of IL-10-aneurized  $T_H1$  cells to prevent GVHD in patients after HLA-haploidentical HSCT. In one trial,<sup>48</sup> donor PBMCs are thawed and cultured ex vivo in the presence of irradiated host PBMCs (obtained before HSCT) and IL-10. These IL-10-aneurized donor T cells are then infused at increasing doses starting from  $10^5$  per kg.<sup>55</sup> The first clinical trial with Treg cells is ongoing in Regensburg, Germany.<sup>56,57</sup> In this study, cancer patients with a high risk of relapse after allogeneic HSCT receive a preemptive DLI after stopping immune suppressive therapy and then 8 to 10 weeks later receive between  $1 \times 10^6$  and  $5 \times 10^6$  freshly isolated donor CD4+/CD25+ Treg cells/ kg of body weight followed by DLI of equal T-cell numbers. In the first five patients sufficient numbers of donor Treg cells were obtained and no toxicities (eg, GVHD, infection, and relapse) were seen.<sup>55</sup> This trial and others that are planned will provide critical information regarding the ex-vivo expansion of Treg cells and on the feasibility and safety using unmanipulated Treg cells for adoptive immunotherapy.

### Autologous Nonspecifically Expanded T Cells

Over the past few years several studies have correlated faster recovery of lymphocyte counts with improved outcome after autologous transplant for some malignancies.<sup>58,59</sup> To determine if T-cell recovery after autografting can be accelerated, June and colleagues have administered T cells expanded ex vivo using anti-CD3 and anti-CD28 to patients with myeloma and non-Hodgkin lymphoma (NHL) after autografting and showed rapid reconstitution of lymphocytes.<sup>60,61</sup> In the myeloma study,<sup>61</sup> immunotherapy was combined with vaccination and a single, early, posttransplant infusion of in-vivo vaccine-primed and

ex-vivo-costimulated autologous T cells. This treatment was followed by posttransplant booster immunizations, which led to the rapid induction of clinically relevant immunity as well as improved T-cell proliferation in response to antigens that were not contained in the vaccine.<sup>61</sup> These results show that adoptive transfer of autologous CD3/CD28-stimulated T cells is feasible and safe and that the combination of vaccine therapy and adoptive T-cell transfer leads to enhanced memory T-cell responses. Follow-up studies are evaluating effects on tumor responses.<sup>62</sup>

Another autologous ex-vivo expanded immunotherapy product that has been evaluated in the clinic is cytokine-induced killer (CIK) cells, a unique population of CTLs with a characteristic CD3+ CD56+ phenotype. In a clinical study, patients with relapsed NHL or Hodgkin disease were treated with escalating doses of autologous CIK cells generated by culturing apheresis products with interferon- $\gamma$ , OKT3, and IL-2.<sup>63</sup> No significant toxicity was seen and there were partial responses and disease stabilizations.<sup>63</sup> Because these were heavily pretreated patients who had all relapsed after transplantation, this approach may have greater activity in a setting of minimal residual disease.

### Antigen-Specific T-Cell Therapies

The use of antigen-specific CTLs may overcome the problem of alloreactivity and may also allow expansion of low-frequency cells. To generate these cells ex vivo requires a defined antigen and an antigen-presenting cell that can effectively present the antigen to T cells with appropriate costimulatory signals. Therefore, it is a significant challenge to generate T cells specific for tumor antigens if the malignant cell presents antigen poorly, and the putative target antigens are weak. However, proof of principle has been shown by studies administering donor-derived CTLs specific for viral antigens to reconstitute immunity following HSCT.

### EBV-Specific Cytotoxic T Cells

Immunotherapeutic strategies aimed at targeting EBV have now been used for over 15 years. All EBV-associated malignancies are associated with the virus' latent cycle, and three distinct types of EBV latency have been characterized<sup>64,65</sup> with varying expression of EBV latent proteins (Fig 59-1). Latency Type III is expressed in lymphoblastoid cell lines (LCLs), which can be readily produced by infecting B cells in vitro with EBV and is characterized by expression of the entire array of nine EBV latency proteins. This pattern of EBV gene expression characterizes the EBV-LPD that occur in individuals severely immunocompromised by solid-organ or stem cell transplantation, congenital immunodeficiency or human immunodeficiency virus (HIV) infection. Latency Type II is the hallmark of EBV-positive Hodgkin disease where a more restricted array of proteins including EBNA1, BARF0, LMP1, and LMP2 are expressed. In latency Type I, found in EBV-positive Burkitt lymphoma only EBNA1 and BARF0 are expressed. Because EBNA1 is not well processed by the Class I processing machinery,<sup>66</sup> tumor cells expressing Type I latency may not be a good target for immunotherapy approaches. However,

**Figure 59-2.** Generation of Epstein-Barr virus (EBV)-specific cytotoxic T lymphocytes.

Step 1: Peripheral blood mononuclear cells (PBMCs) are infected with a laboratory strain of EBV (B95.8) to generate an EBV-transformed B lymphoblastoid cell line (LCL).

Step 2: Irradiated LCLs are antigen-presenting cells to stimulate T cells specific for EBV at an effector to target (E:T) ratio of 40:1.

Step 3: The EBV-specific cytotoxic T lymphocytes (CTLs) are stimulated with irradiated LCL at weekly intervals at an E:T ratio of 4:1 starting from Day 10. Interleukin (IL)-2 at 50-100 U/mL is added twice weekly to the cultures from Day 12. The stimulations with LCL and IL-2 is continued until sufficient numbers of T cells have been expanded.

Step 4: CTLs are frozen and undergo extensive quality assurance/quality control (QA/QC) including HLA typing, phenotyping, assessment of HLA type, phenotype, and cytolytic function before being released for clinical use.

immunotherapy approaches targeting EBV antigens do have potential for treating Type II and Type III latency EBV tumors.

#### **EBV-Associated Lymphoma after Transplantation**

Risk factors for development of EBV-PTLD include the degree of mismatch between donor and recipient, manipulation of the graft to deplete T cells, and the degree of immunosuppression used to prevent GVHD.<sup>4</sup> EBV-associated PTLD arising after marrow transplantation is an ideal model to evaluate the ability of T cells to target EBV-positive tumor cells because these tumors are highly immunogenic expressing all nine latent cycle EBV antigens, including the immunodominant EBNA3 antigens. Furthermore, the outgrowing EBV-infected B-cell tumors have the same phenotype and pattern of EBV gene expression as do LCLs, which are an excellent antigen-presenting cell (Fig 59-1).

EBV-specific T cells can be generated in vitro using donor lymphocytes infected with a laboratory strain of EBV to initiate an LCL line that is an excellent antigen-presenting cell for presenting viral antigens. Irradiated LCLs are used to stimulate PBMCs and expand EBV-specific CTLs (Fig 59-2). EBV-specific T-cell lines have been used as prophylaxis for EBV-induced lymphoma in over 60 patients after HSCT who underwent a

T-cell-depleted HSCT or who were transplanted for an EBV-associated malignancy<sup>4,6,67</sup> and none of the patients treated with this approach developed PTLD, compared with an incidence of 11.5% in a historical nontreated control group.<sup>6</sup> These results have been confirmed by another group.<sup>68</sup> (See Table 59-2.)

Immunotherapy using EBV-CTL has also been used to treat patients with overt lymphoma. This strategy was successful in five of six patients and showed by gene marking that CTL accumulated at sites of disease.<sup>6</sup> Other groups have also obtained encouraging response rates<sup>38,72</sup> including one study in patients who had recurrent PTLD after initial therapy with rituximab.<sup>75</sup> In another study, one patient who received CTL as treatment died with progressive disease 24 days after infusion.<sup>76</sup> In this patient, the cytolytic activity of the generated CTL line was directed mainly against two HLA-11-restricted epitopes in the EBNA3b gene. However, after CTL infusion only virus with an EBNA3b deletion could be detected, allowing the tumor to evade the immune response.<sup>76</sup> This experience suggests that it is preferable to infuse a product with broad specificity.

In recipients of solid-organ transplants, the severe impairment of T-cell function as result of the required immunosuppressive regimen after transplantation also places these patients at risk

EBV = Epstein-Barr virus; HSCT = hematopoietic stem cell transplantation; CR = complete response; ATG = antithymocyte globulin.

for the development of PTLD with incidence dependent of the type of organ transplanted and the degree of immunosuppression. Because reducing immunosuppression can often control LPD, administration of EBV-specific CTLs might be an alternate means of restoring the immune response. In this clinical scenario, the organ donor is not HLA-matched and often is not available, and the tumor often arises from recipient cells. Therefore, most studies in solid-organ recipients have used autologous CTLs generated from peripheral blood of transplant recipients.<sup>77-79</sup> The results of these studies are summarized in Table 59-3. These studies have shown that the approach is safe and that EBV-specific immunity can be transiently restored. However, the persistence of CTLs is less than that observed after HSCT transplantation, perhaps because of the continuing immunosuppression that these patients receive to prevent rejection.

An alternative approach is to use closely matched allogeneic EBV-specific CTLs. A Phase II clinical trial has evaluated this

strategy in HSCT and solid-organ recipients who had failed to respond to conventional PTLD therapy. Response rates were 64% and 52% at 5 weeks and 6 months, respectively.<sup>73</sup> Patients with closer HLA matching donors showed better responses at 6 months.

### **EBV-Associated Type II Latency Tumors**

EBV-associated nasopharyngeal carcinoma, Hodgkin disease, and NHL that develop in the immune competent host show Type II latency where viral gene expression is limited to the immunosubdominant latent membrane protein (LMP)1 and LMP2, EBNA1, and EBERs,<sup>85</sup> which are weak targets for CTL activity. Nevertheless, these subdominant EBV antigens are potential targets for immunotherapy approaches. Phase I dose-escalation studies have evaluated the use of autologous EBV-specific CTL for patients with EBV-positive Hodgkin disease or nasopharyngeal carcinoma.<sup>7,86</sup> The Hodgkin disease study involved

| Haque et al <sup>73</sup>    | 31              | Heart, liver, kidney, lung, small bowel   | Yes                                | Closely matched allogeneic EBV specific CTL | At 6 months after CTL: 12 CR, 3 PR, and 16 persisting/ progressive PTLD |

EBV = Epstein-Barr virus; CR = complete response; PR = partial response.

14 treated patients, of whom seven received gene-marked CTLs. The infused CTLs expanded *in vivo*, persisted up to 12 months and trafficked to tumor sites.<sup>7</sup> EBV-CTLs were well tolerated, and had some antitumor activity with five patients (two treated with active disease) remaining in complete remission up to 40 months, one having a partial response, and five having stable disease. Lucas and colleagues also saw activity using EBV-CTL from partially HLA-matched normal donors.<sup>87</sup> Five of six patients with Hodgkin disease had reductions in measurable disease and the maximal duration of response was 22 months.<sup>87</sup>

EBV-CTLs have been administered to 10 patients with EBV-positive nasopharyngeal carcinoma who were in relapse or who had high-risk disease.<sup>86</sup> The four patients with high risk disease remain in remission after treatment and two of the six patients in relapse entered complete remission and remained disease free 24 to 42 months after CTL infusion.<sup>86</sup> Comoli et al<sup>88</sup> also treated 10 patients with relapsed disease and saw responses in six—two with partial responses and four with stable disease.

Although these results using EBV-specific CTL in Type II latency tumors have shown some activity (Table 59-4), the response rate is less impressive than that seen in EBV-LPD after HSCT. Moreover, apart from the patients with relatively low tumor burden who have demonstrated durable responses, the majority of the antitumor responses have been transient, and no patient with aggressive, bulky relapsed disease has been cured by CTL therapy alone. This may be due to a lack of specificity of the EBV-specific CTLs for the immunosubdominant LMP1 and LMP2 antigens present on the Type II latency tumor (Fig 59-1).

A follow-up study has shown that LMP2-CTLs could be generated from normal donors using dendritic cells genetically modified with a recombinant adenovirus encoding

LMP2 (Ad5LMP2). for the initial stimulation, followed by stimulation with LCL that had been genetically modified to overexpress LMP2a or LMP1 and LMP2 by transduction with an Ad5f35LMP2a vector or a Ad5f35LMP1-I-LMP2 vector, respectively.<sup>91</sup> LMP2-specific CTL lines using this methodology were administered to 16 patients with EBV+ve Hodgkin disease or EBV-positive B-cell or T/NK-cell NHL.<sup>89</sup> The LMP2-specific CTLs expanded and persisted *in vivo* without adverse effects. Nine of 10 patients treated in remission of high-risk disease remain in remission, and four of six patients with active relapsed disease had a complete response.<sup>89</sup> These studies are being extended using autologous T cells enriched for both LMP1 and LMP2 for the treatment of EBV-positive lymphoma and nasopharyngeal carcinoma.

### CMV-Specific Cytotoxic T Cells

Inability to control CMV reactivation following allogeneic HSCT is caused not only by low antigen-specific T-cell numbers but also by impairment of the T-cell function *in vivo*.<sup>92</sup> CMV prophylaxis and treatment with adoptively transferred, donor-derived CMV-specific CTLs has been successfully used with CMV-specific CD8+ clones or polyclonal CTL lines (Table 59-5). In the first study from Riddell and colleagues, CMV-specific T-cell clones were derived from sibling donors after stimulation with autologous fibroblasts pulsed with CMV.<sup>2,99</sup> There were no adverse effects and CMV-specific immune responses were reconstituted, although long-term persistence of infused CTLs was seen only in recipients who developed recovery of CD4+ CMV-specific T-cell responses. Other groups have also reported successful reconstitution of immunity to CMV by administering CMV-specific CTLs generated by stimulation of PBMCs with

EBV = Epstein-Barr virus; HD = Hodgkin disease; NHL = non-Hodgkin disease; HIV = human immunodeficiency virus; CR = complete response; CRU = complete response unconfirmed; PR = partial response; NR = no response; SD = stable disease; HSCT = hematopoietic stem cell transplantation; NPC = nasopharyngeal carcinoma.

dendritic cells pulsed with CMV antigens<sup>100</sup> or the HLA-A2-restricted peptide NLV derived from the CMV-pp65 protein.<sup>101</sup> CMV-specific CTLs have also been used therapeutically with encouraging results.<sup>93</sup> These methodologies for generating CMV-specific CTLs all require prolonged ex-vivo activation and expansion. To overcome this problem a recent study used tetramer selection of CMV peptide-specific T cells directly from peripheral blood and relied on expansion in vivo after adoptive transfer. Infused CD8+ T cells expanded by several logs after infusion, and cleared CMV infection in eight of nine cases.<sup>97</sup>

### Adenovirus-Specific T Cells

Another alternative to expand virus-specific T cells is to stimulate T cells with the infectious antigen of interest and then “capture” the responding cell that is producing effector cytokines such as interferon- $\gamma$ . This strategy has been used to isolate adenovirus-specific CTLs for clinical use. Cells were incubated with adenovirus lysate in vitro to produce CD4+ and CD8+ T cells that were highly specific for adenovirus and exhibited markedly reduced alloreactivity. Feuchtinger et al<sup>102</sup> infused adenovirus-specific CTLs generated using this approach into nine pediatric patients with systemic adenovirus infection following allogeneic HSCT. All patients tolerated the infusions, and they exhibited a dose-dependent and sustained in-vivo expansion of adenovirus-specific CTLs associated with clearance or decrease in viral load in five of six evaluable patients.<sup>102</sup> Only one patient developed acute exacerbation of chronic GVHD. The efficacy was independent of T-cell dose, implying in-vivo expansion in the presence of active viremia from even low numbers of transferred cells.

### Trivirus-Specific CTLs

Because it would be preferable to target more than one virus, methods have been developed to generate multivirus-specific CTLs for adoptive immunotherapy. The initial focus was on CMV, EBV, and adenovirus as common viral reactivations seen in the posttransplant period. Trivirus-specific T cells were reactivated by using mononuclear cells transduced with a recombinant adenoviral vector encoding the CMV antigen pp65 for the first stimulation followed by subsequent stimulations with EBV-LCLs transduced with the same vector. The resulting CTLs had specificity for all three viruses and were administered to 10 HSCT recipients.<sup>74</sup> After adoptive transfer there was recovery of immunity to CMV and EBV in all patients, but adenovirus-specific T cells were detected only in recipients who had evidence of adenovirus infection pre-infusion. Reactivations or infections with all three viruses were cleared. This approach is being extended to additional pathogens.

### Fungal-Specific T Cells

Although profound neutropenia following HSCT remains an important risk factor for opportunistic invasive fungal infections, most cases arise after neutrophil recovery in the context of potent immunosuppressive therapy for GVHD prevention or treatment. Perruccio et al recently detailed the results of the first use of *Aspergillus*-specific adoptive therapy following HSCT.<sup>103</sup> Ten patients with *Aspergillus* pneumonia and positive galactomannan antigenemia were treated with *Aspergillus*- and CMV-specific donor-derived T-cell clones. In all, galactomannan antigenemia decreased to normal within 6 weeks, with nine patients clearing the *Aspergillus* infection.<sup>103</sup>

### Tumor-Specific T Cells

Clinical immunotherapy targeting nonviral antigens is challenging especially when considering adoptive immunotherapy for malignant disease. Many of these tumor antigens are self antigens, and as a result of self-tolerance mechanisms, CTLs against these antigens are of low frequency, have low T-cell receptor avidity, or are anergic. In the allogeneic setting, preclinical studies have shown that it is possible to generate leukemia-specific CTLs using dendritic cells as antigen-presenting cells.<sup>104</sup> A report has detailed a patient with relapse CML who attained complete remission following infusion of leukemia-specific CTLs generated from the original allogeneic stem cell donor.<sup>105</sup>

In the autologous setting, dendritic cells pulsed with defined tumor peptide epitopes have been used as antigen-presenting cells. With this approach, CD8+ CTLs specific for the melanocyte differentiation antigens, Melan-A and gp100 peptides, could be generated from the PBMCs of HLA-A2-positive patients.<sup>106,107</sup> In 10 patients with metastatic melanoma who received autologous CTLs in conjunction with low-dose IL-2, three had mixed

responses and five had stable disease. The *HLA-A\*0201* melanoma line pulsed with Melan-A peptide analogue could also be used successfully as an antigen-presenting cell, obviating the need to generate dendritic cells from individual patients. In this study,<sup>108</sup> 10 patients with metastatic melanoma were infused with Melan-A specific CTLs followed by exogenous IL-2 and interferon-α. One achieved complete remission, three had partial or mixed responses, and three had stable disease. Limitations of this approach are that CTLs generated from peptide-pulsed antigen-presenting cells are predominantly, if not exclusively, CD8+ and that targeting a single peptide epitope increases the potential for tumor escape.

An alternative strategy, that circumvents some of the concerns regarding peptide pulsing, is to generate tumor-infiltrating lymphocytes (TILs), which can be screened for recognition of melanoma cells using an interferon-γ secretion assay, and then expanded with OKT3. Such TIL lines usually contain both CD4+ and CD8+ T cells and can be shown to have specificity for MART-1 or gp100 epitopes.<sup>109,110</sup> Clinical trials using TIL and high-dose IL-2 in nonlymphocyte-depleted patients resulted

in objective responses in roughly a third of patients with most responses being transient.<sup>111</sup>

## Genetically Modified T Cells

### T Cells Transduced with $\alpha\beta$ -T-Cell Receptor

An alternative strategy to target weakly immunogenic tumor antigen is to alter the antigen specificity of T cells by gene modification. T cells can be transduced with genes encoding a different antigen receptor: either physiologic  $\alpha\beta$ -T-cell receptor (TCR) heterodimers or artificial chimeric T-cell receptors.<sup>112,113</sup>

Several  $\alpha\beta$ -TCR heterodimers specific for tumor antigens have been cloned, either from autologous CTL culture<sup>114,115</sup> or from an *HLA-A\*0201* transgenic mouse model whereby high-avidity murine TCRs can be cloned.<sup>116,117</sup> These include the TCR recognizing MART-1 and gp100 melanoma/melanocyte differentiation antigens, the NY-ESO-1 CTA, and a p53 epitope expressed on approximately 50% of cancers of common epithelial origin.<sup>118</sup> Although some inefficiency from heterologous pairing between endogenous and transduced TCR chains is expected, primary T cells transduced with cloned  $\alpha$  and  $\beta$  TCR chains do mediate anti-tumor activity *in vitro*.<sup>114,116-118</sup> To investigate the anti-tumor ability of genetically engineered T cells *in vivo*, one group administered peripheral blood lymphocytes transduced with the genes encoding the alpha and beta chains of the anti-MART-1 TCR. After transduction, approximately 30% of the CD8+ T cells expressed the  $\alpha\beta$ -TCR heterodimer specific for MART-1. The genetically modified T cells were administered to 15 patients with metastatic melanoma and persistence of the T cells was seen in all patients for  $\geq 2$  months after infusion. Two of the 15 patients had anti-tumor responses and in both patients the T cells were still detected in the peripheral blood at 1 year after infusion. This study suggested that T cells expressing  $\alpha\beta$ -TCR heterodimers specific for tumor antigens may have therapeutic potential *in vivo*.<sup>118</sup> However, the main drawback of cloned TCR is HLA-restriction which limits its use to a subset of patients with particular HLA type.

### T Cells Transduced with Chimeric Antigen

Another strategy for the generation of tumor-specific T cells is the transduction of T cells with chimeric surface proteins that transmit TCR signals in response to target cells. Such proteins are composed of an extracellular domain (ectodomain) usually derived from immunoglobulin variable chains, which recognizes and binds target antigen. This domain is attached via a spacer to an intracytoplasmic signaling domain (endodomain) usually the cytoplasmic segment of TCR- $\zeta$  chain, which transmits an activation signal to the T cell. Genetic engineering of CTLs for redirected CD30-, kappa-, CD20-, and CD19-specific target cell recognition has been achieved and these approaches are in the process of being translated to the clinic.<sup>9,119-121</sup> However, chimeric receptor signaling produces only limited activation of the T cells, and clinical trials in patients with solid tumors have shown that T cells expressing transgenic antigen-specific chimeric

receptors have limited therapeutic activity, in part because engagement of the chimeric receptor alone is insufficient to sustain T-cell growth and activation.<sup>122</sup> One means of solving this problem is to transduce antigen-specific T cells rather than non-specifically activated cells and take advantage of the costimulation provided to the native TCR by antigen. This approach has been evaluated *in vitro* using CTLs specific for EBV, CMV, and influenza.<sup>123-125</sup> An alternate strategy is to provide additional costimulatory signals, and the signaling domain of the TCR has been combined with specific endodomains derived from different costimulatory molecules including CD28, 4-1BB, or OX40.<sup>126-128</sup>

### T Cells Transduced with Suicide Genes

As discussed above, the infusion of an unmanipulated T-cell product will contain alloreactive cells able to induce GVHD. One means of reducing this risk is to transduce the donor T cells with a suicide gene that can be activated if the recipient develops GVHD. The most commonly used suicide gene is herpes simplex virus thymidine kinase (HSV-TK) that renders transduced T cells sensitive to the cytotoxic effects of ganciclovir. HSV-TK-transduced T cells have been evaluated in several clinical trials<sup>129-131</sup> that have shown that GVHD can be effectively controlled by ganciclovir-induced elimination of the transduced T cells. However, the thymidine kinase suicide gene is virus derived and potentially immunogenic<sup>132</sup>; therefore, new nonimmunogenic suicide genes based on inducible Fas and caspase 9 have been developed.<sup>133-135</sup> In these constructs the Fas and caspase 9 molecules have been fused to a human FK506 binding protein to allow conditional dimerization. In both *in-vitro* and *in-vivo* studies, T cells stably transduced with a retroviral vector coding for the dimerizable gene can be selectively eliminated after the exposure to a chemical inducer of dimerization.<sup>133,135</sup>

## NK Cells

NK cells are effectors from the innate immune system that also mediate antiviral and antitumor immunity.<sup>136</sup> Unlike T cells, NK cells do not undergo clonotypic gene rearrangement in order to express antigen receptors. Through a complex array of receptors they are able to determine non-self from self. There are several classes of receptors, including killer immunoglobulin-like receptors. NK-cell receptors may be activating or inhibitory so that NK-cell activity is regulated by quantitative differences in cumulative inhibitory and activating signals. The presence or absence of the respective ligands on recipient cells determines if NK cells will be primed to kill the targets.<sup>137</sup> In the clinical setting of mismatched HSCT, donor vs recipient NK-cell alloreactivity has been associated with better outcome, particularly in patients with acute myeloid leukemia who undergo transplantation while in remission.<sup>138</sup> Several immunotherapy approaches using NK cells have been tested in the clinic and recent studies have shown that haploidentical NK cells infused after lymphocyte depleting chemotherapy can have antitumor effects.<sup>139</sup>

## Improving Cellular Immunotherapy Approaches

### Improving Ex-Vivo Generation

One of the limitations of adoptive immunotherapy is the time taken to generate sufficient numbers of antigen-presenting cells to generate antigen-specific CTLs. Several groups have evaluated if artificial antigen-presenting cells can serve as a substitute. A number of approaches have been used including grafting ligands for the TCR and costimulatory surface molecules onto mouse fibroblasts or beads.<sup>62,140,141</sup> A second limitation is suboptimal persistence of infused cells and several investigators have attempted to identify the optimal phenotype of infused T cells. It is likely that a product containing both CD4 and CD 8 cells and both effector and memory cells will be required.<sup>142-144</sup> It is therefore important to correlate in vivo function with the source of antigen-presenting cells and T-cell culture conditions.

### Lymphocyte Depletion to Improve Expansion of T Cells In Vivo

As discussed above, outside the setting of HSCT, poor lymphocyte survival or function has been a frequent limitation in immunotherapy studies. Several groups have evaluated whether administration of lymphocyte-depleting chemotherapy such as fludarabine or monoclonal antibodies may induce an environment that would promote the homeostatic expansion of infused T cells.<sup>109,145</sup> This strategy may also have a second benefit by depleting Treg cells. Clinical studies have already shown expansion of T cells specific for antigens expressed on solid tumors after lymphocyte depletion.<sup>146</sup>

### Genetic Modification of T Cells to Overcome Tumor Evasion Mechanisms

Tumor cells evade a transferred T-cell response by several mechanisms such as downregulation of MHC and costimulatory molecules and secretion of inhibitory cytokines by the malignant cell population.<sup>147</sup> One cytokine, which has devastating effects on CTL proliferation and function, is transforming growth factor-beta (TGF $\beta$ ), which is secreted by a wide variety of tumors as a powerful mechanism by which the tumor cells can escape the immune response.<sup>148,149</sup> The importance of this mechanism is illustrated by the observation that transgenic mice genetically engineered so their T cells are insensitive to TGF signaling are able to eradicate tumors.<sup>150</sup> Moreover, adoptive transfer of T cells transduced with a dominant-negative TGF $\beta$  Type II receptor (DNR) resulted in eradication of tumor cells.<sup>151</sup> Human in-vitro studies have shown that that DNR-transduced CTL were resistant to the antiproliferative effects of recombinant TGF $\beta$  and long-term expression of this construct had no deleterious effects on the function, phenotype, or growth characteristics of the transduced-CTL lines.<sup>152</sup> CTL expressing the DNR may, therefore, have a selective advantage in vivo in patients with TGF $\beta$ -secreting tumors. A study to test this hypothesis will open

shortly now that in-vivo safety studies in a murine model have been completed.<sup>153</sup>

## Regulatory Considerations for Adoptive Immunotherapy

In the United States, human cells, tissues, cellular and tissue-based products (HCT/Ps) that have been more than minimally manipulated (cultured ex vivo, transduced or activated ex vivo) are referred to as Type 351 products and must be prepared under good manufacturing practice (GMP) regulations to ensure their safety, purity, and potency. In cellular therapy, guidance from the Food and Drug Administration show GMP as a continuum, so that as an approach moves through Phase I and II clinical trials the application of GMP will become more rigorous, until in a Phase III study manufacture would be a fully validated process. A Phase III product would also need validated release criteria, which are test specifications designed to ensure that the product is sterile and pure, and has the desired functionality. In the United States new good tissue practice (GTP) regulations came into effect in May 2005 to cover HCT/Ps that were minimally manipulated (eg, were not cultured ex vivo, genetically modified, activated ex vivo, etc), and that were intended for autologous use, or use in a first- or second-degree blood relative. Cellular products that fall into this classification are referred to as Type 361 products and require manufacturing of the product under GTP regulations. In general, these cover personnel, procedures, facilities, environmental control and monitoring, equipment, supplies and reagents, recovery, processing and process controls, process changes, process validation, labeling controls, storage receipt, predistribution shipment and distribution, records, tracking, and complaints.

Implementation of the components of either GMP or GTP is a time-consuming and labor-intensive process that requires the development, implementation, and maintenance of numerous components. Professional societies, such as the Foundation for the Accreditation of Cellular Therapy and AABB have developed an accreditation process that takes into account GTP regulations and provides a framework around which compliance can be built. Both organizations have developed standards that are harmonized with regulatory requirements, so that accreditation by either organization assists with regulatory compliance.

The challenge of bringing adoptive cellular therapy protocols from the laboratory bench to the bedside has also been recognized by funding agencies, and the NIH has designated specialized centers for product assistance to provide consulting, manufacturing, and regulatory support to other research centers.<sup>154</sup>

## Conclusions

T-cell therapies have produced definitive benefits in the treatment of relapsed leukemia and lymphoma after transplantation

and EBV-associated malignancy. However, clinical studies have also identified limitations of such therapies including inadequate persistence or expansion. With increased knowledge of the optimal methods for generation of T-cell products, identification of additional antigen targets, and optimization of gene therapy approaches to enhance the function of adoptively transferred, adoptive immunotherapy strategies may find broader indications in the therapy of cancer and infections.

Gene therapy, the use of DNA that encodes or corrects a gene for medical therapy, is achieved by transfer of genetic material to a patient's cells. Gene therapy can be achieved by repairing the defect of the endogenous gene (called targeting a gene) or by introducing additional genetic material into the genome. The specific manner by which gene therapy is performed varies significantly based on the disease to be treated, the gene to be inserted, the target cells of insertion, the vector used to transmit the gene, and the route of administration of the gene. This chapter discusses these variables as well as the current successes and challenges in the field of gene therapy.

Some of the many potential diseases that may be treated using gene therapy are listed in Table 60-1. It is hoped that the target diseases for gene therapy will eventually include most serious diseases for which the molecular etiology is well understood. Gene therapy may prove useful for gene replacement for congenital enzyme deficiencies or gene abnormalities. For treatment of cancer, gene therapy may be used to induce selective cancer cell death. Alternatively, cancer treatment could be achieved by using gene therapy to replace a missing tumor suppressor gene, to insert a chemotherapy drug-resistance gene selectively into normal cells, or to enhance the immunogenicity of cancer cells. It is also hoped that gene therapy will be developed to treat infectious diseases such as AIDS.

### Gene Therapy and Transfusion Medicine

Transfusion medicine is the science of administering cells or other biologic materials (eg, serum, isolated clotting factors) to treat patients. The growing field of gene therapy has affected transfusion medicine on several levels. First, gene therapy is introducing new biologicals for transfusion in the clinic setting. Gene therapy falls within the purview of transfusion medicine

**Table 60-1.** Diseases that May Be Treated Using Gene Therapy

| Disease Type             | Examples of Diseases                   |
|--------------------------|----------------------------------------|
| Gene deficiency/mutation | Hemophilia                             |
|                          | Cystic fibrosis                        |
|                          | Thalassemia                            |
|                          | Severe combined immunodeficiency       |
|                          | Gaucher's disease                      |
|                          | Sickle cell anemia                     |
| Cancer                   | Lack/mutation of tumor suppressor gene |
| Autoimmune diseases      | Rheumatoid arthritis                   |
| Infections               | AIDS                                   |

because it often requires the infusion of either gene-modified cells or direct administration of vectors that contain the therapeutic gene. As with blood components, the safety and efficiency of gene therapy agents must be optimized. Therefore, as gene therapy strategies are found to be effective in preclinical studies, quality control and infection control measures need to be developed for the clinical laboratory.

Second, hematopoietic cells are excellent targets for gene therapy trials. They are easily accessed and may be incubated ex vivo with the vectors containing the genetic repair material. Autologous marrow or peripheral blood stem cell (PBSC) transplantation already provides a relatively safe standard of care for some malignancies, and the circulation of these cells suggests that hematopoietic cells may be used as gene delivery systems even for nonhematologic diseases. Ideally, one needs only to infect the "stem" cells in order to get large-scale amplification and long-term expression of a transgene.

Third, gene therapy strategies are under development to treat several diseases that directly affect transfusion medicine, including hemoglobinopathies and clotting factor disorders. For example, hemophilia A, in which patients lack expression of functional clotting Factor VIII, is likely to be one of the first diseases to be treated successfully with gene therapy. This is because

functional Factor VIII protein product can be produced by any cells in the body, not necessarily the normal site of production in the liver, as long as the protein is secreted into the circulation. Also, the levels of circulating Factor VIII that are necessary for therapeutic efficacy need not be highly regulated as long as there is at least 5% of the normal physiologic level present.

## Vector Design

The many aspects that go into designing an ideal gene therapy vector are based largely on the specific disease to be treated, the target cells, and the therapeutic strategy. Three major considerations are which gene to insert, which vector to use, and how to administer the vector.

### What Gene Should Be Inserted and Where Should It Be Inserted into the Genome?

Based on the disease to be treated, the gene that will be inserted can confer a variety of attributes. The gene can provide a functional form of a missing or defective gene, it can be a gene designed to give the cell in which it is expressed a survival advantage, or it can act as a suicide gene designed to kill the cell in which it is expressed. See Table 60-2 for examples of each of these gene insertion strategies. For inherited diseases in which there is a nonfunctional gene product, such as cystic fibrosis, gene therapy approaches are being taken to add a functional gene. Similarly, for inherited diseases in which a gene is missing, such as thalassemia, the gene for the fully functional protein product is inserted. For cancer, the genes to be inserted can take one of several different forms. For example, one could insert a suicide gene selectively into the cancer cells. An example of one such “suicide” gene is HSV-TK (herpes simplex virus thymidine kinase), which can phosphorylate ganciclovir, which is then incorporated into the DNA, preventing its replication and thereby killing the cell. Alternatively, one could replace a missing or mutated p53 gene

with the wild-type gene, which could restore normal apoptotic (cell death) machinery to the cell.

In addition to determining which gene to administer, gene regulatory elements must be inserted in order to achieve appropriate gene expression levels. The process by which a gene is transcribed into messenger RNA (mRNA) and then translated into protein is controlled at multiple levels. For some therapeutic genes, the level of expression does not need to be highly regulated (eg, circulating level of clotting Factor VIII in hemophilia or adenosine deaminase levels). In contrast, other therapeutic genes, if expressed at either too high or too low a concentration, could be deleterious (eg,  $\beta$ -globin). If diabetes is going to be treatable by gene therapy, then insulin must be produced in response to elevated circulating glucose levels and reduced when the glucose level falls below normal levels. Every cell type in the body, although containing the same genomic DNA, presents a different pattern of gene expression. This process is controlled at multiple levels, the most common of which is transcriptional control by gene promoters, enhancers, and silencers in the specific context of a cell's nucleus. Promoters that are used only in specific cell types (eg, the insulin promoter in pancreatic cells) are referred to as cell-type-specific or tissue-specific promoters. Research has been focused on designing the regulatory domains of the transgenes (the promoters) so that the gene is either regulated as it would normally be in the cell with a tissue specific promoter, or regulated by an inducible promoter.

Another level of control for gene expression is to design gene therapy vectors that affect only specific target cells, so that the transgene is not expressed inappropriately in the body, and is not expressed by cells in which it would be deleterious. In the last few years, control of where a gene therapy vector may integrate in the genome has grown more critical. For example, in the case of recent clinical trials in X-linked immunodeficiency, discussed in further detail below, the therapeutic retroviruses integrated into a region of the genome, where they led to activation of proto-oncogenes that caused the patients to have leukemia. In addition the genome architecture adjacent to the proviral

**Table 60-2.** Genes Targeted in Gene Therapy to Date

| Gene Type                                | Disease                                                        | Gene                                                              | Target Cell                  |
|------------------------------------------|----------------------------------------------------------------|-------------------------------------------------------------------|------------------------------|
| Replacement of missing or defective gene | Thalassemia                                                    | $\beta$ -globin                                                   | Hematopoietic stem cell      |
|                                          | Sickle cell anemia                                             | $\beta$ -globin                                                   | Hematopoietic stem cell      |
|                                          | Severe combined immunodeficiency                               | Adenosine deaminase                                               | T lymphocyte                 |
|                                          | Cystic fibrosis                                                | Cystic fibrosis conductance regulator                             | Respiratory epithelial cells |
|                                          | Hemophilia                                                     | Clotting Factor VIII or IX                                        | Hepatocyte                   |

| Suicide gene                             | Graft-vs-host disease caused by allogeneic donor T lymphocytes | Thymidine kinase gene<br>(kills cell when exposed to ganciclovir) | Hematopoietic stem cell      |
|                                          |                                                                | Cytosine deaminase<br>(kills cell when exposed to 5 FU)           | Hematopoietic stem cell      |

integration site can lead to silencing of transgene expression. The use of “insulating” genetic material at the extremity of the therapeutic cassette may prevent the ability of the inserted genetic material to perturb the activity of surrounding genes of the area of integration. Each of these concerns theoretically can be overcome if efficient gene targeting can be attained.

How Should the Gene Therapy Be Administered?

Gene therapy vectors can be applied to cells *ex vivo* and then returned to the patient. Alternatively, viral vectors that are replication incompetent (incapable of replication) and nonviral vectors can be directly administered to the patient for infection of target cells *in vivo*. So far, most animal and human clinical trials have used *ex-vivo* infection of patients’ cells with retroviruses. This allows for selection of virally infected cells before use in order to guarantee vector insertion.<sup>1</sup> The *ex-vivo* approach minimizes infection of unintended cellular targets, and because the cells are washed free of unincorporated viral vector before infusion, this approach significantly decreases the potential risks of exposing the patient to large amounts of viral vector. This approach has been used for hematologic disease in which the target cells can be harvested from patients and returned by intravenous transplantation. On the other hand, direct administration of vectors to the patient overcomes the difficulties of maintaining fully functional target cells *ex vivo*. However, because there are risks associated with transgene expression in unintended host cells, it is critical that the vector administered *in vivo* have target specificity or have little toxicity if expressed by cell types other than the intended target tissue. This *in-vivo* infection has been used mostly in clinical trials to treat patients with cystic fibrosis. Adenoviral vectors containing a normal version of the cystic fibrosis conductance regulator gene that is mutated in cystic fibrosis are inhaled and subsequently enter respiratory epithelial cells. Viral vectors have also been developed that can be administered either by intramuscular or by direct injection into the liver for the treatment of hemophilia.

What Vector Should Be Used?

The ideal vector should have no toxicity to the patient, should not cause an immune response, should be able to hold a large amount of genetic information (large gene-carrying capacity), should have target specificity or the ability to program target specificity, should infect target cells with a high efficiency, should have controllable gene expression (persistent versus inducible), and should have a controlled integration site that prevents nonspecific effects. The choice of which vector to use may also be based on the level and longevity of expression desired. Depending on the application, some genes need to be expressed over the long term in the individual (eg, replacement of a missing globin gene in thalassemia) and, therefore, must be incorporated into the genomic DNA of a cell population that will endure (the hematopoietic stem cell), and others may require only transient expression (eg, induction of tumor cell death) for which adenoviral vectors can be useful. Each application requires the design

of specific gene elements for insertion into specific vectors that will target appropriate levels of gene expression to the appropriate tissues.

Of course, no viral or nonviral vector yet achieves all of these goals; different vectors have different advantages and disadvantages. Many research laboratories are developing strategies to optimize current vectors to meet the criteria for an ideal vector. Provided below is an overview of the successes and remaining challenges in three of the most well established viral vector systems for clinical trials, retroviruses, adeno-associated viruses, and adenoviruses. Table 60-3 summarizes the salient features of these viral vectors. Nonviral techniques that are under development for gene therapy are discussed below as well.

Viral Vectors

Retroviruses

Retroviruses, the first gene therapy vectors to be used, generally have an enveloped single-stranded RNA genome and are approximately 100 nm in diameter. For applications using retroviruses, the therapeutic gene is inserted between the two long terminal repeats (LTRs) at each end of the retroviral genome and replaces three key normal viral genes (*gag*, *pol*, and *env*). Without these genes, the virus is no longer able to proliferate. The LTRs are critical for incorporating the therapeutic genes into the genomic DNA of the target cells and may also be required for expression of the inserted genes. The maximal insert size for the expressed gene(s) is approximately 8 kb, which can be quite limiting because the coding region for many genes is longer than 8 kb, and often more than one gene (eg, a therapeutic gene and

a selectable marker) may need to be included in the retroviral vector.

There are multiple types of retroviruses used in gene therapy research, including gamma retrovirus or oncoretroviruses, lentiviruses, and spumaviruses. To date, most retroviral vectors assessed for clinical trials have been based on murine leukemia viruses (MLVs). As described below, lentiviral vectors based on RNA sequences from human immunodeficiency virus (HIV) are better than oncoretroviruses at infecting nondividing cells. Although the therapeutic vector, in this case, is based on the HIV genome, these vectors do not contain the genes in the virus that can cause AIDS. The ability to transduce nondividing cells is associated with the viral genes (eg, gag matrix protein MA, the regulatory protein Vpr, and viral integrase) that efficiently shuttle the virus into the nuclei of target cells. Lentivirus can transduce primate<sup>2</sup> and human<sup>3</sup> hematopoietic stem cells (HSCs) more efficiently than the oncoretroviruses because the majority of HSCs are in G<sub>1</sub> or G<sub>0</sub> phase of the cell cycle. Recently, the human foamy virus (HFV) has been used as an alternative gene therapy vector to murine leukemia viruses and HIV-1 vectors. HFV is nonpathogenic, has the unique property of completing reverse transcription before entering its target cells, and infects multiple cell types including hematopoietic cells.<sup>4</sup> Although progress has been made in the last few years, the full cell biology of this virus is not yet well defined. Studies showing infection of nondividing cells<sup>5,6</sup> including unstimulated HSCs suggest that this vector system should be pursued more thoroughly. The unique capability of this virus to transduce metabolically inactive cells appears to be related to the fact that the foamy virus particles contain active reverse transcriptase and, as mentioned, the transcription of double-strand DNA is completed before the entry of the particles in the cell. Therefore, these viruses do not rely on the limited host nucleotide supply for their replication.<sup>7</sup>

### Optimization of Retroviral Vectors

Optimization of retroviral vectors should combine several features, which are described below.

#### Virus Inactivation

For safety reasons, all gene therapy vectors must be incapable of replication in the human host. By removal of the *gag*, *pol*, and *env* genes, replication-incompetent retroviruses (RIR) are produced. Because the genes removed are necessary for packaging the RNA genome into retroviral particles, special “packaging” cells are required to produce retrovirus for use in gene therapy. These packaging cells express the *gag*, *pol*, and *env* proteins because the three genes have been introduced into their genomes. When an RIR vector containing the LTRs and the packaging signal is introduced into such packaging cell lines, its RNA is packaged into infectious particles by the *gag*, *pol*, and *env* proteins. The DNA encoding viral *gag*, *pol*, and *env* is not contained within the viral particles produced, so that even though these retroviruses are capable of infecting target cells, they are not capable of replication. However, if some of the *gag*, *pol*, and

*env* sequences within the packaging cell genome share regions of DNA overlap with the retroviral coding region, there is a risk of recombination between the two, which could lead to the production of replication-competent retroviruses. MLV has the advantages of having the lowest overlap between viral elements and the genes inserted into packaging cells. In contrast, lentiviruses have a large portion of overlap in the N-terminus of the *gag* gene, and HFV requires the greatest overlap between coding sequence and RIR for generating potentially therapeutic viruses. Of note, the oncoretroviruses used for recent clinical studies were produced several years ago, and still contain large portions of the *gag* and *pol* genes, which increase the risk of making replication-competent viruses. Before any retroviruses can be used in clinical trials, however, each batch must be tested extensively in order to ensure that there are no replication-competent viruses present. Ongoing studies are focused on reducing the sequence overlaps without decreasing the titer of the viruses produced.

A step forward in the design of viral vectors was to create self-inactivating vectors by deleting the enhancer promoter sequences from one of the two viral LTRs containing the retroviral promoter and enhancer elements. Given the retroviral cycle, mutation of the transcriptional element at the 3' end of the virus does not affect the ability of the vector to infect cells and incorporate into the genomic DNA. However, after entry into the target cells, the 5' LTR, which is derived from the 3' LTR, also becomes mutated, and the LTR is incapable of promoting transcription. This approach greatly reduces the risk of creating replication-competent virus. The downside is that now the vector no longer has its own promoter, so it needs to be designed with another promoter that will drive transcription of the desired transgene once inside the target cells.

#### Efficiency

Some of the best target cells for in-vitro retrovirus infection are hematopoietic cells. Highly proliferative hematopoietic progenitors, measured by in-vitro colony-forming assays, have been infected successfully by retroviruses. The biggest obstacle to using retroviruses to infect hematopoietic stem cells is that oncoretrovirus do not infect nondividing cells, and hematopoietic stem cells cycle very slowly and are usually in G<sub>0</sub> phase of the cell cycle. The efficiency of infection of HSCs has been increased in recent years by addition of cytokines to the ex-vivo culture medium before and during retroviral infection in order to increase the number of HSCs in the cell cycle. However, such cytokines may also cause HSCs to differentiate so that they lose their long-term repopulating “stem cell” capacity. Retroviral infection and modification of mouse HSCs has been demonstrated using mouse marrow transplantation,<sup>8</sup> and efficiencies obtained have been very high with 80% to 100% of mouse stem and progenitor cells being infected with retrovirus. Infection of human HSCs is less efficient than murine cells.

In contrast to oncoretroviruses, lentiviruses and foamy viruses are able to efficiently infect quiescent cells and, therefore, appear to be more promising vectors for HSC-based gene therapy. Lentiviral vectors have a high efficiency of infection (up to 80%) in human

CD34+ cells from cord blood, cells in peripheral blood that have undergone granulocyte colony-stimulating factor (G-CSF) mobilization, and marrow cells.<sup>9</sup> Similarly, HFV is found to infect more than 80% of human CD34+ hematopoietic progenitors from cord blood.<sup>6</sup> Clinical trials using lentiviral vectors have been initiated for inherited diseases and HIV.

Experimental models for human HSCs, take advantage of the ability of human cells to engraft the marrow of immunocompromised animal hosts. These xenogeneic in-vivo models have been quite useful as preclinical systems. One such model uses sublethally irradiated nonobese diabetic/severe combined immunodeficient (NOD/SCID) mice. The human cells that maintain multilineage long-term engraftment in these mice are referred to as SCID-repopulating cells (SRC).<sup>10</sup> In a related immunodeficient mouse system, human CD34+ marrow cells were infected with an efficiency of approximately 10% by retroviral vectors, and these cells survived in the immunocompromised mouse hosts for at least 8 months.<sup>11</sup>

Specificity and Efficiency

The different degree of retroviral infection between mouse and human HSCs is caused by multiple factors that must be optimized in order to obtain high levels of infection. Much research has focused on two major differences between infection of mouse and human cells, 1) the percentage of stem cells in mitosis and 2) the surface expression of appropriate retroviral receptors. As alluded to above, in order for viral vectors to be expressed in the target cells, they must be able to enter the nucleus. For all viruses, except lentiviral vectors, this requires nuclear membrane breakdown, which occurs when a cell undergoes mitosis. Thus, quiescent, non-dividing cells are more difficult to infect with gene therapy vectors than are actively dividing cells. In mice, approximately 8% of HSCs enter the cell cycle per day in vivo, and about 75% are quiescent in G<sub>0</sub> phase at any time. It is estimated that human HSCs cycle less often than murine cells, and therefore a higher percentage of human HSCs are quiescent than are murine cells.<sup>12,13</sup>

The efficiency of retroviral infection is also highly dependent upon whether the retrovirus can bind to and enter the cell. Different retroviruses have different receptors. (A list of viral vectors and their receptors is given in Table 60-4.) For the retrovirus used most often in mouse cells, the receptor on the cell is CAT-1, an amino acid transporter.<sup>13</sup> In contrast, the retroviruses that have been used to infect human cells, called amphotropic retroviruses, bind to Pit-2, which is a phosphate transporter.<sup>14</sup> It is estimated that the CAT-1 retroviral receptor is expressed on a higher percentage of mouse HSCs than is Pit-2 on human HSCs.<sup>15,16</sup> Preselection of a subpopulation of hematopoietic cells that expresses high levels of the retroviral receptor and stimulation of receptor expression are two strategies that have been attempted to increase retroviral infection of human HSCs.<sup>17,18</sup> Higher levels of infection of human cells have also been achieved using “pseudotyped” retroviruses in which the envelope-encoding gene *env*, which encodes the ligand on the virus coat that binds to the target cells, has been replaced with a gene that is known to bind

Table 60-4. Viral Vectors and Their Receptors

| Virus                               | Receptor or Coreceptor                           |
|-------------------------------------|--------------------------------------------------|
| <b>Retrovirus</b>                   |                                                  |
| • Ecotropic murine leukemia virus   | CAT-1 (cationic amino acid transporter)          |
| • Amphotropic murine leukemia virus | Pit-2 (sodium-dependent phosphate transporter)   |
| • Human immunodeficiency virus      | CD4, CXCR4                                       |
| <b>Adenovirus</b>                   |                                                  |
|                                     | CAR (coxsackie virus and adenovirus receptor)    |
|                                     | $\alpha_v\beta_5$ or $\alpha_v\beta_3$ integrins |
| <b>Adeno-associated virus</b>       |                                                  |
| • Parvovirus B19                    | Red-cell-specific protein                        |
|                                     | Heparin sulfate proteoglycans                    |
| • AAV2                              | Fibroblast growth factor receptor 1              |
|                                     | $\alpha_v\beta_5$                                |

well to HSCs.<sup>19,20</sup> One protein that has been studied extensively is the gibbon ape leukemia virus (GaLV) envelope protein, which binds to a receptor called Pit-1.<sup>21</sup> Retroviruses pseudotyped with GaLV infect more than twice as many hematopoietic progenitors than the standard amphotropic retrovirus.<sup>22,23</sup> Gammaretrovirus and lentivirus are much easier to pseudotype than foamy virus.<sup>24</sup> After effective pseudotyping approaches are developed, this should allow for construction of vectors that are targeted to specific cells.

An additional level of specificity is to express the transgene on a tissue-specific promoter. For hematopoietic diseases, limiting expression of the therapeutic gene to differentiated cells rather than more primitive stem and progenitor cells could reduce the risk of genotoxicity of the vector. For example, vectors have been designed to treat erythroid disorders in which the  $\beta$ -globin gene is driven by a promoter that is active only in red cell precursors; preclinical studies using mouse models have shown promising therapeutic results.<sup>25</sup> A similar vector has also given promising results for a vector encoding human Factor IX.<sup>26</sup> Lineage-specific expression has also been achieved in T cells and B cells.<sup>27,28</sup>

Specific Chromosomal Targeting

All retrovirus vectors integrate randomly into genomic DNA. Based on the integration site of the viral DNA, expression of endogenous genes can be modified (genotoxicity). If this gene were a pro-oncogene, the activation induced by viral insertion could cause cancer. As discussed below, this is what occurred in a recent clinical trial in which four patients developed leukemia. The components that influence retroviral integration sites in the genome are not known. Ongoing studies are revealing general patterns of integration that characterize different vectors. For example, oncoretroviruses such as MLV integrate preferentially within a few kilobases upstream of transcriptional start sites in

DNA regions containing CpG islands (regions rich in cytosine residues next to and 5' to guanine residues). Lentiviruses also tend to insert near actively transcribed genes, but the integrations are not necessarily clustered near transcription start sites. Foamy viruses tend to integrate outside of genes, with both clusters and gaps.<sup>29,30</sup>

### Risks

The major risks associated with viral vector-based gene therapy are the generation of replication-competent viruses and integrations that lead to activation of oncogenes or silencing of tumor suppressor genes.

### Replication-Competent Viruses

Replication competent retroviruses develop either by recombination of the constituent parts of the vector system with endogenous viral sequence in the viral producer cell lines or by activation of endogenous proviral sequences. The significant risks of retroviral vectors for gene therapy were elucidated when primate studies were initially performed before 1992. CD34-selected marrow cells of the monkeys were infected with replication competent viruses from packaging cell lines. There were, however, some replication competent viruses that formed by rearrangement that had not been detected by the existing assays for replication-competent viruses. Upon infusion, three of eight monkeys subsequently developed lymphomas containing the active rearranged retrovirus.<sup>31</sup> As mentioned, investigators are optimizing the safety by creating self-inactivating (SIN) vectors, and minimizing the regions of homology between the vectors and the producer cells. Currently, all clinical trials require very stringent testing to guarantee that the retroviral vector to be used in humans is entirely replication incompetent.

### Genotoxicity (insertional mutagenesis)

Genotoxicity is caused by the insertion of the provirus in proximity to a tumor suppressor gene or pro-oncogene. The presence of a strong promoter of viral origin near a proto-oncogene can lead to transcriptional activation of the gene and ultimately the development of neoplasia. Unfortunately, this has occurred in a clinical trial for X-linked immunodeficiency.<sup>32-35</sup> More details regarding this trial are provided below in the Clinical Trials section. The best approach for minimizing oncogene activation may be the use of vectors such as lentiviruses and foamy viruses, which tend to integrate into areas of the genomes that are not oncogenic. However, additional evaluation of the possible risks associated with these vectors is required before they are ready for clinical trials.

No strategies are available currently for directing the integration of the transgenes in a safe, specific spot in the genome. Preliminary data suggest that an alternate approach, the addition of insulator sequences at each end of the transgene, can reduce the genotoxicity of retroviral insertion.<sup>36</sup> These *cis*-acting insulator sequences are designed to prevent the genome information contained inside the vector from interfering with the adjacent

endogenous neighboring genes. The best characterized chromatin insulator to date is derived from the chicken  $\beta$ -globin locus control region.<sup>37,38</sup> Developing vectors with tissue-specific promoters also addresses genotoxicity because these promoters allow improved spatial and temporal control of transgene expression.

### Challenges

The most important challenges for translating viral gene therapy into a compelling alternative treatment for hematologic diseases are 1) to create vectors with no adverse effects, 2) to ensure long-term therapeutic effects, and 3) to standardize protocols for highly controlled, efficient, high quality vector production.

### Prevention of Gene Silencing

Even if the insertion site causes no genotoxicity, expression of the therapeutic transgene can get silenced because of epigenetic modulation of the chromatin (eg, histone methylation) presumably because the host cell recognizes that the inserted DNA sequences are being expressed inappropriately. The elimination of a known silencing element within the U3 domain of the LTR, the use of a robust promoter (eg, PGK), the introduction of an intron sequence, and the incorporation of other transcriptional regulatory elements (eg, WPRE enhancers) are all strategies that have been evaluated to ensure long-term expression of the transgene. For example, SIN vectors, which lack functional domains of the LTR region, are less prone to silencing. These strategies are undergoing evaluation, and it is not yet clear that they will be useful for clinical studies.<sup>39</sup>

### Vector Production and HSC Modification

Additional problems with long-term retroviral infection of HSCs currently being addressed include establishing techniques for concentrating retrovirus onto the cells,<sup>40,41</sup> improving retroviral survival in vivo,<sup>42,43</sup> and optimizing infection efficiency into specific target cells.<sup>20</sup>

---

## Adeno-Associated Virus

Adeno-associated virus (AAV) is a nonpathogenic, replication-defective, 4.68 kb, single-stranded DNA virus that requires external factors for infection. The name AAV was given because helper virus, usually adenovirus, is necessary for infection and replication. Advantages to AAV vectors over retroviruses include the ability to infect nondividing cells and insertion as DNA rather than RNA. This is a potential advantage over retroviral vectors because some genes, most notably  $\beta$ -globin, require the presence of introns for optimal expression, and these introns are likely to be spliced out when the retroviral RNA is reverse transcribed into DNA.

The inverted terminal repeats (ITRs) that are located at each end of the AAV genome are sufficient to package the single-stranded DNA into viral particles. When a gene therapy vector is made from AAV, the therapeutic gene can be inserted in

place of nearly the entire normal viral protein-coding domain (4.5kb) as long as the flanking ITRs remain intact. These vectors are packaged into viruses by supplying the required rep and cap AAV proteins separately. This is usually achieved by inserting both a vector plasmid encoding the therapeutic gene and a packaging plasmid encoding the *rep* and *cap* genes into cells also infected with adenovirus. Replication-incompetent AAV vectors are produced by lysing the cells to release viruses, and destroying the “helper” adenovirus with heat. In the absence of helper virus, AAV does not replicate and remains integrated in the genomic DNA of the producer cell. AAV is not pathogenic (approximately 80% of humans are seropositive for AAV type 2), making it suitable for gene therapy. AAV can infect nondividing cells and remain latent for prolonged periods in an episomal state. That is, AAV persists in cells without inserting into the genomic DNA (thus avoiding insertional mutagenesis) and does not trigger a robust immune response. Unlike the retroviruses, different naturally-occurring AAV variants, with more than 100 different capsid proteins, confer target cell specificity for AAV infection.<sup>44</sup> In addition, because of its genetic simplicity, AAV virus sequences can be mutated to increase the specificity of gene delivery; such modified AAVs are called recombinant AAVs. With repeated infections, AAV incorporates stably into the endogenous genome with a frequency of 1%, but most AAV remains in the episomal state. When AAV does integrate, it integrates randomly in the cells.<sup>45</sup> When more of the initial AAV genome is maintained, although the integration frequency is still quite low, the integration is targeted to a specific area of the genome (19q13.3), which is transcriptionally active. The targeted integration of the AAV is a unique characteristic among all known eukaryotic viruses, and, because the integration site appears to be nononcogenic, investigators are working on methods to maintain the targeted integration while making the AAV replication incompetent.

AAV vectors efficiently infect CD34+ human marrow progenitor cells. From 80% to 90% of CD34+ cells in suspension cultures and 50% to 95% of myeloid colonies differentiating in vitro from transduced CD34+ cells demonstrate AAV-induced transgene expression. A high percentage of transduction (up to 23%) has also been reported for CD34+ human cord blood cells.<sup>46</sup> In murine transplantation models with AAV-infected hematopoietic cells, no cytotoxic response to AAV occurs; mice transplanted with AAV-transduced marrow have long-term multilineage reconstitution,<sup>46</sup> and the transgene is still detectable after 6 months. In secondary mouse recipients (another test for whether self-renewing stem cells have been infected), a small but significant percentage (1%) of marrow cells were still transduced. A study in nonhuman primates demonstrated that 15 months after transplantation of AAV-modified autologous marrow cells, approximately 1 in 10 cells in the circulation was still modified. Modified cells were also detected in the marrow, and in specific subpopulations including granulocytes, B cells, and T cells.<sup>47</sup> Wang et al<sup>48</sup> developed capsid-modified, helper-dependent AAV vectors carrying the  $\beta$ -globin locus control region (LCR) to drive green fluorescent protein (GFP) expression. GFP expression was

detected in an erythroleukemia cell line. In primary CD34+ human cells, more than 40% expressed GFP at high levels.

AAV has been used in Phase I and II clinical trials for various diseases including Parkinson's,  $\alpha_1$ -antitrypsin deficiency, cystic fibrosis, and hemophilia B; however, no clinical trials using AAV-infected hematopoietic cells have been reported. Although this virus has been considered the safest vector in gene therapy (explaining the abundant ongoing clinical trials that are in place using this vector), the use of AAV in a clinical trial was recently associated with a severe adverse event.<sup>49</sup> In this clinical trial for the treatment of rheumatoid arthritis, a tumor necrosis factor, alpha (TNF- $\alpha$ ) inhibitor protein was delivered by an AAV vector that shuttled the gene into the joints. The trial, beginning in the fall of 2005, enrolled 127 patients without any serious adverse effects, but one patient during the second administration of the vector in the summer of 2007 developed a severe reaction to the vector that led to death in few days. This event is now, appropriately, under intense scrutiny. In addition, other investigators have shown that after several administrations of AAV in a mouse model of the lysosomal storage disease mucopolisaccharidosis VII, the vector integrated in a specific area of the genome on chromosome 12, which led to dramatic overexpression of the provirus and development of hepatocellular carcinoma.<sup>50</sup>

Another major problem with using AAV vectors is the highly variable efficiency of infection reported by different laboratories. One possible explanation for this variability is that different laboratories have different amounts of remaining intact adenovirus, which is coinfecting with the AAV. This is problematic because adenoviral vectors are replication competent. Improved techniques to effectively remove contaminating helper virus are currently being developed. Also, it has been difficult to obtain high titers of pure AAV. A “hybrid” between viral AAV vectors and liposomes (phospholipid-bound vesicles) has been proposed for gene therapy in which the AAV ITRs are used to flank the gene of interest in order to facilitate its insertion into the host genomic DNA, but rather than a viral particle, the DNA is packaged simply in a liposome carrier. Future studies in the AAV field are focused on 1) increasing the tropism of AAV for specific cells and 2) evaluating the “target” integration of the vector and the mechanism and proteins involved in this unique propriety of AAV, which could be therapeutically very important. In addition, deeper evaluation of the risks associated with the use of AAV is under way.

---

## Adenoviral Vectors

Adenoviruses are double-stranded DNA viruses that are approximately 36kb in size. Four early genes are expressed at the beginning of the viral cycle, and are required for DNA replication and viral propagation. The late genes, which encode structural proteins, are transcribed after DNA replication. Unlike retroviruses, adenoviral vectors are quite stable in vitro, can be produced and concentrated to high titers, and can infect quiescent, postmitotic cells. After the adenovirus enters a cell, its

genome is released and maintained as an episome (circular DNA separate from the nuclear genomic DNA) in the cell. Because the adenoviral DNA does not incorporate stably into the genomic DNA of the cell, adenoviral gene expression is transient. The duration of expression of a gene on an adenoviral vector varies significantly based on the longevity and cell cycle status of the cell that is infected. Adenoviruses infect many different cell types, and there are more than 50 different types of adenoviruses that are associated with disease in humans. The diseases caused by adenoviruses are transient and usually are not serious unless the patient is immunocompromised. The cell membrane receptor for adenovirus fiber protein is called CAR for coxsackievirus and adenovirus receptor. The normal cellular function of CAR is not yet known. Similar to other types of viruses, interaction with a second membrane coreceptor is necessary for internalization of bound adenovirus. For adenoviruses, this second interaction is between the penton base of the virus and integrins on the cell surface including  $\alpha_v\beta_3$  and  $\alpha_v\beta_5$ .

Adenoviral vectors have been tested extensively in models to treat cystic fibrosis, and have been used for modifying HSCs as well. The most widely used adenoviral vector is based on the Ad5 virus, belonging to adenovirus subgroup C. Human CD34+ hematopoietic stem/progenitor cells do not express CAR or the  $\alpha_v$  integrins at levels high enough for efficient Ad5 vector-mediated gene transfer. Therefore, when hematopoietic cells are exposed to adenovirus, there is only low-level transgene expression.<sup>51</sup> In contrast, human monocytes have relatively high levels of  $\alpha_v$  integrin and CAR.<sup>52</sup> Strategies to increase gene transfer efficiency of Ad5-based vectors include prolonged incubation of CD34+ cells with high concentrations of vectors, formation of virus-polycation complexes before infection, and cytokine stimulation of CD34+ cells. However, none of these approaches has led to significant improvement of transduction. More recent approaches have been focused on enhancing recognition of hematopoietic cells by adenoviruses by genetic or chemical modifications of the fiber/knob domain of the virus.<sup>53</sup> For example, investigators have replaced the entire fiber gene or the knob part of the Ad5 vector genome with the corresponding gene from Ad35, which does not require CAR expression on the target cell.<sup>54,55</sup> These modified adenovirus vectors show efficient (30-70%) gene transfer with little evident of cellular toxicity into hematopoietic cells, including CD34+ cells and primitive progenitor cells.<sup>56</sup> The infected populations were viable, and retained their ability to form colonies in short-term culture assays<sup>54</sup> as well as their ability to confer multilineage repopulation in vivo after transplantation into immunodeficient mice.<sup>53,56</sup>

The transient expression of this vector could have some potential applications for hematologic diseases such as transient overexpression of immune-response molecules for immunotherapies against leukemias or for transient expression of “stem cell genes” for expansion of HSCs in vitro without permanently affecting the genome of the cells and their progeny.

Ongoing challenges with adenoviral vectors include the immune response mounted by the host, the transient nature of

transgene expression due to lack of genomic insertion, and the inherent low affinity for hematopoietic cells. In clinical trials using adenoviral vectors to treat cystic fibrosis, problems arose because of an inflammatory response to the vectors. In addition, in cystic fibrosis there is a relatively low level of integrin expression on the airway epithelium.<sup>57</sup> Inflammation against adenovirus was also to blame in September 2000, when an 18-year-old patient with ornithine transcarbamylase deficiency, an inherited liver disease that causes life-threatening levels of ammonia to build up in the blood, became the first known death caused by gene therapy. This event demanded the attention of the public as well as that of regulatory agencies and committees that oversee and approve human gene therapy protocols. The patient, who had managed his disease with oral medication and a special diet, developed acute hepatitis after receiving an adenoviral gene therapy vector via the portal vein. Since that time, the Food and Drug Administration (FDA) has investigated several laboratories across the country and has found one failure to comply with National Institutes of Health (NIH) and FDA procedures. These findings raise the ethical quandary of whether to stop or slow the progress of gene therapy by tightening all regulations or to move ahead because patients with rare and untreatable diseases and their families want the trials to continue.

---

## Nonviral Gene Therapy

Nonviral vectors for gene therapy are also undergoing intensive investigation.<sup>58</sup> Unlike viral vectors, nonviral vectors do not need to overcome the extensive immune mechanisms that destroy some viral vectors in vivo, and they do not have the risk of there being replication-competent forms of the vector. However, the application of nonviral gene therapy to humans has been severely limited by the poor efficiency of gene delivery to the cells. Several nonviral strategies under development are described briefly below.

### Episomal Plasmid DNA

The most common nonviral gene therapy approach is based on the transfer of plasmid DNA containing the correct cDNA sequence and regulatory elements of the gene of interest. The main challenges with this technology have been 1) the efficiency of gene delivery inside the cells, 2) appropriate shuttling of the vector from the cytoplasm to the nucleus where the plasmid is transcribed, and 3) the transient expression induced. Although plasmid DNA is not thought to be immunogenic, methylation of plasmid DNA may contribute silencing of transgene expression, which occurs when this strategy is tested in vivo. The DNA methylation issue can be overcome at least in part by making the therapeutic plasmids in cells that are incapable of methylating the DNA. However, the delivery of the plasmid DNA to the nuclei of the target cells is still a major concern. Approaches for increasing the passage of nonviral vectors into the cell, and into its nucleus include addition of 1) ligands for receptor-mediated endocytosis,

2) polypeptide sequences that assist DNA compaction, 3) endosomal disruption sequences, and 4) nuclear-import signals.

Among the technologies being developed for plasmid delivery are physical methods such as DNA microinjection, electroporation and gun injection, or chemical methods in which the plasmid DNA is combined with liposomal formulations or basic proteins and polymers such as polyethylenimine, to assist the plasmid cell entry by binding and/or enveloping the DNA through a charge interaction. Because of the transient expression of the transgene, the use of plasmid DNA for hematologic diseases has not been extensively studied.

### Integrated Exogenous DNA

Exogenous DNA, in circular as well as linear form, can spontaneously integrate into genomic DNA. Although this is a very rare event, there are some enzymes that have the capability to catalyze such reaction. This is the case for enzymes such as transposase, which are involved in the insertion of transposon elements into the genome, and site-specific integrases, which are found in bacteriophages and are able to first recognize unique nucleic acid sequences and then to mediate integration at that site. On the basis of this knowledge, investigators have developed nonviral vectors in which plasmid DNA is integrated into the genome of a target cell with the help of these enzymes. Two of these systems—the Sleeping Beauty vector (transposase-based method) and the phiC31 vector (integrase-based method)—are described below.

### Sleeping Beauty Vector

Transposable elements were not available for genome manipulations in vertebrates until recently, when an active element was resurrected from transposon fossils found in fish genomes.<sup>59</sup> This element, called Sleeping Beauty transposon, shows efficient transposition in cells of a wide range of vertebrates, including humans. The integration of a corrected copy of the gene of interest is achieved by transfecting the target cell with two plasmids: one containing the therapeutic gene flanked by the transposable element and the other providing expression of the transposase. The Sleeping Beauty transposon carrying the therapeutic gene is “cut” out of the plasmid vector by the transposase and then “pasted” directly into the chromosome. The efficiency of this process is quite high (up to 10%) and the tropism is for both dividing and nondividing cells. The vector does not appear to be toxic or to be associated with a dramatic immune response after repeated administration *in vivo*. The integration of the vector in the genome is random (transcribed and nontranscribed regions), with a general preference for adenine and thymine (AT)-rich DNA, microsatellite repeats, and a small bias toward genes and their upstream regulatory sequence.<sup>60</sup> The next challenge for this kind of technology will be to confer “specificity” for the integration site. Such targeted transposon integration at specific DNA sites is being tested by coupling a site-specific DNA-binding domain to the transposase.<sup>61</sup>

This system has been used for gene transfer into human CD34+ cord blood cells. When the vector containing GFP and the transposase was delivered to the cells via electroporation,

transgene integration reached a frequency of 6% and was stable for over 4 weeks. However, the gene transfer of more primitive cells (CD34+/CD38−) was less efficient because these cells were particularly sensitive to damage induced by the electroporation. Thus, although this vector may have an interesting potential application in gene therapy for hematologic diseases, the delivery of vector into primitive cells without damage is a significant challenge.<sup>62</sup> A Sleeping Beauty vector with erythroid-specific expression of  $\beta$ -globin is under investigation.<sup>63</sup>

### Recombinase

The phiC31 integrase is a site-specific recombinase originally isolated from a *Streptomyces* bacteriophage. The phiC31 integrase catalyzes precise, unidirectional recombination between its 30 to 40-bp attP and attB recognition sites in the genomic DNA. In mammalian cells, the enzyme also mediates integration of plasmids bearing attB into genomic DNA at sequences that have partial sequence identity with attP, termed pseudo attP sites. The integrase approach involves delivering the gene of interest as a plasmid also containing the integrase recognition site attB (40bp). The integrase pairs attB with the endogenous pseudo attP sites and catalyzes genomic integration. The system has been used successfully in gene therapy experiments in mouse liver and muscle, human skin, rat retina, and rabbit joints with an efficiency of 10% and with just a single copy integrated.

The great advantages of this vector in gene therapy is that pseudo attP sites are rare in mammalian cells.<sup>64</sup> A bioinformatics analysis revealed that phiC31 integrase-mediated integration into human pseudo attP sites was mostly (56%) distributed among 19 pseudo attP sequences. The integration sites were not close to cancer genes in the genome, suggesting that cancer risk may be minimal. However, a serious concern is that aberrant events were described, including large deletions and chromosomal rearrangements.<sup>65</sup>

To date, published data on using phiC31 for hematologic diseases have focused on optimization of phiC31 integrase-mediated integration into human T-cell lines.<sup>66</sup> The phiC31 integration sites in these cells were frequently located in intergenic regions on chromosomes 13 and 18 that may be preferred in hematopoietic cells. PhiC31 was used effectively to restore functional  $\gamma$ c protein in a mutant cell line, supporting the possible application of the phiC31 integrase-mediated genomic integration strategy as a gene therapy approach for treating SCID-X1.

### Gene Targeting

Gene targeting strategies attempt to directly correct the endogenous DNA sequence rather than introducing the therapeutic DNA by random insertion into the genome. In addition to allowing for potentially permanent correction of a gene disorder, such gene targeting avoids the risks associated with harmful mutations caused by the chance integration of the therapeutic DNA, prevents delivery of extra copies of the transgene, and allows for control of gene expression by the endogenous regulatory mechanisms. The technology is based on promoting homologous

recombination, which mediates the exchange between the endogenous (dysfunctional) target sequence and the corrected donor DNA sequence. Investigators have used several different targeting approaches including chimeric RNA-DNA oligonucleotides, short single-stranded oligonucleotides, triplex DNA, and small DNA fragments, in order to modify specific bases of various reporter genes, as well as different gene mutations associated with human disorders. These vectors, which vary in length and chemistry, in most cases are designed to be homologous to the target locus except for the nucleotides to be replaced.<sup>67,68</sup> Although each of these approaches has induced targeted homologous recombination, the frequency to date is too low for clinical applications.

### Zinc Finger Nucleases

Novel strategies are being developed in order to better target the site of homologous recombination. Based on the observation that double-strand breaks in the genome enhance gene targeting by homologous recombination, bifunctional zinc-finger (ZF) proteins are being designed to induce double-strand DNA breaks within specific DNA sequences. The two functional domains of the zinc-finger nucleases (ZFNs) are ZFs customized to recognize specific DNA sequences, and a nuclease domain. The amino acid composition of the ZF domains of proteins determines the specific DNA sequences to which they bind. ZFNs specifically designed to recognize different DNA sequences that flank a specific genomic locus, are fused in frame with the DNA cleavage domain from *FokI* nuclease. After two ZFNs dimerize, one that binds to a DNA sequence upstream and one that binds a different DNA sequence downstream of the target DNA, the nuclease will induce a double-strand break in that specific location. If donor DNA is present, homologous recombination will occur with a frequency up to 10%.<sup>69,70</sup> Although this technology is far away from translation to the clinic, ZFNs are able to stably and specifically modify primary human CD4+ T cells at the endogenous *IL2R $\gamma$*  locus with a frequency up to 6.6%.<sup>71</sup> Ongoing studies are focused on using this strategy for gene correction of sickle cell anemia, X-linked SCID, and Wiskott-Aldrich syndrome.

Recently, investigators have combined technology from lentiviruses and zinc finger proteins using the advantages of lentiviruses, their ability to enter the nucleus, with the site specific DNA nicks created by zinc finger proteins. They have inserted the cDNA for a zinc finger gene into a defective lentiviral vector that cannot incorporate into the DNA. Template (corrected) DNA plus the integrase gene are also introduced in order to achieve targeted gene correction.

## Clinical Protocols

### Basic Design of Clinical Trial Stages

In designing a clinical trial, different goals are defined for Phases I through IV. In Phase I trials, researchers test the treatment in a small group of people (usually 20 to 80) for the first time to

evaluate its safety, determine a safe dosage range, and identify side effects. Phase I studies are thus primarily concerned with safety and secondarily with the feasibility of the work proposed. In Phase II clinical trials, more people (100 to 300) are recruited in order to evaluate whether the therapy is effective and to further evaluate its safety. Most gene therapy protocols are currently in the Phase I or Phase II stages. In Phase III studies, larger groups of people (1000 to 3000) are treated in order to confirm that the therapy is effective, to monitor side effects, and to compare it with existing treatments. Factors involved in safety include production of sterile replication-incompetent vectors, prevention of adverse reactions, and minimization of patient immune responses against vector. Phase IV studies are postmarket trials that provide additional confirmation of the efficacy and safety of the regimen. Regulatory considerations for all clinical trials are assessed by multiple reviewers with different levels of oversight, including an institutional scientific review committee, institutional human investigation committee, institutional biosafety committee, the NIH recombinant advisory committee, and the FDA.

### Clinical Gene Therapy Successes and Failures

Several clinical trials of gene therapy for hematologic diseases have been completed. In all of these trials oncoretroviruses were used and a functional LTR promoter drove expression of the transgene. Overall, approximately 20 patients have been treated, and 80% are healthy and have recovered from their genetic defect.

### Clinical Trials for X-Linked Severe Combined Immunodeficiency

The first success in gene therapy was achieved by a French group who treated 10 children with X-linked SCID, in which there is a complete lack of functional T and natural killer (NK) lymphocytes in affected boys because of mutation of the gene encoding the shared subunit of the receptors for interleukins 2, 4, 7, 9, and 15.<sup>33,72,73</sup> A murine retrovirus vector was used to introduce the cDNA for the missing receptor *ex vivo* into autologous CD34+ marrow cells, and the cells were returned to the patients. Because of the survival advantages of the corrected HSCs over the endogenous defective cells, preconditioning was not necessary to obtain long-term engraftment in these patients. Circulating T and NK cells that contained the therapeutic transgene were detected in nine of 10 patients and the functional activity of the T and NK cells were the same as in normal unaffected children for at least the first 2.5 years following gene transfer. However, four of the 10 patients developed leukemia caused by insertional mutagenesis of the proviral vector near the proto-oncogene LMO2.<sup>32</sup> Unfortunately, one child died of leukemia; the other three patients are responding well to antileukemic therapy.<sup>74</sup>

At the same time, a very similar clinical trial was performed by a British group in which four children<sup>75</sup> and two adults<sup>76</sup> affected by X-linked SCID, were treated with autologous CD34+ marrow HSCs that were transduced with a gammaretrovirus (almost

identical to the vector used in the other clinical trials) encoding the corrected sequence for the receptor. In this study, the four children had restoration of functional immunity whereas the treatment was not effective in the older patients. To date, at least one patient treated in the British trial has developed leukemia. No reason is yet known for the different incidence of leukemia in the French and British trials; more time has elapsed since the French trial was performed so the comparison is not yet final.

### Clinical Trials for Adenosine Deaminase Severe Combined Immunodeficiency

Retroviral vectors containing the missing adenosine deaminase (ADA) gene were used to transfect autologous cord blood cells, which were then returned to three newborns who had been diagnosed with ADA deficiency in utero. Using in-vitro retroviral infection protocols that achieved levels of infection of 5% to 40% of hematopoietic stem and progenitor cells, the patients had low percentages (0.01 to 0.001%) of detectable circulating blood cells containing vector sequences after 1 year.<sup>77</sup> In these human studies, no replication-competent retrovirus has been detected. After 5 years, the authors reported that there were still some circulating cells that contain the transgene. Because these children are being treated with an oral form of pegylated-ADA (the standard of care for the disease), the potential therapeutic effect of the inserted transgene cannot be assessed.<sup>78</sup> Aiuti et al<sup>79</sup> have performed more recent clinical trials for ADA deficiency using an improved protocol for gene transfer into HSCs. In this clinical trial, the patients were not treated with pegylated-ADA and, to provide an initial engraftment advantage for the modified HSCs, patients received a low intensity, nonmyeloablative conditioning regimen using busulfan. Unlike X-SCID, the corrected cells in ADA deficiency do not have a strong survival advantage. Autologous CD34<sup>+</sup> marrow cells were transduced with the retroviral vector ex vivo, and infused into the patients.<sup>79</sup> After 47 months, all of the patients were healthy and cured from the genetic immunodeficiency associated with ADA deficiency.<sup>80</sup> Similar success was also recently obtained in another ADA-SCID patient treated with autologous CD34<sup>+</sup> cells transduced with ADA-expressing gammaretrovirus. As in the trials conducted by Aiuti et al, the patient received a nonmyeloablative conditioning regimen. However, in this case, the patient was undergoing pegylated-ADA treatment, which was stopped just before transplantation.<sup>81</sup>

In all of these clinical trials the vector used and the technical procedures for preparing the HSCs were very similar. A recent analysis of the different viral insertion sites in the genomes of patients from the three clinical trials<sup>82</sup> showed that the proviral insertion was similar in all three trials, and was not random but clustered near promoters of genes in GpC islands. No significant differences were found in the viral insertion sites between the patients who did or did not develop leukemia in the French trial.<sup>74</sup>

### Clinical Trial for Granulomatous Disease

To date, two patients affected by chronic granulomatous disease (CGD), characterized by neutrophil dysfunction with impaired oxidative antimicrobial activity, have been treated with gene therapy. As in the ADA-SCID trials, autologous HSCs were transduced with a gammaretrovirus encoding a functional copy of the transgene called gp91(phox), and the patients were treated with nonmyeloablative conditioning before infusion of the genetically modified cells. The patients had a robust amelioration of symptoms including clearance of infection associated with engraftment of corrected cells.<sup>83-85</sup> A careful evaluation of insertion sites and clonality analysis, revealed that although the initial marrow reconstitution was polyclonal, with time there was selection for cells having the provirus inserted in the promoter of genes involved in survival and cells division. Both patients showed insertions in the MDS-Evil locus, which is known to be associated with leukemia. One patient lost the transgene expressing cells and died of infection and, at last report, the other has remained well, without progression to leukemia.<sup>86</sup>

### First Clinical Trials Using Lentivirus Vectors

Lentiviruses are extremely promising vectors for gene therapy. The first Phase I clinical trial using this vector has recently been performed for the treatment of five patients with chronic human immunodeficiency virus (HIV). In this case, the vector is not used for delivering a corrected copy of a gene but, rather, for transcribing an antisense RNA sequence against the HIV envelope with the goal of impairing viral infection. Autologous CD4<sup>+</sup> cells were expanded ex vivo, transduced with the lentivirus vector, and infused into the patients. The treated patients showed an increased cellular response to HIV and improved the memory response of T cells. In one of the patients, the lentivirus-based gene therapy led to a robust antiviral response. At 21 to 36 months after treatment, there was no evidence of genotoxicity from insertional mutagenesis.<sup>87</sup>

---

## Designing a Clinical Vector Laboratory

Gene therapy holds much promise for the treatment of malignant and nonmalignant diseases. But, just as there is the potential for benefit, there is also the potential to cause harm. Safety measures are being put into place at all levels from the basic science laboratories and centers where the work is being tested to the establishment of federal regulations designed to safeguard the patients, the people working with the transgenes, and the general public. The clinical stem cell laboratory, where gene therapy vectors are applied to the cells ex vivo, must be compliant with very stringent regulations designed to maintain safety and sterility. These complex and thorough regulations need to be followed in order to be within the limits of current good manufacturing practice (cGMP) regulations. By definition, cGMP regulations are “methods to be used in, and the facilities or controls to be used for, the manufacture, processing, packing, or holding

of a drug to assure that such drug meets [safety] requirements ... and meets the quality and purity characteristics that it purports or is represented to possess.”<sup>88</sup> The cGMP requirements are put into place to ensure that all procedures are performed in as safe and controlled a manner as possible. All of the general principles of cGMP are outlined by the FDA in the Code of Federal Regulations (CFR) in 21 CFR 210 and 211, 21 CFR 600s, and 21 CFR 820. Some of the key elements of cGMP encompass raw materials, maintenance of equipment, complete standard operating protocols, validation, record-keeping, and personnel training. Several professional organizations including the Foundation for the Accreditation of Cell Therapy and AABB have voluntarily established comprehensive standard-setting and accreditation programs that encompass all phases of cell collection, processing, and transplantation. Additional standards specifically for gene therapy are under constant development and improvement by the United States Pharmacopoeia (USP), the USP Biotechnology and Gene Therapy Subcommittee, and its Advisory Panel on Gene and Cell Therapies.<sup>88</sup>

## Summary

Gene therapy continues to offer much promise for the treatment of genetic and acquired diseases. Gene therapy has been used to treat patients with X-SCID, ADA-SCID, CGD, and HIV, and applications to other diseases are currently being tested in clinical trials. Transfusion medicine laboratories are currently involved in clinical gene therapy trials and, in the future, when these therapeutic modalities are approved, will oversee what may be “routine” administration of gene therapy vectors and vector-infected cells. This oversight requires extensive knowledge of cGMP as well as risk prevention/infection control in gene therapy.

**Clay Quint<sup>1</sup> & Laura Niklason<sup>2</sup>**<sup>1</sup> Fellow, Biomedical Engineering, Yale University School of Medicine, New Haven, Connecticut, USA<sup>2</sup> Associate Professor, Anesthesiology and Biomedical Engineering, Yale University School of Medicine, New Haven, Connecticut, USA

The fields of tissue engineering and regenerative medicine have evolved into a unified discipline with an interdisciplinary approach being a large part of the merger. The first use of the term tissue engineering in the public domain was at the proceedings of the Granlibakken workshop in 1985<sup>1</sup>: "Tissue engineering is the application of principles and methods of engineering and life sciences toward fundamental understanding of structure-function relationships in normal and pathological mammalian tissues and the development of biological substitutes to restore, maintain, or improve tissue function." This was a broad definition that focused on the incorporation of living cells into acellular, related structures as a source for tissue replacements. In addition to providing a definition of tissue engineering, the basic components necessary to create a tissue-engineered product were identified. These components included a cell source, a method to induce specific tissue growth, and a biomaterial to act as a scaffold.<sup>2</sup> The principles of tissue engineering have been translated to clinical applications with the Food and Drug Administration (FDA) approval of products in the areas of skin substitutes, bone formation, and cartilage. Tissue engineering has the potential to revolutionize medical care by replacing diseased or damaged tissue without the use of conventional organ or tissue transplantation.

---

**Overview of Tissue Engineering**

A cell source or method that can be used for all cell lineages and has the required characteristics to make it safe, reproducible, and without any immunologic rejection has not been developed. The options for a cell source are primary autologous, allogeneic, xenogeneic, or stem cells. Cells can be cultured with low rates of bacterial contamination through the use of antibiotics

and sterile technique. However, concerns about xenogeneic contamination remain if feeder cells or sera from other species are used in the cell culture conditions. An alternative to primary tissue is to induce progenitor cells to differentiate into a specific cell type. Difficulties associated with the usage of primary tissue often include the need for an operative procedure, inability to obtain sufficient normal cells, inability of cells to proliferate, and the presence of cells with the same genetic predisposition for development of a disease. Another complication of primary cell sources is the need to efficiently isolate a specific cell lineage with low contamination rates from other cell types. Cell sorting methods, such as magnetic or fluorescent cell sorting, provide a reliable method if the cell type has specific membrane proteins with known antibodies.

**Stem Cell Sources**

Stem cells are an attractive cell source for tissue engineering applications. Adult stem cells or human embryonic stem cells each offer their own set of advantages and challenges. Adult stem cells can typically be harvested by less invasive procedures from marrow, fat, or skin. Because these cells are autologous, no immunosuppressive medications are needed when the tissue is implanted in the donor. Purification difficulties and a reduced differentiation potential of adult stem cells as compared to embryonic cells, however, prevent use of these cells for all applications. Adult stem cells do not involve human embryos or any of the ethical controversies related to the collection of embryonic cells. The potential use of embryonic stem cells has created a national debate over ethical issues, because an embryo must be destroyed to harvest the cells. In the United States a limitation currently exists on public funding but not on private funding for human embryonic stem cell research.

**Scaffolds**

A scaffold should enable the creation of a three-dimensional formation of tissue in vitro and in vivo. Properties for the ideal tissue-engineered scaffold are the support of cell attachment, ability for the cells to proliferate and differentiate, allowance for

diffusion of nutrients and waste, and ability to simulate mechanical properties found *in vivo*.<sup>3</sup> Biomaterials can be categorized as synthetic polymers, natural materials, or inorganic matter; they can also be classified as being biodegradable or permanent.<sup>4</sup>

The preference for tissue-engineered scaffolds has been on biodegradable natural materials and polymers. Natural materials include collagen, gelatin, fibrinogen, dextran, glycosaminoglycans, and chitin. Examples of biodegradable synthetic polymers are polylactic acid (PLA), polyglycolic acid (PGA), and polycaprolactone (PCL). The properties of natural materials are their similarity to the native biologic environment, minimal toxicity, and degradation by natural enzymes.<sup>4</sup> The limitations of natural materials include batch-to-batch variability from different animal sources, and potential immunologic reactions if materials are of xenogeneic origin. The most commonly used FDA-approved biodegradable synthetic polymers are polyglycolic acid and polylactic acid. These synthetic polymers are degraded by hydrolysis. Copolymers of PGA and PLA can be designed in specific ratios to match the degradation process for the individual tissue requirements.<sup>4</sup>

Scaffold fabrication techniques provide a variety of methods to form a structure, alter the mechanical properties, and change the degradation rates. Fibers can be woven or knitted to form structures with controlled pore sizes.<sup>5</sup> The molecules self-assemble under the appropriate conditions. Natural materials, such as components in the extracellular matrix, often are capable of forming scaffolds by self-assembly.<sup>5</sup> Solvent casting and particulate leaching techniques involve dissolving a polymer in a solvent, and then casting into a mold filled with a porogen (eg, sodium chloride or gelatin). Gas foaming is a process wherein a polymer is prepared by compression molding, or where the gas, for instance CO<sub>2</sub>, is dissolved into the polymer melt. The structure is exposed to high pressure CO<sub>2</sub>; then, as the pressure is reduced, pores remain when the CO<sub>2</sub> evacuates.<sup>3</sup> Electrospinning is a method in which a polymer forms nanofibers as an electrified jet is deposited on a metallic collector.<sup>3</sup>

## Skin Tissue Engineering

The field of skin tissue engineering has developed in response to the clinical need for skin substitutes. The clinical applications that skin substitutes have focused on are burn injuries and chronic wounds. The estimated incidence of deaths from fire and burns in the United States is 4500 each year, and there are approximately 45,000 hospitalizations per year to treat burn injuries.<sup>6</sup> Chronic wounds that require skin substitutes are caused by arterial occlusive disease, venous disease, and pressure ulcers. These wounds affect more than 2 million people in the United States.<sup>7</sup> Although the need for skin substitutes in this group is less acute than in the burn group, the morbidity as a result of these chronic wounds is significant. For patients with nonhealing lower leg ulcers, such wounds can eventually lead to an amputation.

## Structure and Function

The structure of skin consists of the surface epidermis and the deeper layer of connective tissue, the dermis. The epidermis is mostly keratinocytes, which are responsible for the barrier function and strength of the epidermis. The connective tissue layer of the dermis contains fibroblasts, few adipose cells, blood vessels, mast cells, nerve endings, hair follicles, and glands. The main component of the connective tissue matrix is collagen, with other matrix molecules such as elastin and reticulin. The skin functions to provide a barrier between the body and the external environment, and to provide sensation, temperature regulation, and vitamin D production. The most important function of the skin as related to skin substitutes is for the epidermis to restore the skin barrier.

The origins of the field of tissue engineering derived from the establishment of skin substitutes. The early leaders in this field in the 1980s were Burke and Yannas at the Massachusetts General Hospital and Massachusetts Institute of Technology.<sup>8</sup> They developed a bilayer artificial skin substitute with a temporary silastic epidermis and collagen dermis that could support the growth of dermal fibroblasts from the wound bed.<sup>8</sup> Other investigators developed similar methods using allogeneic keratinocytes with collagen gel or on PGA mesh.<sup>9</sup> The first skin substitutes were approved by the FDA in the late 1990s for applications of venous leg ulcers and for temporary covering of partial-thickness burns.

## Design Goals for Skin Substitutes

An intact epidermal layer provides a barrier function to prevent fluid losses and to inhibit infection. An ideal skin substitute will permanently heal into the wound bed to replace the dermal and epidermal layers in a timely manner, to form a desirable cosmetic result, to have minimal risk of infection or immunologic rejection, and to have a low cost. The standard material for covering large burn wounds is an autologous split-thickness skin graft. Autologous skin grafts function to permanently heal into the wound bed, contain an epidermal and dermal component, and have no risk of immunorejection. Skin substitutes are a viable alternative to autografts because they are readily available, do not require donor site harvest, and allow for better healing than dressing changes alone. The skin substitutes provide a temporary coverage over the wound; eventually, they get rejected or require a secondary thin epidermal autograft. Because most of the skin substitutes do not heal into the wound, they promote healing by stimulating cytokines and growth factors in the wound bed to recruit and direct host cells to repair the wound site.<sup>10</sup>

Early alternatives to the standard of autologous skin grafts were allogeneic skin grafts and porcine xenogeneic skin grafts. Allogeneic skin grafts have been the preferred material for temporary coverage as a skin substitute over xenografts. The beneficial properties of the allogeneic skin graft are that it prevents desiccation of the wound, prevents fluid losses, has a dermal component, and stimulates repair of the wound bed for eventual

placement of an autograft.<sup>11</sup> Porcine skin grafts are temporary skin grafts that have similar properties to allogeneic skin grafts, with the addition of being more readily available and cheaper. Because allogeneic and xenogeneic grafts do not incorporate into the wound, these grafts carry the potential risk of infection and eventual immunorejection.<sup>11</sup>

### **Acellular Skin Substitutes**

The group of acellular skin substitutes includes Biobrane, AlloDerm, Integra, and TransCyte. Biobrane (UDL Laboratories, Rockford, IL) is a synthetic bilaminar skin substitute that was introduced in 1979. The outer layer is silicon rubber, while a secondary layer consists of a nylon mesh that is covalently bound to Type I porcine collagen.<sup>4</sup> The outer layer silicon pore size allows for drainage of exudate and permeability to topical antibiotics, but the small pore size acts as a barrier to bacterial invasion.<sup>4</sup> Additional properties of Biobrane are adherence to clean wounds, stimulation of ingrowth of cells from the wound bed, ease of application, and a shelf life of at least 3 years. Biobrane may be used for superficial partial-thickness burns, over a meshed autograft, and in donor sites. Biobrane has demonstrated a reduced time to re-epithelialization when compared to traditional therapy of topical antibiotics and dressing changes for burn injuries.

AlloDerm (LifeCell, Branchburg, NJ) is a dermal skin substitute that removes epithelial cells from harvested human skin to leave an acellular dermal matrix. AlloDerm is approved for treatment of partial to full-thickness burns and chronic wounds. AlloDerm has similar properties to allogeneic grafts, except the immunologic response is reduced because of the processing of the tissue.<sup>12</sup> The clinical use of AlloDerm for partial-thickness or full-thickness burns is similar to that of the dermal component, but an ultra-thin autograft is needed over the AlloDerm. The advantage of the ultra-thin autograft is that it reduces the morbidity or loss of donor site grafts, due in particular to scar formation. It has been shown that an acellular allograft with a thin autograft produces equivalent healing rates at 14 days in comparison to split-thickness skin grafts.<sup>13</sup> Further case studies have demonstrated high success rates of AlloDerm with a split-thickness autograft.<sup>14</sup>

Integra (Integra Life Sciences, Plainsboro, NJ) is a bilayer skin substitute that was approved in 1996 for use in partial-thickness and full-thickness burns. The dermal component is a biodegradable collagen-chondroitin-6-sulfate matrix with an epidermal layer that is a thin silicone elastomer. The thin silicone layer acts as a barrier to bacteria and controls moisture loss. The dermal component encourages the adherence and growth of the wound bed. After 2 to 3 weeks when a neodermis has formed, the thin silicone layer is removed and then covered with a thin autograft.

TransCyte (Advanced Tissue Sciences, La Jolla, CA) is also a bilayer skin substitute that was approved in 1997 for temporary coverage for partial-thickness or full-thickness burns with autografting. The outer epidermal component is a silicone thin

film with an inner dermal layer consisting of a nylon mesh coated with porcine dermal collagen with ingrowth of neonatal human fibroblasts. The material is cryopreserved, which destroys the metabolic activity of the fibroblast cells, but the tissue growth factors and matrix remain intact. The growth factors and complex matrix components may create an environment more favorable for the adherence and migration of fibroblasts. TransCyte has demonstrated faster healing times and reduced scar formation in comparison to topical antibiotics in partial-thickness burns.<sup>15</sup>

### **Allogeneic Skin Substitutes**

The allogeneic skin substitutes that are FDA-approved include Apligraf, Dermagraft, and OrCel. Apligraf (Organogenesis, Canton, MA) is a bilayer structure with Type I collagen gel and allogeneic fibroblasts that form a dermal equivalent, onto which allogeneic keratinocytes are seeded to provide an epidermal layer. Dermagraft (Dermagraft, Westport, CT) is a single-layer skin substitute using allogeneic fibroblasts cultured onto a bioresorbable glycolic acid scaffold. OrCel (Forticell Bioscience, New York, NY) is a bilayer material with fibroblasts cultured in a porous sponge as the dermal layer with keratinocytes seeded on the nonporous side of the matrix. Although the fresh form of OrCel is available, a cryopreserved formulation is in clinical trials. The mechanism of wound healing for these skin substitutes is not clearly understood, but they seem to stimulate epithelialization by the fibroblasts' release of growth factors and extracellular matrix to provide recruitment of endogenous cells.<sup>16</sup> The function of the allogeneic fibroblasts likely contributes a temporary response to the wound healing, because at 4 weeks after treatment, only two of 10 patients had Apligraf DNA in the wound site.<sup>17</sup> Apligraf, Dermagraft, and OrCel have all shown improved rate of wound closure when used for chronic ulcers in comparison to conservative treatment with dressing changes.<sup>18,19</sup> The primary application for the allogeneic skin substitutes is for the treatment of chronic ulcers or acute wounds, with limited use for partial-thickness or full-thickness burn injuries. Currently available skin substitutes are listed in Table 61-1.

The current skin substitutes constituted the first step in using tissue-engineered products for clinical applications. These skin substitutes have demonstrated some of the potential successes and challenges that remain to create an ideal tissue-engineered equivalent. The limitations of the existing materials are related to the allogeneic cells that seem to function by recruiting host cells for wound healing instead of primarily contributing to wound healing. Cultured epidermal autograft techniques are not suitable for widespread application because only the epidermis can be created, without a true bilayer structure. The results of the cultured epidermal autografts have been disappointing because they are fragile, require a dermal layer, and require weeks to grow in culture.

The future of skin substitutes may incorporate adult mesenchymal stem cells (MSCs) and gene therapy strategies for optimization. The design of a tissue-engineered skin graft could contain

autogenous cells in a bilayer structure with a dermal and epidermal component. The use of marrow MSCs cultured with autogenous dermal fibroblasts may enhance epidermal regeneration.<sup>20</sup> Gene therapy can be used to upregulate the delivery of growth factors or cytokines to expedite the regenerative process. In animal models, gene delivery with epidermal growth factor has been shown to dramatically accelerate healing.<sup>21</sup> However, for wound healing the upregulation of growth factors should be transient, because continued gene expression might result in adverse effects. The advancement of skin substitutes and a better understanding of the biology of wound healing will likely lead to the development of rationally based designs to specifically treat the pathology of the wound.

## Blood Vessel Tissue Engineering

Cardiovascular disease is the leading cause of mortality in the United States.<sup>30</sup> More than a million arterial bypass procedures performed annually require autologous vessel or synthetic grafts to replace coronary or peripheral arteries.<sup>31</sup> More than 500,000 coronary bypass artery graft procedures are performed annually in the United States, and peripheral disease results in more than 100,000 amputations each year.<sup>30,32</sup> The therapeutic modalities to treat cardiovascular disease are medical treatments, catheter-based interventional procedures, and surgical procedures. The medical treatments focus on disease

modification by treating conditions that lead to cardiovascular disease such as management of hypertension, hyperlipidemia, and diabetes, and cessation of smoking. The interventional procedures such as angioplasty, stents, or thrombolytic therapy offer a less invasive treatment than does surgery for patients with occlusive vessel disease. The surgical options for vascular disease are bypass surgery, endarterectomy, or open thrombectomy.

The currently available conduits for bypass procedures include autologous artery or vein, prosthetic material, and cadaveric vein. Autologous tissue provides the best outcome; however, autologous tissue in many patients may not be available or may not be suitable. Prosthetic materials, such as polytetrafluoroethylene (PTFE) and Dacron, perform well for large-diameter arteries in peripheral vascular disease. In contrast, no prosthetic material is well-suited for small-diameter (less than 6 mm) applications.<sup>33</sup> Another growing area of need for bypass procedures is hemodialysis—more than 250,000 patients require chronic hemodialysis access and frequent graft replacement.<sup>34</sup> Tissue engineering technology has the potential to generate engineered arterial grafts for multiple applications in cardiovascular surgical therapy.

## Structure and Function

A blood vessel is composed of the intima, media, and the adventitia.<sup>35</sup> The intima contains the endothelium, lamina propria, and the internal elastic lamina. The media contains the smooth

muscles arranged concentrically, elastin and collagen fibers, and the external elastic lamina. The adventitia contains connective tissue, fibroblasts, vasa vasorum, and nerve cells. Arterial blood vessels are classified as elastic arteries, muscular arteries, and arterioles. The large elastic arteries have higher elastin content and fewer smooth muscle cells relative to diameter than other vessel types. Muscular arteries contain a greater number of smooth muscle cells in proportion to their diameter, and the adventitia is composed of a thicker layer of connective tissue in comparison to the elastic arteries. The arterioles consist of a thin layer of smooth muscle and range from 40 microns to 9 microns in diameter.<sup>35</sup>

### Design Goals for a Tissue-Engineered Vessel

The primary design goal of a tissue-engineered blood vessel is to create a graft that will maintain patency in small-diameter applications, eg, 2 to 6 mm. The desirable features of the tissue-engineered vessel are a patency rate comparable to autologous vein, similar mechanical properties to a native artery or vein, minimal immunologic or infective risk, a reasonable time to produce the grafts, and cost effectiveness. The reported 5-year patency rates using autologous vein grafts for below-the-knee applications are 50% to 76%.<sup>33</sup> However, the patency rates for below-the-knee bypass with PTFE have a 2-year patency rate of 30% and only 18% after 5 years.<sup>36,37</sup> In cardiac bypass, the 10-year patency rate of autologous vein is 50%.<sup>38</sup> The current blood vessel prosthetics, Dacron and PTFE, both cause platelet and fibrin deposition that leads to thrombosis. Tissue-engineered grafts probably need some amount of lead time to culture, which could limit their clinical utility for some patients. New technology using tissue-engineered grafts will likely be more expensive than the current prosthetic materials. However, because there are no effective, synthetic, small-diameter grafts, the increase in cost for a tissue-engineered graft could be justified when considering reduced cost of chronic wound management, multiple surgical procedures with ineffective material, and reduction in patient morbidity.

### Cell Source

The predominant two cell types that form a vessel are smooth muscle cells and endothelial cells. The contribution of the live smooth muscle cells may not be critical for the function of the tissue-engineered vascular graft. Many tissue-engineered models take advantage of the process of decellularization to reduce the immunologic reaction.<sup>39</sup> The decellularized scaffold is able to maintain the tissue architecture and the extracellular matrix components to encourage repopulation of the graft with host cells.<sup>40,41</sup> The function of the endothelial cell layer on the lumen is to maintain an antithrombotic environment. Studies have shown that without an endothelial coating for a tissue-engineered small vascular graft, there is a significantly higher rate of thrombosis.<sup>41,42</sup> The options for obtaining endothelial cells

from a recipient patient are to use primary vascular endothelial cells, or to isolate progenitor endothelial cells from the marrow or the peripheral blood. Primary endothelial cells from endogenous veins have the benefit of established isolation techniques that reliably produce endothelial cell cultures. The limitations to using a primary endothelial cell source are that it requires an operation to harvest a vein, derived endothelium is venous rather than arterial, and that they will have been exposed to potential disease processes. The most common source for endothelial progenitor cells is from the peripheral blood, although there are also reports of obtaining progenitor cells from marrow. The endothelial progenitor cell can be defined as a cell that has high proliferative capacity, is capable of clonal expansion, and can differentiate into endothelial cells. The first description of endothelial progenitor cells was by Asahara and colleagues in 1997.<sup>43</sup> They demonstrated that the isolated cells from the peripheral blood mononuclear fraction that were sorted for CD34, expressed cell surface markers of endothelial cells such as vascular endothelial growth factor receptor-2 (VEGFR-2) and were positive for CD31. In addition, these progenitor cells exhibited functional properties of endothelium, by production of nitric oxide in response to acetylcholine and to VEGF.

### Scaffold

There are several approaches to developing a scaffold for tissue-engineered vessels. One approach is to use cells to form an extracellular matrix without a synthetic scaffold, while the other approach is to use synthetic polymers or natural materials to form the cell culture scaffold. In the first approach, L'Heureux and colleagues cultured sheets of fibroblasts or smooth muscle cells and wrapped the sheets around a mandrel (scaffold) in several layers to form a tubular structure.<sup>44</sup> The burst pressure, compliance, and the wall thickness were all similar to native arteries.<sup>44</sup> The biomimetic system developed by Niklason and colleagues for small-diameter vessels calls for placing aortic smooth muscle cells on a PGA scaffold under pulsatile flow for 8 weeks.<sup>42</sup> The PGA scaffold degrades, and the resulting vessel is composed primarily of smooth muscle cells and collagen. The tissue-engineered vessel does exhibit contractile properties, although at 20% that of native vessels. The mechanical properties demonstrate burst pressure and compliance similar to native vessels.<sup>42</sup> Other approaches use a collagen gel that is coated with a microporous polyurethane film.<sup>45</sup> The collagen gel is compressed to remove water, and then wrapped with the polyurethane film. The compliance of such constructs in the higher strain range is similar to native arteries.<sup>45</sup> Bruch et al created a tissue-engineered graft by mixing fibrinogen and thrombin in equal volumes into a mold with specific length and diameter.<sup>46</sup> The only mechanical characterization was burst strength, which was significantly less than native arteries.<sup>46</sup> A combination method evaluated in animal models has been to decellularize a native vessel and then to seed this with endothelial cells.<sup>41</sup> There is evidence to suggest that decellularization invokes minimal immunologic

reaction, in comparison to cryopreserved vessels, which lead to moderate immunologic reaction.<sup>47</sup> The tissue-engineered graft developed by Shin'oka et al was designed for low-pressure venous systems, using a copolymer lactide and  $\epsilon$ -caprolactone 1:1 scaffold.<sup>48</sup> The graft is seeded with marrow cells at the time of operation and then sprayed with fibrin sealant, after which the graft is implanted.

### Bioreactor Design

The two most successful bioreactor designs for tissue-engineered vessels are to wrap sheets of fibroblasts around a mandrel or to use a flow bioreactor system to culture a vessel from smooth muscle cells. The first method involves obtaining a skin biopsy to culture fibroblasts.<sup>44</sup> The fibroblasts are grown in sheets, and the first sheet is wrapped around a mandrel to form a tubular structure. The inner sheet is dehydrated to form an acellular inner membrane. Additional sheets of living cells are then placed around the inner membrane, and the tissue remains in culture to mature. The last step of this process involves obtaining endothelial cells harvested from saphenous vein to coat the luminal surface of the graft. The entire process takes approximately 28 weeks to form a vessel for implantation. The second technique is to obtain smooth muscle from a vessel biopsy, and to seed the smooth muscle on a biodegradable PGA scaffold.<sup>42</sup> The scaffold with the cells remains static for 1 week to allow for attachment, and then the construct is exposed to pulsatile flow for 7 to 8 weeks. The luminal side of the graft can be seeded with endothelial cells. This process takes around 10 weeks total to create a vessel for implantation.

### Preclinical Data

Table 61-2 lists some of the important animal models that have combined a cell source with a scaffold to produce a functional vascular graft. L'Heureux recently reported using the fibroblast

sheet scaffold and primary endothelial cells in a nude rat model and an immunosuppressed primate model.<sup>49</sup> The patency rates in both of these studies are high, and there were no graft mechanical failures. In Argentina this has been approved for a clinical study for arteriovenous graft in kidney failure patients and in England for coronary bypass graft.<sup>50</sup> These studies are ongoing and actively enrolling patients. The tissue-engineered smooth muscle grafts seeded with primary endothelial cells by Niklason (unpublished observations) also had high patency rates in a porcine carotid model and no incidence of mechanical failure. Niklason's group has demonstrated the mechanical stability of the tissue-engineered grafts after a decellularization process. The option of decellularization would allow for increased availability with the advantage of being able to create an artery and then to store the construct until needed. Other in-vivo studies have used a decellularized native vessel, and then coated the acellular construct with endothelial cells derived from peripheral blood endothelial progenitor cells.<sup>41</sup> The patency rate could be attributed to the activity of the endothelial cells because they were fluorescently labeled and remained on the graft at the time of harvest. The Matsuda group that used a collagen gel with a microporous polyurethane film combined their unique scaffold with endothelial cells that were derived from endothelial progenitor cells.<sup>48,51</sup> They also had very high patency rates in their carotid canine implant model, and the endothelial cells derived from progenitor cells provided a nonthrombotic environment. An interesting blood vessel graft for the application of large vein bypass for infants has achieved clinical success in Japan. Shin'oka has used a polylactide/caprolactone-reinforced PGA mesh coated with marrow mononuclear cells.<sup>48</sup> In the case study, they performed a cavopulmonary bypass in 23 patients and a sheet graft in 19 patients. The median follow-up was 16.7 months with a 100% patency rate and without any major complications.

PGA = polyglycolic acid; SMC = smooth muscle cell.

## Future of Vascular Tissue Engineering

The field of vascular tissue engineering has demonstrated proof-of-principle methods with various scaffolds and cell sources that are now ready to emerge in the clinical arena. The animal studies provide insight into the potential of the application, but further human trials are needed to determine efficacy once the safety of these devices has been verified in animals. Tissue-engineered vessels appear to be the next generation of small-diameter bypass grafts to address the growing need for alternative materials for small-caliber arterial replacement. If the tissue-engineered grafts perform close to autologous veins in terms of mechanical characteristics and nonthrombotic surface, the morbidity and mortality of cardiovascular disease could be dramatically reduced.

---

## Bone Tissue Engineering

Bone tissue regeneration is a potential clinical treatment to replace loss of skeletal function for orthopedic and oral-maxillary applications. The most common needs for bone replacement materials are for trauma, tumor, infection, and inborn skeletal disorders. The current bone replacement materials are derived from autologous bone, allogeneic bone, demineralized bone matrices, and synthetic biomaterials. The first choice for bone repair has been the autologous bone graft.<sup>53,54</sup> The advantages of autologous tissue are a lack of an immune reaction and the provision of bone cells for osteogenesis. In addition to the direct osteogenic effects, the autologous bone graft can stimulate recruitment of other mesenchymal cells through stimulation by bone morphogenic proteins.<sup>54</sup> However, the use of autologous bone grafting is limited by the morbidity associated with the donor site. The usual sites to harvest bone grafts are the iliac crest and the fibula. After the procedure, up to 20% of patients have significant pain at the donor site.<sup>55</sup> In a large review of iliac crest donor sites, major complications included vascular injuries, deep infections, neurologic injuries, and deep hematoma, with a combined incidence of 6%.<sup>56</sup> An alternative to autologous bone grafting is allogeneic bone grafts. The mechanical properties of processed allogeneic bone tissue are similar to autologous bone, although the ability to induce bone healing is reduced.<sup>53</sup> For smaller defects, such as bone chips in a distal radial fracture or for use in a cervical fusion, allogeneic bone seems to be comparable to autologous bone.<sup>57,58</sup> Allogeneic bone groups had a longer time to fusion in cervical fusion, but this did not affect the fusion rate or collapse rate.<sup>58</sup>

The acrylic bone cements are a biomaterial that has been introduced for fixation of hip prostheses and to repair craniofacial defects. They provide mechanical support, but do not integrate into the bone and are minimally reabsorbed. This results in long-term failure at the interface between the bone and the prosthetic, which has led to metal prostheses coated with hydroxyapatite that do not use bone cement. The cementless hydroxyapatite-coated prosthesis is under investigation to improve osseointegration and prevent bone remodeling that

leads to long-term failure.<sup>59</sup> Another new material for craniofacial defects is a hydroxyapatite-based paste. The paste is readily available, can be easily molded into shape, demonstrates osteoconduction, has good mechanical strength, lacks immune response or risk of viral transmission, and has the potential for bone replacement.<sup>60</sup>

## Structure and Function

Bones are composed of extracellular bone matrix and bone cells that form the shape of long, short, flat, or irregular bones.<sup>35</sup> The bone matrix consists of an organic component of collagen and proteoglycans. The inorganic component of the bone matrix is a calcium phosphate crystal called hydroxyapatite. The bone cells can be classified as osteoblasts, osteoclasts, and osteocytes. Osteoblasts are bone cells that produce collagen, proteoglycans, and form bone. The osteoclasts are the cells responsible for the breakdown of bone by producing an acidic environment that causes decalcification of the bone matrix. The osteocytes are osteoblasts that are surrounded by matrix. The interaction of bone cells with hormones regulates the homeostasis of calcium and phosphate in the blood.

## Scaffold

The structure of the scaffold for bone regeneration is related to the function of bone. A bone scaffold should provide means of cell migration and proliferation, generate appropriate mechanical strength, integrate into the native bone matrix, stimulate vascularization, slowly degrade with increasing cellular infiltration, and not elicit an immunologic reaction. For example, the different requirements for the strength of long bones and for the flexibility of craniofacial bones may lead to the development of different scaffolds for these applications. The matrices used for bone tissue engineering can be classified as calcium phosphate derivatives or as synthetics. Hydroxyapatite is a calcium phosphate compound that is the primary component of bone. Hydroxyapatite as a scaffold offers a high degree of biocompatibility, the osteoconductive potential of hydroxyapatite, and slow degradation. Hydroxyapatite is a porous material that will allow ingrowth of bone and vascular cells.<sup>61</sup> However, hydroxyapatite implants are known to be brittle and lack pliability to conform to irregular forms.<sup>61</sup>

Hydroxyapatite cements have been approved for clinical use for non-stress-bearing cranial defects. The clinical experience with one of the hydroxyapatite bone cements in 100 patients over a minimum of 2 years demonstrated a success rate of 97% and a low rate of infection.<sup>62</sup> Hydroxyapatite cements can be used for craniofacial repairs because they integrate into the bone and can be easily shaped to fit unique three-dimensional structures.<sup>62</sup> The properties of calcium phosphate or hydroxyapatite grafts can be altered by integrating other biomaterials to form a composite material. The composites that investigators have evaluated include calcium phosphate-chitosan, calcium phosphate-poly(lactic acid), and hydroxyapatite-collagen scaffolds. The purpose for fabricating composite calcium phosphate is to

improve the biodegradability and the bioactivity. Pore size and porosity are important factors in bioactivity, affecting cell adhesion, cell growth, the exchange of nutrients and waste products, and vascularization. A calcium phosphate-chitosan composite has shown improved strength characteristics in comparison to calcium phosphate cement alone.<sup>63,64</sup> The fast-setting composite material is prepared by mixing a calcium phosphate-mannitol powder with chitosan water to form a paste that can be molded into shape or injected.<sup>63</sup> A composite material of collagen and hydroxyapatite has been shown to support bone cell growth and act as a biocompatible material *in vivo*.<sup>65,66</sup> There are different processing techniques to produce collagen-hydroxyapatite composites, such as gels, films, coatings, and hydroxyapatite-collagen matrices. The hydroxyapatite-collagen material creates a favorable environment for cell attachment and growth, and the cells are functional as assessed by the deposition of new bone.<sup>66</sup>

### Vascularization

A vascular supply for a tissue-engineered bone graft is necessary for bone growth and survival. The two approaches to vascularize a bone graft are to rely on angiogenesis of the donor, or to form a vascular network within the graft before implantation. The current bone graft substitutes depend on vascularization through angiogenesis from the donor after implantation of the scaffold with bone cells. An explanation for the success of bone tissue engineering in rodents in comparison to larger animal models is that the marrow-seeded grafts in rodents are small enough to allow for diffusion of oxygen and nutrients to allow cell survival before angiogenesis and new vessel formation.<sup>67</sup> One method to improve vascularization is to stimulate angiogenesis on the graft. This may be accomplished by adding a combination of growth factors such as VEGF, platelet-derived growth factor-BB, and transforming growth factor- $\beta$  (TGF- $\beta$ ).<sup>68,69</sup> In a rat cranium bone tissue engineering application, the addition of VEGF was shown to improve vascularization and bone mineralization.<sup>70</sup> However, it is not clear if the addition of the growth factors will vascularize a bone graft in a short enough time to maintain cell viability in a larger graft, such as that required for patients.

The second method would be to vascularize the graft before implantation by heterotopic bone induction or to form a vascular network within the graft *in vitro*. Warnke and colleagues reported a successful extended mandible reconstruction by growth of a custom bone transplant from the latissimus dorsi muscle of an adult male patient.<sup>71</sup> The custom bone transplant was prepared with a titanium mesh that was coated with recombinant bone morphogenic protein 7 (BMP-7) and seeded with marrow aspirate. The bone construct was implanted into the latissimus dorsi muscle for 7 weeks, then was transplanted as a free bone-muscle flap to repair the mandibular defect. A postoperative computed tomography (CT) scan demonstrated new bone formation, and a nuclear scan showed bone remodeling and mineralization inside the mandibular transplant. *In vitro*, bone tissue engineering strategies could utilize a co-culture system to

form a vascular network using endothelial cells in a matrix that is later seeded with marrow cells.

### Growth Factors

Bone morphogenic proteins are osteoinductive factors that can be used to coat scaffolds. BMPs are glycoproteins that belong to the TGF- $\beta$  family and bind to extracellular matrix components. BMPs are the biologically active component in demineralized bone matrix that leads to formation of new bone.<sup>72</sup> BMP-2 and BMP-7 are involved in bone formation and osteoblast differentiation. These recombinant proteins have been used for applications such as spinal fusions, internal fixation of fractures, treatment of bone defects, and reconstruction of maxillofacial conditions. BMPs stimulate bone repair through recruitment, proliferation, and differentiation of MSCs.<sup>73</sup> Preclinical studies have demonstrated the efficacy of BMPs in healing a variety of bone defects in many different animal models. The bone formation and healing of long bone defects with recombinant BMP-2 and collagen scaffolds has been demonstrated in rats, rabbits, and dogs.<sup>74-76</sup> Similar results have been shown with BMP-7 and collagen scaffolds in healing long bone defects in multiple animal species.<sup>77,78</sup>

Two recombinant BMP devices have been approved by the FDA. OP-1 (Stryker Biotech, Hopkinton, MA) has been approved for spinal fusion procedures under the humanitarian device exemption process. The OP-1 device is recombinant BMP-7 and bovine collagen combination that is used to form a paste.<sup>79</sup> The other device is the Infuse Bone Graft/LT-CAGE (Medtronic, Minneapolis, MN).<sup>79</sup> The indication for the device is for lumbar spinal fusion to treat degenerative disc disease. The device consists of a metallic spinal fusion cage with rh-BMP-2 on a bovine collagen scaffold inside the cage.

### Cell Source

The options for osteogenic cells in bone engineering are osteoblasts, periosteal cells, and MSCs. Osteoblasts and periosteal cells can be isolated from a biopsy of the calvarium, periosteum, or trabecular bone.<sup>80,81</sup> Osteoblasts and periosteal cells are autologous, primary cell sources for bone engineering. Mesenchymal stem cells are utilized for bone regeneration, because the cells have a large proliferative potential, can be differentiated down osteogenic lineage, and can be harvested by a less invasive marrow aspiration procedure. The most common cell source for bone tissue engineering applications is currently MSCs.<sup>82</sup>

Mesenchymal stem cell differentiation to osteogenic cells was first described by Friedenstein.<sup>83</sup> Mesenchymal stem cells have been induced to differentiate into osteoblasts, chondrocytes, adipocytes, and myoblasts.<sup>84</sup> Caplan was the first to take advantage of the potential of MSCs by seeding the cells onto a porous calcium phosphate ceramic.<sup>85</sup> In a subcutaneous *in-vivo* rat model, they demonstrated osteogenesis with an early phase resulting from the implanted mesenchymal cells and a late bone growth phase resulting from the host cells. Since these early papers, there have been many studies on the use of MSCs for bone tissue

engineering applications. The use of MSCs on biomaterial scaffolds has accelerated bone formation and bone integration in vivo. Mesenchymal stem cells improved osteogenic potential directly by differentiating into osteoblasts, and indirectly by releasing bone growth factors that enhance migration and differentiation of endogenous osteogenic cells.<sup>86</sup>

Preclinical and Clinical Studies

The evaluation of new cell-based therapies for bone repair are predominantly in the preclinical stages, with only a few human case reports. There are many studies optimizing scaffolds and evaluating the function of the MSCs. A limited number of groups are studying the challenging task of using a biomaterial in combination with a cell source to repair large osseous defects in animal models. All of the studies in Table 61-3 demonstrate that an MSC-seeded scaffold produces significantly greater bone formation than cell-free grafts, and in most of the studies the MSC-seeded scaffolds resulted in similar bone formation as bone grafts. In addition to the use of calcium phosphate as the scaffold, investigators have also used coral. The rationale for coral as a scaffold is the porous structure and more rapid degradation of coral in comparison to calcium-phosphate-based materials.<sup>87</sup> The more rapid degradation time of the coral may reduce the inflammatory response and allow for growth of new bone tissue more quickly.<sup>88,89</sup> The number of cells seeded may be an important variable for bone growth in the implanted graft. High cell density at the time of seeding may have a negative impact on the graft by not allowing the cells to spread out on the graft and proliferate. Another consequence of high cell density without adequate vascularization is the formation of a hypoxic environment in the center of the graft.<sup>87,89</sup>

Case reports have described bone tissue engineering in clinical practice. Vacanti et al reconstructed a distal thumb avulsion with periosteal cells and a coral scaffold.<sup>93</sup> At 3 months the patient was able to return to work, and at 28 months the thumb had normal length and strength. In a separate study, three patients with large bone defects in the extremities were treated

with marrow cells and macroporous hydroxyapatite scaffold.<sup>94</sup> All three patients recovered limb function. Thus, in the appropriately selected patients, it appears that bone tissue engineering concepts can be applied to repair bone defects in humans.

Conclusion

Bone tissue engineering has the potential to provide better treatment options for bone reconstruction in orthopedic, craniofacial, and plastic surgery. Bone tissue engineering may provide a material that will integrate into native bone for a complete functional recovery, without the morbidity associated with autologous donor bone harvest. The integration of marrow MSCs with an optimized scaffold that includes some combination of BMPs will enhance the local environment for bone growth and remodeling by the native tissue. The most efficient technique to vascularize large bone grafts is an important area of research that is needed to improve bone graft survival. The challenges remain to create products that address the wide spectrum of clinical needs, from pliable materials for facial reconstruction to the strength required for long bone reconstruction.

Cartilage Tissue Engineering

The motivation for cartilage tissue engineering is to improve treatments for cartilage degeneration that is caused by disease, trauma, or congenital abnormalities. Some examples of cartilage disorders are osteoarthritis, cartilage injuries, herniated disc, costochondritis, and achondroplasia. Osteoarthritis is the most common cause of arthritis and the leading cause of disability that primarily affects middle-aged and elderly population.<sup>95</sup> The incidence of osteoarthritis in people older than 75 is greater than 80%, and radiologic evidence in those older than 50 is greater than 50%.<sup>96</sup> As the population in the United States continues to age, the demand for treatments that allow patients to maintain an active lifestyle will increase. The surgical options are arthroscopic surgery or joint replacement, although the efficacy of

arthroscopy with debridement or joint irrigation of the knee has been recently challenged.<sup>97</sup> Joint replacement surgery is indicated when the patient no longer responds to nonpharmacologic and drug treatments.

### Structure and Function of Cartilage

The structure of cartilage is composed of a dense extracellular matrix with embedded chondrocytes.<sup>35</sup> The extracellular matrix includes collagen Type II fibers, elastin fibers, and proteoglycans that give cartilage viscoelastic and mechanical properties. Cartilage is avascular and relies on diffusion for nutrients, oxygenation, and removal of waste. The three types of cartilage are hyaline, elastic, and fibrocartilage. Hyaline cartilage is the most common form of cartilage, and consists primarily of Type II collagen and proteoglycans. Hyaline cartilage forms the skeleton of the embryo, which is later converted to bone as the embryo matures. In adults, hyaline cartilage can be found in the trachea, larynx, nose, bronchi, load-bearing joints, and the ends of the ribs. Elastic cartilage contains collagen and elastin fibers; it is found in the pinna of the ear and forms the epiglottis. Fibrocartilage contains more collagen than hyaline, and is found in areas that require great tensile strength. Fibrocartilage is located between intervertebral discs, between the articulations of the hip, and at segments connecting tendons or ligaments to bone. The function of cartilage is to reduce friction of articulating bones and to assist with load bearing.<sup>35</sup>

### Cell-Based Therapies

One cell-based treatment for the repair of cartilaginous lesions is autologous chondrocyte implantations. A first procedure requires the harvesting of cartilage from non-load-bearing region of bone. The tissue is cultured and chondrocytes are isolated and expanded. In a second procedure, the lesion is surgically debrided and the chondrocytes are implanted under a periosteal flap. However, the conclusion of a recent systematic review of three trials and nine case reports revealed there was not sufficient evidence that autologous chondrocyte implantation is more effective than alternative therapies for chondral lesions of the knee.<sup>98</sup> Two other reviews of available evidence by the National Institute of Clinical Excellence and Blue Cross and Blue Shield Association concluded that autologous chondrocyte implantation is not recommended over alternative treatments.<sup>99,100</sup>

### Cell Source

The cell sources for cartilage are harvested primary chondrocytes or MSCs that are induced to differentiate into chondrocytes. Primary chondrocytes can be harvested from articular, septal, auricular, and costal cartilage. Studies have reported different findings on the characteristics of cartilage harvested from various sites in animal models.<sup>101-103</sup> Human nasal chondrocytes proliferate faster than articular chondrocytes, possess a higher chondrogenic potential, and survived 6 weeks implantation into nude mice. Hence, nasal cartilage may be a better cell source than articular cartilage for tissue engineering applications.<sup>101</sup>

Primary chondrocytes can be stimulated to proliferate and differentiate by various factors. Chondrocytes dedifferentiate during in-vitro expansion in monolayer culture, taking on a fibroblast-like morphology and producing macromolecules such as collagen Type I and versican.<sup>104</sup> Chondrocytes can be induced to redifferentiate by the addition of growth factors, forming pellets at a high cell density, and by growth in a three-dimensional scaffold.<sup>105,106</sup> The addition of specific growth factors, such as TGF $\beta$ -1 and basic fibroblast growth factor (FGF), to monolayer cultures has been shown to induce dedifferentiation and enhance the proliferative capacity of the cells in animals and in humans.<sup>106,107</sup>

Many growth factors and combinations of growth factors have been investigated to optimize MSC differentiation into chondrocytes. Basic FGF (FGF-2) has been identified as the most potent mitogen in the FGF family to promote chondrogenesis and proliferation of MSCs.<sup>108</sup> Mesenchymal stem cells induced with FGF-2 in pellets differentiated to chondrocytes in rabbit, dog, and human species.<sup>109</sup> The formation of cartilage from MSCs was superior with FGF-2 in comparison to other growth factors, such as insulin-like growth factor, epidermal growth factor, and platelet-derived growth factor.<sup>110</sup> BMP-2 is found in the mesenchyme of the developing limb and is known to stimulate cartilage formation in culture. Human MSCs in the presence of BMP-2 in a serum-free pellet culture system resulted in chondrogenic lineage development only. Cells from osteogenic or adipogenic lineage were not stimulated with BMP-2. The addition of BMP-2 to mesenchymal pellet culture system appeared to produce cartilage with higher amounts of proteoglycans in comparison to BMP-4 or BMP-6.<sup>111</sup>

### Scaffold

Scaffold materials for cartilage tissue engineering are collagen, hyaluronan, fibrin sealant, and synthetic polymers. Collagen is a good biomaterial for cartilage tissue engineering applications, because it is biocompatible, biodegradable, can be molded into specific forms, and can maintain chondrocyte phenotype vis-à-vis glycosaminoglycan production.<sup>112</sup> In animal models, collagen-based scaffolds with chondrocytes have resulted in better healing in osteochondral injury models than other types of scaffolds. One method to reduce the dedifferentiation of chondrocytes with collagen is to add hyaluronic acid. Hyaluronic acid is a proteoglycan that acts to lubricate joint surfaces and assists cartilage to withstand compressive forces.<sup>113</sup> Hyaluronan must be modified by esterification or other means for structural purposes and to optimize solubility, hydration, and degradation.<sup>114</sup>

A fibrin matrix can also support the growth of chondrocytes, and an in-vivo model demonstrated regeneration of cartilage with articular cartilage defects using a fibrin system.<sup>115</sup> The preparation of fibrin needs to result in a stable gel that can support the growth of chondrocytes, otherwise fibrin gels have been known to shrink in size and degrade in a very short time.<sup>115</sup> Fibrin gels have been produced that are stable with good mechanical strength, and in-vitro cultures have shown

chondrocytes proliferate in these gels with the production of glycosaminoglycans and collagen Type II.<sup>115</sup>

The synthetic polymers PLA and PGA were investigated as cartilage scaffolds early in the study of cartilage tissue engineering. In-vitro studies demonstrated the biocompatibility of PGA with chondrocytes, and early rabbit model studies demonstrated a better healing response of PGA seeded with chondrocytes over PGA scaffold alone.<sup>116</sup>

PGA-seeded scaffolds have resulted in the greatest production of glycosaminoglycans by chondrocytes at 20 days in comparison to alginate, fibrin, and collagen.<sup>117</sup> A concern with the application of PLA/PGA polymers is an inflammatory reaction that develops after hydrolysis of the polymer. However, a laryngotracheal rabbit model with a PLA/PGA copolymer had appropriate clinical function of the implants at the time of harvest at 12 months. The scaffolds were completely resorbed without signs of a chronic inflammatory response.<sup>118</sup> Despite the success in animal models, no PLA/PGA-based materials have progressed to clinical trials.

### Bioreactor Culture System with Mechanical Stimulation

The parameters that have the greatest impact on the production of cartilage in a bioreactor are cell seeding density, mass transfer as modulated by shear stress, and compressive forces.<sup>119</sup> The seeding density of chondrocytes must be balanced by maximizing cell number to produce more extracellular matrix, without using too high of a cell number that limits mass transfer. Limited mass transfer can result in non-uniform cell distribution with higher cell numbers at the surface of the scaffold. The methods to apply shear stress and enhance mass transfer are mechanically stirring the bioreactor, direct perfusion of medium through scaffolds, and a rotating-wall bioreactor that imparts low shears and stirring.<sup>119</sup> Besides the desirable increased stimulation of extracellular matrix, the stirred mechanical systems also produce a more even distribution of cells over the scaffold. A direct perfusion system is a flow system where a cell suspension or media alone directly passes through the pores of the three-dimensional scaffold. Experiments using a direct perfusion culture system demonstrated an increase in the DNA content and an increase in glycosaminoglycans over static culture conditions.<sup>120</sup> However, the tissue-engineered perfused cartilage still has significantly less collagen in comparison to native cartilage.

Compressive forces stimulate differentiation of MSCs to chondrocytes and contribute to structural maintenance of articular cartilage in vivo. The two types of forces that in-vitro systems use are hydrostatic force and compressive force. In vivo, hydrostatic pressure is produced on the chondrocytes by the synovial fluid transmitting pressure to the water contained in the cartilage matrix.<sup>119</sup> Physiologic levels of hydrostatic pressure are in the range of 7 to 10 MPa, and because cartilage is incompressible in this range, only minimal tissue deformation occurs.<sup>121,122</sup> The duration of hydrostatic pressure, total time of application, and magnitude are variables that need to be optimized for cartilage tissue engineering applications. The most common ranges of loads are 0.1 to 15 MPa and the ranges for frequencies are

0.05 to 1 Hz.<sup>119,123,124</sup> Studies have shown that chondrocytes in an agarose scaffold with a strain of 3% to 10% at a frequency of 1 Hz and a culture time of 4 to 6 weeks have an increase in the amount of proteoglycan and collagen in comparison to static cultures.<sup>125,126</sup> In another study by Waldman, bovine chondrocytes were seeded onto a calcium polyphosphate scaffold with 5% compression at 400 cycles per day at a frequency of 0.5 Hz.<sup>127</sup> The scaffold and cells were stimulated every other day for 1 to 4 weeks, with the addition of either 2% shear or 5% shear. The combined 5% compression and 5% shear increased collagen synthesis by 76% and proteoglycan synthesis by 73% over the static controls. The authors noted that greater responses to uniaxial loading, shear, or compression alone, were observed in prior studies.

### Clinical Applications

Tissue engineering of articular cartilage could provide an alternative cell-based therapy to autologous chondrocyte implantation. Because autologous chondrocyte implantation has not shown significant improvements in patients with chondral lesions, other therapeutic options are needed for treatment of these lesions.<sup>98</sup> The only tissue engineered cartilage graft is Hyalograft C (Fidia Advanced Biopolymers, Abano Terme, Italy), which is not FDA-approved but is available in Europe. Hyalograft C is composed of autologous chondrocytes grown on a three-dimensional hyaluronic-based scaffold called HYAFF 11. The scaffold is an esterified derivative of hyaluronic acid that is biodegradable and biocompatible.<sup>128</sup> In a recent multicenter study from Italy, autologous chondrocytes were isolated from a cartilage biopsy harvested arthroscopically from a non-weight-bearing area in the knee. The cells were expanded in vitro and then cultured on the HYAFF 11 scaffold for 14 days. The engineered graft was implanted at the lesion site by a mini-arthrotomy under regional or general anesthesia. In 55 of the 141 patients, a biopsy of the implanted cartilage was taken and evaluated using the International Cartilage Repair Society visual scoring system. At a mean follow-up time of 38 months after the procedure, 71.4% of the patients stated they could do everything or nearly everything that they wanted to do with their joint compared to 4.3% before the surgery. The visual scoring of the repaired tissue at the postsurgery arthroscopy revealed normal or near normal scores in 53 of 55 patients after a mean implantation time of 14.1 months. There were 10 graft failures, which was 5.2% of the study group. The authors stated a limitation of the study was in the design of an observational trial instead of a randomized controlled trial. In a follow-up study to further characterize the nature of the biopsied tissue, biochemical analyses were applied.<sup>128</sup> The average follow-up time from grafting to biopsy was 16 months, with a range of 6 to 30 months. Ten of the 23 cases demonstrated regenerated hyaline cartilage, but a larger sample size is needed to make more definite assessments.

### Future Challenges

The challenge of cartilage tissue engineering remains to develop a therapeutic treatment for cartilage disease or injury. The

success of Hyalograft C in improving clinical symptoms is encouraging, but further evaluation of the mechanical properties and the long-term graft efficacy needs to be undertaken. A reliable cell source has been obtained by primary cell harvest, and MSCs offer an even better potential. By selecting the appropriate cell density, growth factors, mechanical stimulation, and scaffold, tissue-engineered cartilage can be successfully designed for clinical applications.

## Urology Tissue Engineering

The urinary system is exposed to a variety of insults that require reconstruction as a treatment. Frequent reasons for reconstruction in the urinary system include congenital abnormalities, cancer, trauma, infection, and iatrogenic injuries. The primary option for bladder and urethral reconstruction involves the use of gastrointestinal tissue. One congenital anomaly that may require the need for bladder reconstruction is exstrophy of the bladder. The prevalence of bladder exstrophy is 3.3 births per 100,000.<sup>129</sup> The initial treatment for this bladder defect is early primary closure. However, in some cases the bladder is too small for closure or the bladder does not develop to maintain continence. In these cases, tissue harvested from the small bowel or colon is used to augment the size of the bladder.<sup>129</sup>

Cancer of the urinary bladder is the fourth most common cause of cancer in men, and the ninth most common in women.<sup>129</sup> Invasive bladder cancer is treated by radical cystectomy with urinary diversion. The use of selective bladder preservation or partial cystectomy is inferior to radical cystectomy for invasive cancer, meaning that total bladder replacement could significantly enhance quality of life for these patients.<sup>129</sup> Blunt trauma is another cause of urinary tract injury, often associated with pelvic fractures or straddle injuries for the urethra. In the case of large defects that require diversion of the urinary system, use of gastrointestinal tract tissue is the only option.

Bowel segments that are mobilized for bladder reconstructions are associated with various complications. Complications include mucus production, chronic bacteruria, stone formation, rupture, electrolyte imbalance, and metabolic acidosis with a range of incidence from 5% to 44%.<sup>130,131</sup>

### Design Goals for Urinary Tissue

The objective of urinary tissue engineering is to provide an alternative source of tissue that is more similar to native bladder or urethra. The requirements for bladder tissue engineering are to act as a reservoir for urine, contract until empty, integrate with sites of anastomosis to prevent leakage, have mechanical strength to prevent rupture, and not cause excessive stone formation. The structure of the bladder is a hollow muscular organ that functions as a reservoir to hold urine until time of excretion through the urethra. The bladder is composed of transitional epithelium, lamina propria, muscular layer, and an adventitia. The transitional epithelium forms a layer of four to five cells when the

bladder is empty, and two to three layers when the bladder is distended.<sup>35</sup> The viscoelastic properties of the bladder are derived from the smooth muscle, the collagen content of approximately 50%, and elastin content of approximately 2%.<sup>129</sup> The bladder has a physiologic compliance that contains neural input to set the volume for micturition.<sup>129</sup>

### Cell Source

The most common cell source for bladder tissue engineering is a primary cell source from urothelial cells and visceral smooth muscle cells. Primary urothelial cells are autologous and have been demonstrated to expand the cells from a surface area of 1 cm<sup>2</sup> to 4202 cm<sup>2</sup> over a period of 8 weeks.<sup>132</sup> Phenotype and functional characteristics of harvested human visceral smooth muscle cells from normal, exstrophic, and neuropathic bladders have been evaluated. No differences between the normal and diseased bladder tissue with respect to phenotype and degree of contractility were observed.<sup>133</sup> An alternative potential cell source is marrow stem cells or embryonic stem cells that have not been exposed to fibrotic or malignant changes. Because marrow cells can differentiate into smooth muscle, investigators have evaluated if the smooth muscle cells have a similar phenotype and function if placed on a scaffold for bladder applications. One group reported bladder smooth muscle and marrow-derived smooth muscle had similar expression of actin and contractile response to calcium ionophore.<sup>134</sup> An in-vivo study in a hemicystectomy dog model with bladder cell-seeded or marrow cell-seeded small intestinal submucosa graft had similar outcomes in both grafts. After 10 weeks, the two implants had similar levels of alpha-actin with evidence of smooth muscle regeneration and muscle bundle formation.

### Scaffold

The main scaffold types for urologic tissue engineering are synthetic polymers and natural materials derived from acellular tissue matrices. It has been demonstrated that the adherence and proliferation of bladder smooth muscle cells appears to be similar across synthetic polymers, eg, poly(lactic-co-glycolic) acid (PLGA) and PCL.<sup>135</sup> Hybrid materials, such as a PLGA mesh-collagen gel, have also been shown to support the growth of urothelial and smooth muscle cells. The purpose of using a hybrid scaffold is to take advantage of the mechanical strength of the synthetic polymers and the cell adhesion properties of the collagen gel.<sup>136</sup> Tissues that are used to create an acellular matrix for bladder scaffolds are small intestine submucosa, native bladder tissue, and bladder submucosa.<sup>137,138</sup> Bladder replacement grafts composed of small intestine submucosa have demonstrated regeneration of normal bladder with urothelium, smooth muscle, and serosal layers in canine and rat models.<sup>138</sup>

### Preclinical and Clinical Trials

The tissue-engineered bladder has progressed from in-vitro models to a clinical trial. The canine and rabbit models have demonstrated the success in creating an autologous neo-bladder

in vivo. Table 61-4 lists some of these studies that describe the cell source, scaffold, and the outcome. The Atala group has successfully proliferated the bladder urothelial and smooth muscle cells from a small biopsy, and used a cell-free bladder construct as the scaffold. They demonstrated in a canine 50% cystectomy model that the cell-seeded graft had a 99% increase in the capacity of the bladder.<sup>137</sup> Histologic analysis confirmed the presence of nerve fibers in the tissue-engineered bladders. The Atala group has also been applying the same method for urethral replacement.<sup>139</sup> In the study by Kropp in 2004, well-expanded bladders were generated with acellular porcine small intestine submucosa (SIS) in a canine cystectomy model using cell-free grafts.<sup>138</sup> A later study by Kropp revealed improved results with bladder cell-seeded SIS or marrow-derived smooth muscle cell-seeded SIS in comparison to the control group of cell-free scaffolds.<sup>134</sup> In a third study of a canine bladder replacement cystectomy of 90%, the cell-seeded and cell-free scaffolds produced similar results of poor bladder regeneration.<sup>140</sup> The authors attribute the lack of bladder regeneration to a poor vascular network and increased inflammation produced by the large implants. The viability of the implanted graft depends on vascular ingrowth from the surrounding tissues, and the vascular network may not have been able to develop at a rapid enough rate to support such a large tissue graft. The increased inflammation may have been a result of the technique to create the large defect.

In a recent publication, the successful techniques for bladder regeneration in animal models were translated to a human trial.<sup>141</sup> The study identified seven patients with a primary diagnosis of myelomeningocele with poorly compliant bladders. The age range of the patients was from 4 to 19 with a mean age of 11 years. The cell source was from a bladder biopsy, and the scaffold was made from collagen or from a composite of collagen and polyglycolic acid. The scaffold for the first four patients was made of decellularized bladder submucosa. The last three

patients used the composite material that was sized for each individual based on age-appropriate bladder size and dimensions obtained from CT scan. The length of time between the bladder biopsy and the tissue-engineered bladder implantation was approximately 7 to 8 weeks. The patients were followed for 22 to 61 months with a median time of 46 months. The postoperative urodynamic studies with the tissue-engineered bladders showed varying degrees of contractility, capacity, and compliance. The volume and the compliance increased postoperatively, with the most significant improvement in the composite tissue-engineered scaffold that was implanted with an omental wrap. The results of the urodynamic studies were similar to those of gastrointestinal segment augmentations, and the patients did not develop any of the complications associated with the gastrointestinal segment augmentation. The authors commented that they added the composite material to the study because the PGA improved the structural integrity of the tissue while the collagen continued to support cell growth. The positive preliminary data from this trial led to a Phase II trial to provide more data on the efficacy of the tissue-engineered approach to bladder augmentation.

### Future Challenges

The use of tissue-engineered bladders in a clinical application demonstrates the exciting opportunities in the field of urothelial tissue engineering. Additional improvements in the existing approach may be to use marrow stem cells as a smooth muscle cell source, providing a vascular network before implantation, stimulation of neuronal integration into the graft, and continued optimization of the scaffold. Although there is evidence to suggest that viable bladder cells can still be harvested from diseased tissue, if bladder smooth muscle cell can be derived from marrow stem cells it may be a more attractive alternative cell source. Another potential clinical application is bladder reconstruction

after cancer resection, utilizing harvested cells from an area of bladder without any neoplastic changes. The application of bladder tissue engineering for large cystectomies may require a vascular network before implantation, as suggested by data from the canine model.<sup>140</sup> The neuronal integration of the graft is important to restore the natural voiding mechanism. The clinical data demonstrated in myelomeningocele patients that the urodynamics and the dry intervals between straight catheterizations improved postoperatively.<sup>141</sup> Optimization of the scaffold for more desirable properties such as improved mechanical characteristics and improved control over degradation in response to tissue remodeling are two key issues. As tissue-engineered products progress from case studies to commercial applications, process methods to reduce the potential of infection and to achieve high-quality standards will be important issues for these new medical devices.

## Cardiac Tissue Engineering

Cardiovascular disease is the leading cause of mortality in the United States. The number of people in the United States with one or more types of cardiovascular disease is approximately 1 in 3.<sup>30</sup> Patients who survive a myocardial infarction experience myocardial damage that can eventually result in congestive heart failure. Other causes of heart failure include hypertension, cardiomyopathy, valvular disease, and cardiac arrhythmias. The number of deaths related to heart failure increased 28% in the period of 1994 to 2004.<sup>142</sup> The mortality data for heart failure is comparable to that of cancer. The pathophysiology of heart failure is the inability of the heart to maintain adequate cardiac output because of injury to the cardiac myocytes that causes an increase in wall stress and forward pumping failure.<sup>143</sup>

The treatment options for severe heart failure range from pharmacologic therapy to heart transplant. The nonpharmacologic treatments include cardiac resynchronization, coronary revascularization, left ventricular assist device implantation, and heart transplantation. The number of people requiring heart transplantation continues to increase, but the number of people receiving heart transplants has been on the decline over the past 10 years.<sup>144</sup> The 1-year survival for heart transplants is approximately 87%, and the 5-year survival is approximately 77%.<sup>144</sup>

### Design Goals for Cardiac Tissue

The heart is a muscular organ that functions as a continuous pump through rhythmic contraction and relaxation cycles. The three layers of the heart are the epicardium, myocardium, and the endocardium.<sup>35</sup> The epicardium is the outer layer of the heart that provides a smooth layer to prevent friction while the heart is beating. The endocardium is the cell layer lining of the interior of the myocardial wall to create an antithrombotic surface and functions to interact with the circulating blood. The primary layer that forms the heart is the myocardium. The myocardium contains specialized cardiac muscle cells that are striated, involuntary

muscle with many branching cells that are joined by unique intercalated disks.<sup>35</sup> The intercalated disks are gap junctions that permit electrical communication that can pass impulses to a large area of the heart wall, thereby stimulating contraction.

The primary objective of cardiac tissue engineering in the near future will likely be the engineering of patches of myocardium to replace specific areas of diseased heart tissue. The challenge of engineering an entire heart with the ability to contract appropriately with separate chambers, adapt appropriately to physiologic stimuli, and respond to further cardiac disease progression appears too difficult to reach within a reasonable time given current technologies.<sup>145</sup> Another application of cardiac tissue engineering would be to use engineered cardiac tissue for reconstruction of pediatric congenital defects. The use of engineered tissue could potentially grow with physiologic development and prevent multiple surgeries for malformations such as single ventricles, atrial septal defects, or ventricular septal defects.<sup>145</sup>

The alternative cell-based therapies to cardiac tissue engineering are cardiomyocyte transplantation and the injection of marrow-derived cells, or other types of precursor cells, directly into myocardium. Cardiomyocyte transplantation has been studied in animal models by directly injecting fetal or neonatal cardiomyocytes into the injured myocardium. The positive findings of cardiomyocyte transplantation have included beneficial effects on the remodeling process in animal studies.<sup>146,147</sup> Despite moderate improvements in contractile performance related to the remodeling process, cardiomyocyte transplantation cannot replace scar tissue and restore synchronously contractile muscle.<sup>146,148</sup> The major limitation in translating this technology to human clinical trials would be the availability of cardiomyocytes. The intracoronary injection of marrow mononuclear cells, or other marrow-derived cells, in the setting of an acute myocardial infarction in humans, has thus far yielded no improvement in left ventricular function or minimal improvement in recovery.<sup>149,150</sup> Further studies, however, are ongoing.

### Cell Source

Marrow stem cells have been shown in some studies to differentiate into cardiac myocytes.<sup>151,152</sup> Primary cardiac cells are probably not a viable cell source in humans, because they are difficult to harvest and do not readily expand. Cardiac cells derived from rat marrow expressed proteins consistent with cardiomyocytes in vitro, and in a rat infarct model the transplanted cells improved the cardiac structure and function of the heart.<sup>153</sup> Rodent myocardial infarct animal models with cardiac cells derived from marrow have shown improved cardiac function and better ejection fraction with less remodeling of the left ventricle.<sup>152,153</sup> The challenge remains to develop an efficient method to isolate and to differentiate marrow stem cells into cardiac cells, particularly for human patients.

### Scaffold

The synthetic polymers and natural materials have been used for cardiac tissue engineering scaffolds. A study comparing PGA, gelatin, and polylactide copolymer with PCL using rat aortic

smooth muscle as the cell source found the PCL material to have better ingrowth of cells *in vitro* and improved cellular architecture as a cardiac patch compared to the PGA and gelatin.<sup>154</sup> The gelatin scaffold was noted to induce an inflammatory reaction, which was attributed to the xenogeneic (bovine) protein in the gelatin. Natural material using alginate-based scaffolds can form a three-dimensional structure with a uniform cell distribution of cardiomyocytes.<sup>155</sup> A graft composed of fetal cardiac cells in an alginate scaffold was implanted in a myocardial infarct model in rats and was found to undergo intensive neovascularization and had prolonged survival of the cells in the graft.<sup>156</sup> The alginate scaffold was almost completely degraded after 9 weeks, and it was well-invested with differentiated cardiomyocytes.<sup>156</sup>

Collagen gels have been used to form three-dimensional scaffolds that support cardiomyocyte cells. It has been shown that artificial myocardial tissue can be formed from neonatal rat cardiomyocytes inside a three-dimensional collagen matrix.<sup>157</sup> The constructs were prepared by adding a cell solution to preformed, commercially available collagen that was allowed to gel over 4 hours. The collagen matrix was found to support the attachment, proliferation, and synchronous contractions of the neonatal cardiomyocytes in the three-dimensional scaffold. The spontaneous and synchronous contractions were maintained for up to 13 weeks. Zimmermann<sup>158</sup> formed engineered heart tissue by mixing a cell solution of neonatal rat cardiac cells with collagen gel and Matrigel (Becton Dickinson, Franklin Lakes, NJ). After a few days, the constructs were placed in a custom-made stretch device to provide mechanical stimulation. The *in-vitro* tissue demonstrated histologic features of native differentiated myocardium and contractile characteristics of native myocardium. By exposing the cell constructs to stretch stimulation, the force of contraction was greater than twofold in the stretch group compared to the statically grown tissue.<sup>159</sup>

A novel method to engineer cardiac tissue has been developed by Shimizu. The concept is to use a temperature-responsive polymer called poly(*N*-iso-propylacrylamide) (PIPA Am) that covalently attaches to tissue culture polystyrene and supports the growth of cells. When the temperature is lowered to 32°C, the PIPA Am with the cells spontaneously detaches from the underlying polystyrene, with the cell-to-cell connections of the cultured tissues on the upper surface intact.<sup>160</sup> This material has been applied to rat neonatal cardiac cells to create sheets that can be layered together to form a three-dimensional myocardial tissue structure. Electrical and morphologic connections between the cell sheets have been demonstrated.<sup>160</sup>

## Bioreactors

The objective of bioreactor development in cardiac tissue engineering is to stimulate the growth of a three-dimensional structure that is conditioned by mechanical or electrical stimulation. A bioreactor system with a spinner flask causes turbulent flow that results in improved mixing for nutrient and oxygen delivery in comparison to static cultures.<sup>161</sup> Other designs of bioreactor designs have applied stretching or compression to cultured

cells. The exposure of myocardial cells to cyclic stretch resulted in improved proliferation and more uniform distribution of cardiomyocytes on the scaffold, as well as improved organization and more extracellular matrix.<sup>162</sup> The use of electrical stimulation with neonatal rat myocytes has been shown to induce structural differentiation similar to native myocardium, and an increased contractile response in comparison to nonstimulated cultures.<sup>163</sup> One important limitation to the growth of cardiac tissue for human applications is the thickness of the tissue. The thickness of human cardiac muscle is about 1 cm, whereas the thickness of cardiac tissues grown in bioreactor systems is only 100 microns.<sup>164</sup> Lacking a vascular network, cardiac tissue cannot grow significantly beyond 100 microns because delivery of nutrients and removal of waste is limiting.<sup>164</sup> Although bioreactor systems have resulted in great improvements, the next big challenge is to develop a construct and a bioreactor system that provide adequate perfusion to thicker cardiac constructs.

## Preclinical Studies

The preclinical data for myocardial tissue engineering remain in the early stages, with most investigators using neonatal or fetal rodent cells for evaluation of cardiac tissue engineering patches in animal models. In a study by Krupnick, a cardiac patch 4 mm × 4 mm × 2 mm was created with marrow MSCs as a cell source and a scaffold composed of a composite collagen and PLA material reinforced with PTFE.<sup>165</sup> The patches were implanted into the left ventricle of a rat nonfunctioning left ventricle model over a period of 4 weeks. The marrow cells integrated into the host and formed differentiated cardiac muscle by the cell morphology and cytoplasmic reactivity of anti-Troponin C. The authors suggested a cardiac patch could be implanted for human use to replace myocardial scar after infarction concurrently with coronary revascularization. However, the authors commented that a limitation of the animal model is that murine species are relatively resistant to arrhythmias.

Leor and colleagues engineered cardiac grafts with fetal cardiac cells using three-dimensional alginate scaffolds for the regeneration of infarcted myocardium.<sup>156</sup> The porous alginate scaffold was seeded with fetal cardiac cells and incubated for 4 days before implantation. The graft implantation was performed 7 days after myocardial infarct in a rat model and harvested 9 weeks after transplantation. The rats with the grafts demonstrated attenuation of left ventricular dilatation and no change in left ventricular contractility. In contrast, the control group developed significant left ventricular dilatation with progressive deterioration in left ventricular contraction. The cardiac grafts were found to have intensive neovascularization that contributed to the survival of the cells in the graft. The beneficial effects of the graft on cardiac contractility were not likely directly caused by contraction of the implant, because only a small fraction of the implanted cardiac cells survived after 9 weeks.

Zimmermann has reported the construction of an engineered heart tissue that can be constructed *in vivo* and can improve contractile function of an infarcted rat model.<sup>166</sup> The engineered

heart tissue was formed using a suspension of neonatal rat heart cells, liquid collagen, and Matrigel that was formed into circular molds and were subjected to mechanical strain. The myocardial infarct model in the rat was created by ligation of the left anterior descending artery. The engineered heart tissue and control, noncontractile grafts were implanted 14 days after infarct over the area of myocardial scar. The engineered heart tissue showed undelayed electrical coupling comparable to the native myocardium without evidence of arrhythmia at 28 days. The engineered heart tissue prevented further dilation and induced systolic wall thickening of infarcted myocardial segments, superior to control implants.<sup>166</sup>

### Future Challenges

The main challenges for cardiac tissue engineering are a reliable autologous cell source, and the vascularization of large tissues. Most of the studies utilize fetal or neonatal cardiac cells as a cell source. However, an autologous cell source from marrow or other cells is critical to advance cardiac tissue engineering for human applications. Clearly, it may be difficult to obtain viable cardiac cells from older patients with diabetes and other diseases because of impaired proliferative and functional capacity.<sup>167</sup> Methods to isolate, differentiate, and proliferate marrow-derived or other cells to produce cardiomyocytes need to be developed. After implantation, any cardiac graft will depend on neovascularization to maintain cell survival. Even if cell sheets can be used as layers to create a thicker construct, without a vascular network the cells would likely not survive. The potential applications for cardiac tissue engineering are a concurrent augmentation of scar tissue that occurs at the time of coronary revascularization and the reconstruction of congenital cardiac defects.

---

## Corneal Tissue Engineering

A bioengineered cornea has the potential to restore vision when the loss is caused by opacification of the cornea. The cornea is essential to provide the proper anterior refractive surface and to protect the eye against infection and structural damage. The most common causes of opacification of the cornea are injuries or infection that lead to corneal scarring, abnormal shapes of the cornea, and congenital disorders of the cornea.<sup>168</sup> Diseases affecting the cornea such as measles, vitamin A deficiency, trachoma, and parasites are common causes of childhood blindness worldwide.<sup>168</sup> Corneal transplantation is the only widely accepted treatment for severe corneal diseases. The success rate of traditional allograft corneal transplantation is greater than 90% for patients with corneal disorders such as abnormal corneal shapes, traumatic corneal scars, and degeneration.<sup>169</sup>

### Objectives of Tissue-Engineered Cornea

The cornea is composed of an epithelial layer and an endothelial layer. The epithelium is a stratified squamous layer approximately four to six cell layers thick.<sup>168</sup> The tight junctions of the

epithelial cells provide a barrier to bacteria and prevent the entry of tears into the intracellular space. The basal layer of the epithelium contains epithelial stem cells that generate new corneal epithelial cells. The corneal endothelium is a hexagonal monolayer that maintains the fluid regulation of the corneal stroma. The endothelial layer maintains a high water content of around 78%, which ensures a cellular architecture that forms a transparent tissue.<sup>168</sup>

Although the primary treatment for severe corneal disease is corneal allograft transplantation, allograft rejection is the main cause of graft failure in corneal transplantation. The rate of rejection after 5 years has been reported at around 20%.<sup>170</sup> Topical corticosteroids are the mainstay treatment for immunologic rejection. Potential risk factors for immunologic rejection are increased stromal vascularization, prior blood transfusions, positive donor-recipient crossmatch due to preexisting lymphocytotoxic antibodies, young recipient age, larger grafts, and the presence of inflammation at the implantation site.

Synthetic corneal replacements, or keratoprotheses, provide an additional treatment option to those patients who are not candidates for allograft corneal transplantation. The design of the synthetic corneal prosthesis is a flexible material with an optically clear core that is surrounded by a microporous sponge rim.<sup>171</sup> The optical core functions to transmit light and provide refractive power, while the sponge rim is designed to permit fibroblast ingrowth to secure the device into place over the long term. Two FDA-approved keratoprotheses are available for clinical use.

The Dolman-Doane keratoprosthesis is double-plated, and is composed of a central core of polymethylmethacrylate (PMMA) that requires corneal donor tissue to form the rim.<sup>172</sup> The most favorable outcomes using the Dolman-Doane device are for patients with multiple failed grafts, repeated immunologic rejection of corneal allografts, and neovascularization of a corneal graft.<sup>172</sup> The postoperative course must be closely followed for retroprosthetic membrane formation, glaucoma, and retinal detachment.

AlphaCor, previously known as Chirila keratoprosthesis, is a one-piece prosthesis consisting of a central transparent optic region and an outer rim that is entirely manufactured from hydrophilic poly(2-hydroxyethyl methacrylate) or PHEMA. The porosity of the PHEMA sponge encourages biointegration with the host tissue to promote fibroblast ingrowth. AlphaCor has been successful in the treatment of corneal opacities that are not suitable for standard allograft corneal transplantation.<sup>173</sup> The complications of AlphaCor include corneal melting and the formation of retroprosthetic membranes.

### Cell Source

The cell source for corneal tissue engineering is corneal limbal epithelial cells or oral epithelial cells. Severe ocular surface diseases such as Stevens-Johnson syndrome, ocular cicatricial pemphigoid, and chemical or thermal burns often destroy the corneal epithelial stem cells.<sup>174</sup> In unilateral eye disorders, autologous

cultured corneal epithelial cells may be harvested from the unaffected eye and cultured as a sheet. Culture systems have been developed to proliferate and expand corneal epithelial cells that are harvested from primary tissue. In the earliest report of autologous cultivated corneal epithelial cells by Pellegrini, a biopsy from the limbus of the uninjured eye was obtained.<sup>175</sup> The autologous cultured corneal epithelium was implanted onto the cornea of two patients, and was found to restore the corneal surface with a significant improvement in visual acuity. A similar technique used by other investigators placed the biopsied corneal epithelial cells on denuded amniotic membrane in co-culture with a feeder layer of 3T3 fibroblast cells for 2 to 4 weeks.<sup>176</sup> After implantation of the tissue-engineered cornea, the patient had complete epithelialization with a significant improvement in visual acuity that remained stable.<sup>177</sup>

In patients who have bilateral ocular surface defects, the options are to use allogeneic cultured epithelial cells or epithelial cells from another tissue in the patient. The risk of using allogeneic cultured epithelial cells is an increased incidence of rejection and poor clinical outcome. In a small study by Koizumi, cultured allogeneic epithelial cell transplantation was performed in 13 eyes of 11 patients having total corneal stem cell deficiencies using amniotic membrane as a cell carrier.<sup>176</sup> This study resulted in all 13 eyes being free from epithelial defects after 48 hours, visual acuity being improved in all 13 eyes, and 10 of the 13 being restored to good function. Three of the eyes experienced epithelial rejection. To obviate allogeneic cells and immunorejection, epithelial cells from the oral mucosa have also been used for corneal applications.<sup>178</sup> A feasibility study was conducted in a rabbit model with an induced ocular surface injury. Oral mucosa biopsies were cultured for 3 weeks on a denuded amniotic membrane carrier. The cultured oral epithelial sheet had four to five layers of stratified cells with a similar micro-architecture to normal corneal epithelium.

### Scaffold

The scaffolds for corneal tissue engineering function more as carrier substances than as conventional scaffolds. The materials used as the carrier include amniotic membrane and fibrin-based materials. The characteristics that make amniotic membrane appealing for use as a carrier for the growth of epithelial cells are its ready availability, very limited immunogenicity, antimicrobial effect, and the fact that it resembles the basement membrane of the conjunctival epithelium.<sup>174</sup> The early reports of use of amniotic membrane for ocular surface reconstruction in rabbit animal models showed that resultant corneas were clear with minimal amounts of neovascularization.<sup>179</sup> The effect of the amniotic membrane suggested that it facilitated epithelialization without allowing host fibrovascular ingrowth, which can retard clarity of the membrane.<sup>179</sup> These preliminary animal data led to human studies, and amniotic membrane as a carrier substrate has proven to be successful in human corneal implants in multiple studies.<sup>177</sup>

Fibrin and fibrin-based carriers have also demonstrated success for corneal epithelial systems. Despite the advantageous

properties of amniotic membrane, the membrane remains permanently beneath the cultured epithelial cells. This may have some long-term effect on biocompatibility or pose a potential risk for infection. In contrast, fibrin and fibrin-based materials are biodegradable and will integrate with the surrounding tissue. Fibrin-fibronectin gel has supported human corneal epithelial stem cell growth and differentiation, with resultant expression of keratin cell markers consistent with corneal epithelium.<sup>180</sup> Human studies have demonstrated success in transplanting cultured corneal limbal cells on a fibrin carrier from the healthy eye to the contralateral eye.<sup>181</sup>

### Clinical Applications

Corneal tissue engineering has advanced to clinical studies. In patients with unilateral disease, a corneal biopsy from the healthy eye can be used as a cell source to obtain cultured corneal epithelial cells. In the setting of bilateral ocular surface diseases, a replacement cell source comprising autologous oral mucosal epithelial cells demonstrated feasibility in animal models, and this method has been applied to human corneal transplantation.<sup>177</sup> Two separate groups using autologous oral mucosal epithelium with different culture methods have performed corneal reconstruction in small case reports. The major difference in culture methods between the two groups is that one group uses a carrier-free epithelial cell sheet that is produced using temperature-responsive culture surfaces, while the other group uses amniotic membrane as a carrier for the epithelial cell sheet.<sup>177,182</sup> In the first group, four patients were enrolled in the study with one eye each undergoing transplantation.<sup>182</sup> Three of the four patients had undergone allogeneic corneal transplantation that had failed after 1 year despite systemic and local immunosuppression. The oral mucosal cells were harvested and cultured for 2 weeks on temperature-responsive cell-culture surfaces with 3T3 feeder cells.<sup>182</sup> The epithelial cell sheets were removed from the cell-culture surface by reducing the temperature and were transplanted directly onto the denuded corneal surface. Complete re-epithelialization of the corneal surface occurred within 1 week in all four treated eyes.<sup>182</sup> Over the 14-month postoperative period, the corneal surface remained transparent and there was significant improvement in visual acuity. In the second study, there were a total of six eyes in four patients with Stevens-Johnson syndrome (three eyes) or chemical injuries (three eyes).<sup>177</sup> Autologous oral epithelial cells were cultured for 2 to 3 weeks in the presence of 3T3 fibroblasts on a denuded amniotic membrane carrier. The epithelial sheet was transplanted onto the corneal surface and secured in place with sutures. The corneal surface had complete epithelial coverage by 48 hours, and visual acuity significantly improved over the postoperative period.<sup>177</sup> The corneal surface remained stable over a mean follow-up time of 13.8 months.

In a larger study of ocular surface reconstruction with cultured oral mucosal epithelial cells, mid-term results on a total of 15 eyes over a mean period of 20 months were reported.<sup>183</sup> The ocular surface remained stable and transparent in 10 of the 15

eyes, and visual acuity significantly improved in 10 of the 15 eyes. There were five eyes with small and persistent epithelial defects. Three of the eyes healed spontaneously, and two required reoperation.<sup>183</sup> These studies demonstrate that corneal engineering is a promising treatment for patients with severe ocular disease who fail transplantation, or for patients who are poor candidates for conventional corneal transplantation. The success of autologous oral mucosal epithelial cells for corneal tissue engineering applications obviates the need for immunosuppression and for acquiring corneal stem cells that may not be available when disease is bilateral.

# VI Delivery of Transfusion and Transplantation Services

# Recruitment and Screening of Donors and the Collection, Processing, and Testing of Blood

**Kendall P. Crookston,<sup>1</sup> Susan L. Wilkinson,<sup>2</sup> & Toby L. Simon<sup>3</sup>**

<sup>1</sup> Associate Professor, University of New Mexico Department of Pathology, Associate Medical Director, TriCore Reference Laboratories, and Medical Director, United Blood Services of New Mexico, Albuquerque, New Mexico, USA

<sup>2</sup> Associate Professor, Clinical Transfusion Medicine, and Associate Director, Hoxworth Blood Center, University of Cincinnati Academic Health Center, Cincinnati, Ohio, USA

<sup>3</sup> Corporate Medical Director, ZLB Plasma, a CSL Behring Company, Boca Raton, Florida, and Clinical Professor, Department of Pathology, University of New Mexico School of Medicine, Albuquerque, New Mexico, USA

The process of supplying sufficient blood components and derivatives for patient needs is complex, highly regulated, and dynamic in adapting to the local and regional needs. This chapter focuses on the donation and collection process, from recruitment of donors to the receipt of products in the hospital inventory. Physician involvement is essential to this process.<sup>1</sup> An overview of the entire process can be seen in Fig 62-1. In many countries, there are dual systems: one for supplying blood for patient transfusion in the hospital and one for collecting source plasma for derivatives. This chapter reflects such an arrangement, with separate sections for collection of transfusable products and plasma for derivatives.

An understanding of the organization of blood services that are responsible for managing this complex process is addressed. Recruitment of blood donors is described, followed by detailed analysis of the donation process from the perspective of the donor and of the component prepared. Finally, donor adverse events are discussed.

## Organization of Blood Services

Approximately 80 million units of blood are collected worldwide each year by diverse blood organizations that vary based on local health initiatives, government intervention, and available resources.

The British Red Cross is credited with establishing the first organized blood donor service in 1921, identifying a panel of potential donors who would provide fresh blood at the time it was needed.<sup>2</sup> In 1935, the International Society of Blood Transfusion (ISBT) was established as a scientific and educational society to bring together professionals involved in blood transfusion and transfusion medicine worldwide (<http://www.isbt-web.org>). By 1935, a number of blood centers had been

established in Russia, at least two of which were providing blood for patient care.<sup>3</sup> Cook County Hospital in Chicago became the next blood bank in the world to store blood for future use in 1937.<sup>2</sup> The first community blood center was established in 1941 in San Francisco, California. Between that time and when the National Blood Service was established in the United Kingdom (1946) and the American Red Cross began its National Blood Program for civilians (1948), significant advances in transfusion medicine occurred. World War II (WWII) provided a great stimulus for the development of donor services and the banking of blood.<sup>4</sup>

## Organization of Blood Services in the United States

Blood collection for transfusion in the United States is accomplished by a heterogeneous system that has evolved since WWII. Close to half of the blood for transfusion is collected by the American Red Cross (see <http://www.givelife.org>). The other half is collected by nonprofit community blood centers, hospital blood banks, and collection centers operated by the armed services. Most of these nonprofit collection agencies are affiliated with a trade organization known as America's Blood Centers. Most blood centers and major hospitals are affiliated with the professional society AABB (see <http://www.aabb.org>).

Many hospitals have found it impractical to maintain hospital-based collections. Although hospital-based collection still exists, the increasing cost, external regulation, shortage of medical technologists, and variable supply and demand have progressively shifted collection activities to blood centers. In 2006, 95.1% of blood in the United States was collected by blood centers and only 4.9% by hospitals.<sup>5</sup> Even hospitals that collect blood usually do not perform donor testing and out of necessity maintain a supplemental blood contract with the local blood supplier. The US Department of Defense continues to operate an independent blood services organization for its hospitals as well as its military mission.

The concept of regionalization of blood services emerged from the assumption that a blood center should serve the surrounding areas that referred patients to major city medical

## Donor recruitment

*[collecting the right kind of blood at the right time to anticipate needs and avoid shortages and wastage]*

- recruitment organizations
- voluntary vs paid donors
  - donors of blood products for transfusion are usually voluntary
  - donors of plasma for fractionation are often paid (eg, Austria, China, Germany, USA)
- physician referral for autologous or directed donation

|

## Predonation information

*[intended to protect the recipient and the donor]*

- self exclusion
- donor interview
  - health history (cardiovascular, neoplasia, autoimmune disease, etc)
  - medication use
  - lifestyle risk factors (paid/received money for sex, incarceration, tattoos, etc)
  - travel history (malaria endemic areas, Chagas risk, UK BSE risk, etc)
  - TRALI risk assessment (previous pregnancy, received transfusion, etc)

directed physical examination (blood pressure, pulse, vein exam, temperature, etc)

hemoglobin or hematocrit screening (protein screen for source plasma donors)

platelet count (if required)

|

## Component collection

*[product selection depends on local needs, what the donor is eligible to donate, and maximizing the donation potential]*

whole blood (450 to 500 mL)

apheresis collection

- RBC (up to 2 units)
- platelet (up to 3 units)
- plasma (up to 4 units)
- combinations of the above

additional blood specimens collected for donor testing

treatment of any donor reaction

## Component preparation/ testing

component separation

- RBCs
- whole-blood-derived platelets
- plasma
- cryoprecipitation

## Blood donor testing

ABO grouping/RhD typing

Screening for red cell antibodies

infectious disease testing

- serologic (HBV, HCV, HIV, syphilis, Chagas, etc)
- nucleic acid (HCV, HIV, WNV, etc)

**Figure 62-1.** The blood donation process: from donor to recipient.

- component modification
  - leukocyte reduction
  - gamma irradiation
  - pathogen inactivation
- quality assurance testing (platelet count, product volume, coagulation factor activity, etc)
- bacterial testing (platelets)
- plasma fractionation (IVIG, immune globulin, coagulation factor concentrates, etc)
- other testing (cholesterol, anti-HLA, etc)

### Postdonation information

- donor illness/self-deferral via confidential unit exclusion
- review/follow-up of any donor reaction
- positive infectious disease testing on subsequent donations ("look-back")
- information learned on subsequent donation that would have resulted in donor deferral (travel, history of disease, etc)

### Labelling of products for distribution

*[all legal and industry standards are met and testing is satisfactory]*

- inventory management to ensure sufficient stock when needed and to minimize outdate of products

### Blood products in hospital inventory

- selection of suitable product and appropriate use (crossmatch, clinical indication, etc)
- local component modification before transfusion
  - gamma irradiation
  - leukocyte reduction
  - plasma reduction/washing
  - pooling (whole-blood-derived platelets, cryoprecipitate, etc)
  - preparation for special procedures (aliquoting units, neonatal exchange transfusion, etc)
- documentation of recipients clinical information (antibodies, modifications, etc)
- evaluation and treatment of transfusion reactions
- notification of recipients in case of product recall or "look-back"

**Figure 62-1.** Continued

centers. This allows the entire geographic area to support the needs of its patients, whether they are cared for in the community or a referral center. By managing the blood within a region in a systematic way, waste can be reduced through the use of technological innovations and careful inventory management. Resource sharing arrangements help blood service organizations move blood around to different centers that are in need.

Since 2001, the annual blood transfusion rate in the United States has remained stable at about 50 units of Whole Blood (WB) or Red Blood Cells (RBCs) per thousand people. This was a change from the ever-increasing transfusion rate curve of the previous decade.<sup>5</sup> The amount collected in 2006 was 52.9

units per thousand total population.<sup>5</sup> This translates to 16.2 million units of WB/RBC collected that was transfused to 5.0 million recipients (an average of 3.0 units each).<sup>5</sup> The number of platelet concentrate-equivalent doses transfused has also remained stable at around 10 million.<sup>5</sup> In total, over 30 million total blood components were transfused in 2006. Essentially all components collected for transfusion in the United States are from volunteer donors; in contrast, the majority of plasma for fractionation is collected from remunerated donors, as discussed later. (The FDA definition of volunteer donor allows for remuneration as long as it cannot be directly converted to cash.)

## Organization of Blood Services Outside the United States

Almost all developed countries have adequate blood services, maintaining a full range of donor screening and quality assurance procedures, while producing most of the components needed in the region. However, there exists a wide variety of dissimilar organizational structures that are successful in meeting the transfusion needs of areas served. These models can be centralized or decentralized, governmental, military, private, hospital-based, or mixed. For the most part, the local transfusion system reflects the administrative system of each country. The World Health Organization (WHO) encourages strong governmental leadership in establishing national transfusion networks.<sup>6</sup> Overall, the provision of blood services worldwide is heterogeneous and varies both with historical development, the socioeconomic development of the region, and the influence of national scientific and political factors.<sup>6</sup>

Recruitment is sometimes carried out by independent organizations that have a special relationship with the collecting agency, such as a country's national Red Cross. The International Federation of Blood Donor Organizations was established in 1955 as a support network for donor recruitment (see <http://www.fiods.org>). More than 155 nations participate. The goals of the organization include member state self-sufficiency in blood from voluntary, unpaid blood donors; improvement in safety; and, in turn, confidence in the national blood supplies through development of minimum standards for donations, inspection, and quality assurance.

In 1975, the 28th World Health Assembly passed a resolution recognizing the value of voluntary blood donation and called on member states to promote national blood transfusion services based on voluntary, unpaid donations.<sup>6</sup> Voluntary donation has been a goal for some time, as it is perceived to be a safer alternative. In 2002 the European Union approved legislation that established comprehensive standards for blood products that included a requirement for voluntary donation.<sup>6</sup> The WHO Global Database on Blood Safety 2004 report collected data from 172 countries representing 95% of the world population.<sup>7</sup> The report shows that there is still inadequate collection in developing countries, which account for 80% of the world's population, but collect only 45% of the world's blood supply. This "gap" is often closed by the use of paid donors. Since 2001, there have been tangible improvements in the proportion of volunteer donors, but family/replacement donors and paid donors are still a significant source of blood for transfusion in many developing and transitional countries. More than 2.2 million units were collected from paid blood donors in 2004. Nevertheless, countries are increasingly moving toward voluntary blood donation. In 2001-2002, 63 countries were collecting less than 25% of their blood from voluntary, unpaid donors; by 2004, this had decreased to 46 countries. Particularly encouraging was the increase from 25% to 47% in the proportion of total donations collected from voluntary, nonremunerated blood donors in developing and transitional countries. During the same period in developed countries, 92%

of donations were from voluntary unpaid donors, as compared to about 67% in developing and transitional countries. The ultimate goal of the WHO and its supporters is that countries should collect all blood from unpaid volunteers. By 2002, 39 countries had achieved 100% unpaid voluntary blood donation, of which five were developing countries. By 2004, this number had risen to 50. During this time, a total of 60 countries reported an increase in the percentage of blood donated by voluntary unpaid blood donors, while 41 countries maintained the same level. Unfortunately, 37 countries showed a decline in the percentage of blood donations from nonremunerated, voluntary blood donors.<sup>7</sup>

The WHO recommends that, at minimum, all blood for transfusion should be screened for human immunodeficiency virus (HIV), hepatitis B virus (HBV), hepatitis C virus (HCV), and syphilis. In 2004, 41 out of 148 countries (28%) that provided data on screening for these four transfusion-transmissible infections were not able to screen all donated blood for one or more of these infections.<sup>7</sup> Even in countries that are able to screen essentially all of their blood, the risk of transfusion-transmitted infection varies. For instance, in 2002, the residual risk of infection from *screened* blood was 10 to 20 times greater in Latin America than in certain industrialized countries.<sup>6</sup> However, some progress is being made globally in decreasing the amount of blood transfused without testing; the number of units for which the four WHO-recommended infectious disease tests were *not performed* decreased from 6 million in 2002 to 1.5 million in 2004. The most marked reduction was seen in the African region where the number of units with tests *not performed* was reduced from more than 1 million in 2001 to 380,000 in 2004.<sup>7</sup>

Developing countries often struggle to provide the same level of safety as countries with established blood procurement systems. The costs of procurement and testing of the blood are often prohibitive. For instance, in sub-Saharan Africa, despite a long history of blood transfusion,<sup>8</sup> blood services are fragmented. Blood is sometimes in short supply and safety is variable. Fewer than 3 million collections were performed in 2004 for a population of 700 million. Of 40 countries in sub-Saharan Africa, 28 countries have yet to implement national quality systems in their blood transfusion services.<sup>7</sup> The economic disparity among the countries of the world in blood procurement and testing may be greater than any other area of health care. Some industrialized countries have implemented a "precautionary principle" that has meant high costs for marginal safety improvements when measured by standards such as quality adjusted life-years.<sup>9</sup> In stark contrast to the "precautionary principle," a portion of the world's blood supply is still transfused without testing. In addition, when testing can be performed, there may not be resources to notify and counsel donors about positive test results, such as HIV. This provides an opportunity for the world community to make a great impact on global health through collaboration and collegiality. In response, the WHO established the Global Collaboration for Blood Safety in 1994, a forum which is a voluntary partnership of internationally recognized organizations, institutions, associations, agencies, and experts from developing and

developed countries that are concerned with the safety of blood and blood products (see <http://www.who.int/bloodsafety/gcbs>).

## Recruitment of Blood Donors

The first task of a regional blood center is to recruit adequate numbers of donors to provide for patient needs. Traditionally, this requires a strong association between the blood center and the population in an area, as well as the cultivation of an altruistic spirit within the community.<sup>10</sup> As described by Titmuss, the act of giving blood clearly demonstrates the integration of individuals into society.<sup>11</sup> However, as discussed throughout this chapter in more detail, a fragile balance exists between blood supply and blood demand in the United States. A recent report calculates that only 111 million individuals in the US population are eligible to give blood based on age and exclusionary factors for established risks. Previous calculations estimated this number at 177 million eligible blood donors.<sup>12</sup> These findings come at the same time the baby boomers, a mainstay of the donor base, approach those years when exclusionary factors increase and only a small fraction of eligible donors donate the “gift of life.” The recruitment of blood donors is now the most challenging task at the blood center.

Many studies have attempted to explain why people do, or do not, become blood donors. Other studies have sought to determine the motivation to repeat the donation process. These studies have evaluated demographic and sociological/psychological characteristics as well as donor motivation for giving or not giving blood. The challenge is to apply these findings to the everyday recruitment of blood donors.

### Donor Demographics

The demographics of current blood donors provide the blood center with insights into where and to whom they might focus marketing and recruiting efforts. As expected, individuals who are integrated into American society at upper socioeconomic ranges are more likely to volunteer in community efforts, give money to charitable causes, and donate blood than individuals in marginalized populations who are struggling at lower socioeconomic levels.<sup>13–15</sup> Donors who are older ( $\geq 50$ ) and who have more education (college graduates) are more likely to return as repeat donors than those who are younger and who have not gone to college.<sup>16–20</sup> Thus, blood donor organizations are challenged to recruit a more diverse group of donors who are not represented in the traditional donor pool.

### Donor Motivation

The earliest studies showed that the concept of altruism has been associated most often as the reason for giving blood.<sup>21,22</sup> In volunteer blood programs across the globe, the unselfish act of giving blood for the welfare of others remains the centerpiece of blood donor recruitment initiatives. But other motivators include the concepts of community need, and social

pressure to conform to expectations or desires of an individual or group. People donate because someone asked them to, they have heard about an emergent need for blood, or because others are doing it. Convenience to donate has also been identified as an important factor and blood centers understand the value of strategically located fixed donation sites and the need for mobile operations.<sup>23</sup>

More recent studies have examined the role incentives have on donor motivation. Blood credits (eg, credit toward blood units required by members of a family or community group) were most attractive to donors as incentives, as well as cholesterol screening and a prostate-specific antigen (PSA) screening in men. In general, small incentives or tokens of appreciation were more likely to appeal to younger donors than older donors.<sup>24</sup> In a follow-up study, first-time donors were positively influenced by incentives, but this finding was also related to the younger age of these donors.<sup>25</sup> In another study, first-time donors were more likely than repeat donors to be encouraged to donate and less likely to be discouraged if offered cash, event or lottery tickets, or merchandise. Donors attracted by cash were more likely to have a risk for transfusion-transmitted infections. Medical testing and blood credits were attractive to both first-time and repeat donors.<sup>26</sup>

Younger and first-time donors also decided to donate because of a family member, friend, or coworker. Younger and first-time donors were also motivated to donate because of testing for infections. Donors with a college degree were less likely to donate to improve their health (eg, by receiving PSA or cholesterol screening) or because of family or peer influence.

More than 90% of respondents to a questionnaire administered to donors of varied ethnic backgrounds cited a desire, responsibility, or perceived duty to help others as an important or very important motivator to donation. Being asked to participate in a work-related blood drive was also an important motivator and not being asked was a deterrent. Getting the results of a health screen appealed to many donors. More than 50% of respondents did not find any of the incentives (gifts, tickets, time off work, reward) important at all in their decision to donate.<sup>27</sup>

In a recent Canadian study, the importance of altruism as a motivator to donation was noted along with family and social influences.<sup>28</sup> Blood centers need to identify potential donors who are more likely to be motivated by the message to “make it available for themselves if required” as well as potential donors more likely to respond to an appeal to “make it available for someone close to you.”<sup>29</sup> In another randomized, controlled trial donors received information about the indication for transfusion of their blood and the recipient’s status. Donors were enthusiastic about receiving this information. However, no significant increase in donation frequency could be demonstrated.<sup>30</sup>

### Deterrents to Donation

There are many deterrents to blood donation. Some deterrents, such as inconvenience, perceived incompetence of personnel

performing blood collection activities, and the lack of cleanliness of a given facility or operation are clearly within the control of the blood center. But, some deterrents, including the perception that blood donation is not important, the belief that one can contract a disease by donating, and the desire to remain ignorant of any positive results from infectious disease testing on the donation are more difficult to overcome.

The most frequently mentioned negative motivator to donation is fear,<sup>28,31,32</sup> including fear of needles, seeing blood, weakness, dizziness, and discomfort. In some individuals, these types of fears may never be overcome. Education programs tailored to overcome fear and heighten the awareness of need may be helpful.

Medical disqualification is also a frequently given reason for nondonation. However, several studies have shown that many perceived reasons for nondonation have been invalid or imagined.<sup>21,31</sup> At least for some individuals, invoking a medical disqualification is more appealing than admitting to some type of "fear" relative to blood donation.

Treatment by blood center staff and the donor's perception of staff competence, coupled with donor sense of well-being during and after donation influence the likelihood of donor return, although highly committed donors are generally not deterred by the occasional bad experience during donation.<sup>15,16,23,33</sup> Donation-related symptoms including dizziness, nausea, and fainting are a significant reason for donor nonreturn.<sup>34</sup> Several strategies have been proposed to mitigate symptoms and increase donor returns.<sup>35,36</sup>

Temporary deferral has a significant impact; deferred donors return less frequently than nondeferred donors and are more likely to lapse from donation.<sup>37-39</sup> In a further study, repeat donors who reported a previous temporary deferral were more likely to lapse, but the association disappeared when other factors such as accessibility, satisfaction with last donation, and perceived need for blood were adjusted.<sup>33</sup> Of interest, several lapsed donors incorrectly viewed themselves as permanently deferred for temporary conditions such as low hemoglobin or hematocrit.<sup>32</sup>

### Sociological and Psychological Theories of Blood Donation

Many theories exist about donor motivation, and several excellent reviews are available with more detail on this complex aspect of blood donor recruitment.<sup>37,40-42</sup>

Opponent-process theory has been used to explain why some individuals repeat the process of donation and become committed, habitual blood donors. Donors experience a "warm-glow" after donation, which may represent an opponent process in response to negative feelings experienced before and during initial donations.

Attribution theory suggests that people who have taken an action (eg, donating blood) without external coercion or large reward, are likely to attribute to themselves a predisposition toward that action. Once they have attributed such a tendency to

themselves, or once they decide that they are the kind of people who do such things, they are more likely to act in ways consistent with that attribution in the future.

In the model of commitment, four processes are proposed: coping with and neutralizing the negative aspects of donation; developing internalized motives for donation and integrating them into one's self-concept; developing a behavioral intention to continue giving blood; and finally, developing a self-sustaining habit of donation.

The theory of reasoned action states that all behavior is preceded by a behavioral intention that can be measured by seeking an estimate of the probability of acting on that specific behavior. Intention is a function of two additional factors, the individual's attitude toward performing the act and the perceived expectations of others for what one should do in a particular situation. This theory has been, in general, effective in explaining donor action related to blood donation. For example, donors who verbally expressed their intention to donate when recruited were more likely to attend the drive than those who were merely reminded that a drive was occurring. Likewise, when donors are informed of a blood mobile and also sent a checklist of dates to which they could commit (forming an intention), they were more likely to give blood when compared to donors who were merely informed of the drive through the media.

The attitudes of donors and nondonors in three areas including affect, cognition, and behavior have been reported.<sup>43</sup> In terms of affect, donors were more likely to indicate that blood donation made them feel generous, assured, relaxed, and useful. Nondonors were more likely to indicate that donation made them feel uncomfortable and ill. On cognition scores, more nondonors believed that blood donation was dangerous and appeared to know little about the process. Donors were more likely to cite that blood donation is worth any inconvenience and is an important civic duty. For behaviors, donors ranked more favorably those behaviors that reflected the donation process. The authors concluded that blood donor behaviors may be more strongly determined by affective and emotional processes rather than by carefully reasoned decisions.<sup>43</sup>

It appears from the recent literature that the model most likely to predict future blood donation behavior is the theory of planned behavior.<sup>44, 45</sup> This model postulates that behavior can be determined by intentionality, which in turn is affected by attitude (positive or negative evaluation of the behavior), subjective norm (perception of social pressure), and perceived behavioral control (perceived ease or difficulty in performing the behavior). Several studies involving nondonors concluded that this model predicted 31% to 72% of the variance in intention to future blood donation. In a recent study<sup>46</sup> based on the theory of planned behavior and experienced donors, 65% of the variance in donation intention and 50% of the variance in attitude was accounted for. Self-efficacy showed the strongest positive relationship to donation intention, followed by attitude, subjective norm, satisfaction, and personal moral norm. Prior vasovagal reactions related negatively to intention to donation.<sup>46</sup>

## The Collection Process for Blood Components for Transfusion

### Donor Evaluation

The twofold purpose of blood donor screening is to minimize the risks to both the blood recipient and the donor. Donors should be informed as early as possible about all aspects of the donation procedure and about the importance of critical self-evaluation and self-exclusion for those who do not qualify. Prerecruitment information about donor qualifications and predonation information about risk factors for transmitting infections through transfusion should lead to self-deferral by some donors. When the donor presents for donation, written educational material is given, including a list of deferral medications. Acceptable donor age is 17 and above in most centers, but there is considerable variation in practice. Recent efforts have convinced governments to allow 16 year olds to donate. Experience with healthy donors over the age of 65 has generally been favorable; thus, the need for an upper age limit is questionable.<sup>19</sup>

Answers to donor history questions in a confidential setting provide another opportunity to obtain information about potential risk. Only 3 years after the founding of AABB, a list of 21 diseases and conditions were introduced on the “donor record card” that was intended to be used nationwide for screening criteria.<sup>47</sup> This was based more on the medical judgment of the day than on clear-cut data or evidence. Many of the current medical deferrals are still based less on data and more on a combination of opinion, tradition, and “conventional wisdom.”<sup>47</sup> With the advent of HIV, a second phase in the development of the questionnaire was based on epidemiologic evidence and included direct questions about sexual risks. The FDA stressed a face-to-face interview, rather than filling out a questionnaire, in hopes of ensuring complete honesty in answering the questions. Such data as history of hepatitis and possible exposure to HIV are used to deter donations from persons with potentially infectious exposures. This is done in order to reduce the pretest probability of finding true positive results during laboratory testing. In other words, the precollection donor screening process reduces the amount of blood collected that can transmit infectious diseases. Although laboratory testing is very sophisticated, it can never completely eliminate the risk of an infected unit. Reducing the number of infectious units that make it to the testing laboratory will reduce the number of infectious units that make it through the testing process undetected (ie, false-negative test results).

The donor questionnaire is a dynamic document that is updated as new risks become apparent.<sup>47,48</sup> The interview process is ineffective if it becomes too onerous or lengthy. If there are too many questions, important issues about high-risk behavior might be obscured, and the ultimate purpose of the interview process would be defeated. In the United States, a Uniform Donor History Questionnaire (UDHQ) has been created to standardize criteria used for all tissue and blood donations and reduce the complexity, burden, and possible confusion. Donors

are queried using broad-based capture questions to make screening more efficient (see <http://www.aabb.org>). Certain questions are designed to eliminate the need for further exploration of the subject if the answer is no. The questions are asked in reverse chronologic order. Questions start with the day of presentation, proceeding backwards and query about donor health status, travel, medications, and other items associated with increased risk, either to donor or recipient (eg, “in the past 48 hours . . .” “in the past 6 weeks . . .” “in the past 12 months . . .” “have you ever . . .”). Some medications are cause for deferral because the indication for use increases the donor’s risk in donating (such as antiseizure medications) and others are cause for deferral in order to protect blood recipients (for example, the use of potentially teratogenic medications such as isotretinoin). Still other medications might suggest a condition where the donor may not be able to give consent (eg, Alzheimer’s disease).

A comprehensive treatment of the screening process has recently been published.<sup>48</sup> Screening questions address items such as the following:

- Current state of health.
- Medication use (including aspirin).
- Pregnancy.
- Recent blood donations or immunizations.
- Receipt of a transfusion/transplant/graft.
- Sexual practices that may increase the risk of HIV.
- Body piercing or tattoos.
- Incarceration.
- Exposure to hepatitis.
- Travel to areas where certain diseases are endemic (eg, malaria, Chagas’ disease).
- Use of clotting factor concentrates.
- Injection of any drugs not prescribed by a physician.
- History of diseases such as malaria, Chagas’ disease, babesiosis, cancer, cardiovascular disease, a bleeding condition, or a family history of Creutzfeldt-Jakob disease.

During the interview, prospective donors might become aware of disqualifying factors in the health histories but feel too embarrassed or coerced to admit to disqualifications. Provisions must be made at all collection sites for a person to exit at any time without examination and the opportunity must be provided for the donor to easily indicate that collected blood not be used for transfusion. Mechanisms have been established for confidential unit exclusion that provide for this either at the donation site using a confidential form or barcode, or by anonymous telephone call after donation.

Donors also receive an abbreviated physical examination including monitoring for symptoms of current disease processes, body temperature, heart rate and rhythm, and the ability to comprehend the screening questions and give consent. Consent for donation should also include the possibility that the donor will be listed in a deferral registry if the history or testing preclude donation. In some areas, laws may require that public health authorities be notified when donors test positive for certain diseases.

A blood sample is tested before donation to make sure the hemoglobin level is at least 12.5 g/dL or a spun hematocrit is at least 38%. This screening for anemia is the minimum requirement for allogeneic whole blood donation in many countries. Other automated procedures such as red cell, platelet, and plasma collection by apheresis technology may require more rigorous hemoglobin cutoffs and have minimum height and weight guidelines. Blood centers in the past most often measured red cell mass using copper sulfate, but recently more objective measurement methods that measure hemoglobin or hematocrit have been employed. In the copper sulfate method, a drop of capillary blood from a fingerstick sample is dropped into a copper sulfate solution with a specific gravity of 1.053. Sinking of the drop indicates a hemoglobin of 12.5 g/dL or above. The copper sulfate method, although well accepted for decades, suffers from problems with both specificity and sensitivity. Because of the former, donors who fail are often retested with a spun hematocrit. This test can also err in accepting individuals who are proven anemic by a venous sample taken at the same time.<sup>49,50</sup>

A prospective donor with a diagnosis of chronic, degenerative, or infectious disease should be deferred from blood donation. Donors whose histories carry significant risk and those who have tested positive for infectious diseases are placed on deferral registries. For some deferrals, “re-entry” pathways back into the donor pool have been made available when the risk is no longer present. On occasion, donors attempt to donate in spite of permanent deferral. Reasons include a desire to obtain results of infectious disease testing, to receive credit for community service, a misunderstanding about the reason for deferral, and erroneous recruitment by the blood center staff.<sup>51</sup>

The effectiveness of the donor interview in deferring individuals who have risk factors that could affect the safety of the product has been a subject of investigation. Most recently the Retrovirus Epidemiology Donor Study has shown areas where improvement is needed. Younger donors (less than 25 years of age) have more behavioral risk factor than older donors. Educational reinforcement is needed for this group.<sup>52</sup> Most donors skim the educational material and fail to assimilate the information. Thus, more effective materials are needed. However, some high-risk donors seem resistant to any attempt at education and test-seeking behavior is a particular problem.<sup>53,54</sup> Computer-assisted self-interviewing (typically using a touch screen) has become an increasingly popular vehicle for donor screening. Data from this group suggests that it is probably able to reduce the number of high-risk donors by increasing self-deferral.<sup>55</sup>

Once the donor has been appropriately evaluated to ensure that the risk to the donor and to the recipient is acceptable, then blood collection may occur.

## Blood Collection

This section first addresses the traditional collection of whole blood and its separation into components, followed by discussion of newer automated apheresis technology.

## Whole Blood Collection

Despite the many technologies for automated collection, some blood centers—indeed entire countries—are able to produce the bulk of needed inventory from whole blood collections. A typical whole blood collection takes 45 to 60 minutes, including the interview, physical examination, aseptic scrub, antecubital venipuncture, and monitoring for postdonation reactions in a canteen area where refreshments are offered. The blood draw itself should be accomplished in approximately 10 minutes, with periodic agitation to mix the fresh blood with the anticoagulant in the draw bag to reduce clotting. The tubing is clamped before the needle is removed so that air is not drawn into the blood bag. Blood samples are taken into pilot tubes for testing. This is normally done from the blood tubing at the conclusion of the donation or from a diversion pouch filled from the first blood collected, a process that captures contaminating skin organisms. The tubing is sealed and the needle is disposed of without recapping. The donor holds firm pressure over the venipuncture site and then a pressure bandage is applied. The donor is instructed to keep the pressure bandage on and avoid strenuous activity for a prescribed amount of time, to increase fluid intake for the next day or two, and to spend at least 15 minutes in the canteen area. Reactions usually occur at the end of donation in the donor chair or in the area where refreshments are served. If the donor leaves immediately against advice, risk of injury might be increased (see “blood donor adverse events” below). Staff monitoring the postdonation canteen area must be vigilant in assessing for signs of reactions and proactive in preventing fall injuries.

Whole blood collection has the longest cumulative experience and requires fewer resources than automated collection. For countries in the process of developing simple, reliable collection networks, whole blood is the logical first step, with or without component separation.

## Component Separation

Whole blood may generally be stored for up to 21 days. However, the vast majority of whole blood collected in countries with well-established blood systems is separated into components. This allows longer shelf life, better inventory management, and more choices and resources for patient care. Whole blood may be separated by centrifugation into RBC, platelet, and plasma components according to density. Using a “closed” system that is not ever open to outside air is important to prevent contamination with microorganisms during collection and component separation. Centrifuge-separated components are transferred from the original whole blood draw container to satellite bags through integrally connected plastic tubing. Adding nutrients and saline to the red cells permits storage at 1 to 6°C for up to 42 days. The preservative solution may be held sterilely in one of the integral transfer bags until the plasma is separated into a third bag after centrifugation. Then the solution may be added back to the red cells in the original bag.

Platelets may be separated from the whole blood or allowed to break down without being separated. In Europe and many areas of the world, “buffy-coat” platelets are produced by using

a “hard” spin initially to separate all cellular elements from the plasma. Then the buffy coat containing the platelets, white cells, and a significant amount of red cells is further processed to separate the platelets. In the United States, an initial “soft” spin separates platelet-rich plasma from the red cells and then a “hard” spin separates the platelets from the plasma. Additional information about platelet preparation and storage may be found in Chapter 12. Platelets are typically stored from 5 to 7 days at controlled room temperature before expiration. In 2006, the mean age of whole-blood-derived and apheresis platelets at the time of transfusion was 2 and 3 days respectively.<sup>5</sup>

Plasma separated and frozen within 8 hours is called Fresh Frozen Plasma (FFP), while plasma frozen within 24 hours after phlebotomy is known as FP24. Each contains coagulation factors in quantities adequate for most patient indications. FP24 represented only 15% of the 4 million units of plasma transfused in the USA in 2006.<sup>5</sup> However, with the recent concern about transfusion-related acute lung injury (TRALI) and the exclusion of women who have been pregnant and possibly transfusion recipients from plasma donation, the amount of FP24 transfused is expected to increase dramatically. This is because blood centers are attempting to make plasma from all eligible donors of the needed types, even though the plasma logistically cannot always be frozen within 8 hours.

After separation from the red cells, plasma may be pooled and treated with solvent and detergent to decrease the risk of transfusion-transmitted disease. In addition, the pooling enables quality control of coagulation factors per lot and the dilution dramatically decreases the risk of TRALI.<sup>56,57</sup> Some countries in Europe rely on this process for the vast majority of plasma transfused.<sup>56</sup> Solvent/detergent-treated plasma is approved for transfusion in the United States; however, there are currently no companies producing this product.<sup>57</sup>

Preparation of cryoprecipitate involves thawing frozen plasma at 4°C in a circulating waterbath, followed by centrifugation so that the supernatant plasma can be drained into an integrally attached storage bag. The remaining cold-precipitated material is then refrozen at  $\leq -18^{\circ}\text{C}$  and stored for up to 1 year. A total of 1.2 million units of cryoprecipitate were prepared in the United States in 2006, 98% of which were produced by blood centers.<sup>5</sup> In some regions in Europe, cryoprecipitate is not produced, because the use of factor concentrates for inherited bleeding disorders and the use of plasma or fibrinogen concentrate for hypofibrinogenemia have proven satisfactory.

### Leukocyte Reduction

Leukocyte reduction is accomplished by passing WB or RBC units through filters that remove white cells (WBCs). Ideally, this should be done as soon after collection as possible but no longer than 72 hours. Leukocyte reduction has been shown to be more effective when performed before storage because some of the adverse effects of transfusion are caused by factors produced or released by leukocytes during storage. Although leukocyte reduction can reduce untoward events, significant amounts of WBC still remain

in leukocyte-reduced products (up to  $5 \times 10^6$  WBC/unit in the United States and  $1 \times 10^6$  in Europe). In the United States from 2004 to 2006, there was a 9.9% decrease in transfused prestorage leukocyte-reduced units and a 52.7% decrease in transfusion of poststorage leukocyte-reduced units.<sup>5</sup> This decrease reflects the decrease in use of whole-blood-derived components. Automated apheresis collections often have technology that produces leukocyte-reduced products during the collection process.

### Automated Collection

Over the first decade of the 21st century, advances in technology combined with a desire to optimize donations has led to a dramatic increase in automated collection of blood components. The collection of platelets by apheresis has increased coincident with the greater availability of automation and implementation of bacterial testing of platelet products. In the United States in 2006, apheresis-derived platelets increased 9.0% from 2004 (8,338,000 to 9,092,000); simultaneously, the transfusion of whole-blood-derived platelets decreased by 15.7% (1.5 million units to 1.3 million).<sup>5</sup>

Choice of which automated product(s) to collect depends on a number of factors, including blood type, height, weight, gender, risk of having antibodies that could cause TRALI, platelet count, hematocrit, the available collection technology, and the time the donor has available to donate. Minimum donor qualification requirements for the various automated collection methods have developed historically—often independently. Therefore, some procedures have minimum requirements and length of deferrals that may differ from other procedures. A 2-unit RBC product is produced by an apheresis procedure where 2 RBC units are collected at the same time, while returning donor plasma and often additional saline solution. In the United States there is a 112-day deferral for donation of a 2-unit RBC product that also precludes platelet and plasma donation on some instrumentation. At the same time, a donor of a combined automated platelet, plasma, and red cell collection is deferred only 56 days for red cells, but may often continue donating platelets and plasma again during the red cell deferral.

Selection of which product(s) to draw from a given donor may be complex in a center with many choices. Obviously, the first concern is which product is most needed for patient care at that time. In addition, an underlying theme in blood banking is to maximize collection of universal donor group AB plasma and universal donor group O red cells. Many centers avoid collection of RBC units from group AB donors because many of these RBC units are wasted, because only group AB recipients may use this blood. Recently, risk of antibodies that may cause TRALI has also disqualified donors from plasma and possibly platelet donation who are at risk of having these antibodies. Finally, there may also be minimum height, weight, and hematocrit requirements that vary by technology and by gender. Therefore, a large male with a high platelet count might donate three units of platelets by apheresis, while a small woman who has TRALI risk might donate only an RBC product.

With proper attention to donor interviewing and care of the donor, the blood donation process can be a pleasant and safe

experience for the donor, while providing a safe and efficacious product to the recipient—the goal of the whole process.

## **Testing**

Blood specimens drawn from the donor at the time of collection are sent for blood typing and infectious disease testing. Many hospitals that still collect blood find it more economical to send out the testing and receive the results electronically. Bacterial testing of platelet units is sometimes also done centrally.

### **ABO/Rh Testing**

Donor centers routinely test blood from each donation for ABO and Rh(D) type (and K in some countries). “Forward” typing occurs by addition of antibody directed toward the A, B, and D antigens on donor red cells to obtain the blood type. “Reverse” grouping is performed by adding donor plasma to reagent red cells bearing A or B antigens to detect naturally occurring donor antibody to A and B antigens. Algorithms ensure concordance of forward and reverse typing.

“Rh-negative” donors lacking D antigen undergo an additional step in the blood screening process to determine if their cells possess the weak-D antigen. As a rule, when in doubt, blood centers err on the side of calling a donor D positive, to avoid the chance of giving Rh-positive blood to an Rh-negative patient. At the transfusion service (recipient) level, the patient is typed and, if in doubt, the transfusion service errs on the side of calling recipients Rh-negative, so they will not inadvertently be stimulated to make an alloantibody to D. The processes are optimized for these two divergent purposes. This is the reason that discrepancies may sometimes be discovered when blood donors become patients and their D typing may appear to change from positive in the blood donor setting to negative in the blood recipient setting.

### **Antibody Screening**

Donor plasma is also added to reagent red cells bearing an array of clinically significant red cell antigens. This is to screen for unexpected alloantibodies to epitopes in the Rh, Kell, Kidd, Duffy, and other antigen systems. Plasma from donors bearing alloantibodies is not used for transfusion; however, because RBC units contain so little plasma, these may be made available from donors with alloantibodies with the appropriate labeling. The screening of the donor for alloantibodies eliminates the need for the transfusion service to screen for donor antibodies to red cells and eliminates the need to perform a “minor” crossmatch (donor plasma mixed with patient red cells).

### **Infectious Disease Testing**

Serologic and nucleic acid amplification testing (NAT) for infectious disease is carried out in most developed countries. The exact tests performed in a center depend on the incidence of the diseases in the population and also on availability of resources for testing. Testing requirements have changed frequently in recent years. Currently, infectious agents for which serologic screening is performed in the United States include HIV-1/2, HCV,

HBV (HBsAg; HBe), human T-cell lymphotropic virus, types I/II (HTLV-I/II), Chagas’ disease, and syphilis. NAT is performed for HIV-1/2, HCV, HBV, and West Nile virus. Supplemental or confirmatory testing is often performed when licensed tests are available. This is useful for donor counseling and to potentially allow the donor to be eligible for a “re-entry” protocol (which in the United States must conform to FDA guidance). Generally speaking, a donor is deferred even if the screening test is known to give a false-positive result. This is because the test has become uninformative in that donor—ie, it cannot discriminate whether the donor has the disease. This often happens when blood testing laboratories change from one testing platform to another (eg, switching to a different instrument manufacturer). It is not unusual to have a higher number of deferrals concurrent with the implementation of the new technology because of the false-positive tests. Some countries—such as England—may be more donor-centered in their testing algorithms. For instance, if a donor is known to be false positive on a certain screening platform, subsequent specimens may be routed to an alternate platform, rather than deferring the donor. If a donor is known to have visited an area in which malaria is endemic, the donor might become eligible to donate after a short deferral period if a supplemental malaria test is performed, rather than be deferred as long as US donors. In 2006 in the United States, approximately 1% of allogeneic whole blood donations had positive results on infectious disease screening tests, resulting in the destruction of 151,000 units of blood.<sup>5</sup>

In addition to serologic and NAT assays, bacterial culture is becoming widely used to test platelet products. Because platelets are stored at room temperature, rather than refrigerated or frozen, there is a greater chance that bacteria in the product might grow. These organisms may come from normal skin flora that contaminate the bag during phlebotomy or they may be transiently circulating in the donor’s blood during collection.

## **Distribution**

When a blood component has successfully completed processing, testing, and record review, then it is “labeled,” meaning that it has met all standards and is ready for infusion. Many countries are adopting ISBT 128, an identification system developed by ISBT that incorporates comprehensive bar-code labels intended to set a global safety standard for the identification, labeling and information processing of human blood, tissue, and organ products across international borders and disparate health-care systems.<sup>58</sup>

The vast majority of a typical area’s blood supply is stored in hospitals for use when it is needed, rather than at the blood center. Availability and turnaround time are key components for determining allocations to each hospital; these depend on usage patterns and transportation distance from the blood center. Even a very small hospital that is a great distance from its blood supplier might have 10 or 20 RBC units on its shelves in preparation for the acute motor vehicle trauma that might occur once or twice a year. Many blood centers monitor inventories in the hospitals. The center can then rotate out blood that may be

expiring soon from the hospitals that use less blood to large hospitals and trauma centers that will be able to use the blood before expiration. In the United States in 2006, significantly fewer RBC and whole blood units expired (25% reduction) than in 2004. These included 252,000 allogeneic (nondirected) units, 131,000 autologous units, and 5,000 directed units. The outdate rate (expiration) fell from 3.2% in 2004 to 2.4% in 2006, the lowest outdate rate in recent years.<sup>5</sup> The estimated mean age of RBC units was approximately 17 days at the time of transfusion.<sup>5</sup> Even the small number of allogeneic RBC units that do expire after 42 days are likely to have been available for several patients that ended up not using the blood; the expired blood, therefore, fulfilled its purpose for collection—it was there when it was needed. The low outdate rate suggests that blood centers have become more efficient at delivering the appropriate product when needed. However, when the expiration rate drops too low, then the safety margin of having enough blood at any particular time is reduced. Fewer hospitals reported shortages in 2006 in comparison with 2004 or earlier data. Although the range of days for postponed surgeries was 1 to 120 days, all but two of 117 hospitals reported delays of 1 to 16 days, a much narrower range than in previous years.<sup>5</sup>

## The Collection Process for Source Plasma

The handling of source plasma donors differs in several respects from the handling of whole blood and apheresis donors providing blood products for hospital transfusion. Source plasma is collected by apheresis specifically for further manufacture into biological derivatives, in contrast to “recovered plasma,” which is the plasma remaining after RBC production from whole blood donation. About half of the recovered plasma collected for fractionation comes from Europe. Many European countries have maintained national programs that fractionate recovered plasma from volunteer donors. However, the demand for biological therapies worldwide requires the additional supply from remunerated donors. Almost all source plasma is collected in Austria, Germany, China, and the United States from donors who receive remuneration. In 2005, source plasma accounted for 63.5% of the plasma for further manufacturing worldwide. Approximately half of the 22 million liters collected came from North America with the United States accounting for 98% of the North American total. Of the US total, 8.5 million liters were source plasma and 2.3 million liters were recovered plasma. In the past, there has been a 4 to 1 ratio between source and recovered plasma in US plasma products, and this has generally continued. However, worldwide it is projected that growing automated component collections by apheresis will cause the percentage of source plasma to increase, as blood centers draw less plasma that is not used for direct patient care. In fact from 2000 to 2005 the volume of recovered plasma collected declined by about 14% while the volume collected as source plasma increased by about 4%. About 25% of the total plasma for fractionation comes from Europe, 20% from Asia and the Pacific and small amounts

from the Middle East, North Africa, and Latin America. In the United States in 2006 there were an estimated 12.4 million collections; this number varied between 10.3 and 13.8 million from 2002 to 2006. The number of collection centers during that time decreased from approximately 400 to 315, with annual volume per center increasing to about 39,000 collections annually.<sup>59</sup>

The United States provides about half of the world's source plasma requirements for two reasons: First, under FDA regulations source plasma donors can donate more plasma, more frequently, than is the case in most countries. Second, the United States has a well-developed source plasma industry that has invested in a network of centers that compensate donors for their time and inconvenience.

Source plasma typically is collected in fixed sites without mobile collections. Either the Autopheresis-C (Fenwal, Lake Zurich, IL) or the PCS-2 (Haemonetics, Braintree, MA) is used for nearly all collections. Recruitment is typically by word of mouth, newspapers, radio, and posters. The donor groups are heterogeneous. Sites near college campuses attract student donors. Medium-sized cities and towns are favored over larger metropolitan areas. Payment in the United States varies between \$25 and \$40 for each normal donation of source plasma. More money is paid for donations from immunized donors for hyperimmune plasma (rabies immune plasma, tetanus immune plasma, hepatitis B immune plasma, anti-D plasma, etc) and by those from donors with disease-state antibodies needed for diagnostic manufacture.

In addition to specific national regulations and guidance, in the United States and Europe the International Quality Plasma Program (IQPP) of the Plasma Protein Therapeutics Association (see <http://www.PPTA.org>) offer a certification if quality standards are met (see Chapter 19). This self-regulation includes the following:

- Community-based donors—donors must have a permanent address in the vicinity of the center.
- Qualified donor standard—each donor's plasma is used only after two medical screenings and required viral testings are successful and less than 6 months has elapsed between donations.
- National donor deferral registry—all US donors deferred for viral marker testing are entered into a registry that must be checked before each applicant (ie, not qualified) donor is accepted.
- A viral marker standard that requires centers to keep their viral marker rates below established levels.
- A 60-day inventory hold so units from a donor with a subsequent positive test or disqualifying information can be removed before being pooled.

The community-based donor standard discourages transient individuals from donating, as this population has been associated with an increased incidence of infectious disease markers. Photosensitive nail coloring is applied under the fingernails to ensure the donor donates only at one donor center at a time. A minimum weight of 50 kg (110 lb) must be met. At each donation the hematocrit and total protein are determined from a fingerstick blood sample. The hematocrit must be 38% or greater and protein 6.0 g/dL or greater. The protein is measured using

a refractometer (the only point-of-care device currently available that meets the FDA requirement).

Initially the donor is subjected to an extensive interview similar to that used for blood donors followed by physical examination by a physician. In the United States, a qualified physician substitute may be used (a nurse, paramedic, or other health professional). They are trained to do the physical examination and operate under the guidance of the center medical director. The physical examination consists of external eye, ear, and nose exam, with an examination of the throat with tongue blade and light. Lymph nodes in the neck area are palpated. Auscultation of the back and front of the chest for lung abnormalities is followed by auscultation of the heart. The abdomen is examined for liver and spleen enlargement. A short neurologic and extremity review completes the examination. In some centers a urine dipstick for protein and glucose may be performed. After passing these initial tests, the donor can donate as an applicant donor. The donor must initially and every 4 months pass tests that include serum protein electrophoresis, total protein, and syphilis. The physical examination with full interview is repeated annually, or if the donor has not presented in the past 6 months. An informed consent must be executed on the first donation and again whenever the consent is changed. Collected units are held until the donor has two successful donations without any positive infectious disease markers. If the donor does not return for the second donation, the plasma is considered an "orphan" unit and cannot be used for injectable product.

In the United States the donor donates according to a nomogram: Body weights of 50 to 67.5 kg, 68 to 79 kg, and greater than 79 kg can donate 625 mL, 750 mL, and 800 mL of plasma respectively, net of anticoagulant. Some centers infuse saline at the end of the donation. After a brief rest in the donation chair, the donor collects the remuneration and is thanked for donating. Refreshment and recovery areas are not common in plasma donor centers, although centers provide additional attention to first-time donors. In the United States, donors are allowed to donate no more than twice in 7 days, with at least 2 days between donations. A donor could theoretically donate 104 times per year (65 to 83 L, depending on donor weight).

The Council of Europe recommendations limit the amount of plasma collected per session to 650 mL, net of anticoagulant and no more than 1.5 L per week. There is a 25-L annual limit (or 28.5 L including anticoagulant). Current German national guidelines set in 1999 allow donations of up to 750 mL plasma including anticoagulant twice weekly (or 850 mL if a male donor weighs over 85 kg or a female donor weighs over 90 kg), with an annual limit of 28.5 L. Donors must weigh a minimum of 50 kg and have a hemoglobin level of 12.5 g/dL in females and 13.5 g/dL in males. Immunoglobulin G (IgG) is typically measured at every fifth donation, and total protein every fifth donation must be at least 60 g/L. (The European guidelines state these should be done at suitable intervals but at least annually).

To determine if less restrictive donation standards (closer to those in the US) were safe, 21 German plasma donor centers participated in a study known as SIPLA. They found that donors

weighing greater than 70 kg could donate 850 mL each session up to 60 times per year with appropriate monitoring (up to 51 L total per year). Currently there is an effort to change European requirements to be consistent with these findings.<sup>60,61</sup>

Each donation by a source plasma donor is tested serologically for HIV antibody, HBsAg, and anti-HCV. NAT is performed on each donation for HBV, HCV, and HIV. A positive test results in deferral. This is regardless of results of confirmatory tests that are performed for donor counseling. In addition, NAT tests for hepatitis A and parvovirus are also performed. If positive, the units are discarded but donor status is not affected and there is no counseling.

Because of the importance of developing a history on each donor, donor centers cultivate relationships designed to attract long-term donors who donate often. The average US donor donates four to five times a month and remains in the program for months to years. Some very dedicated donors are given vaccines to provide rabies immune plasma, tetanus immune plasma, hepatitis B, or other immune plasma in order to make specialty immunoglobulins.

Rh-negative donors who are not of childbearing potential can become donors of Rh-immune plasma for manufacture into Rh Immune Globulin. This is done by immunization with carefully "qualified" D-positive red cells. Long-term consistent donation is particularly important for these specialty donors.

There are additional requirements for donors receiving red cell immunizations including physician performance of the initial physical examination and a separate informed consent, physician presence when immunizations are given, and a specific physician approval of the red cells to be injected. A laboratory must be specially licensed to produce immunizing red cells. Meticulous preparation of the red cells for immunization occurs. Red cells from whole blood donors are frozen and stored for over a year. Only when a year's viral marker testing remains negative can the cells be deglycerolized and used to immunize a donor. When the red cells from a specific whole blood donor are first used, they are given to one to three recipients for a year. When viral marker testing is negative throughout the year for those recipients as well as the donor, the cells are then "qualified." Plasma from these donors is used to manufacture Rh Immune Globulin and the pool must contain a sufficient concentration (titer) of antibody to allow acceptable product to be made.

Rates of viral marker test positivity in donors are monitored and IQPP-certified plasma centers are expected to take steps to reduce levels when they rise above predetermined alert levels. Source plasma donors are more likely male, younger, and larger in size than volunteer whole blood donors. In addition, they are more ethnically diverse. Some of these factors act to increase prevalence and incidence of viral diseases. Socioeconomic status and compensation programs might play a role as well. With the push toward nonremunerated donations worldwide, the payment of plasma donors has been criticized. Nevertheless, monetary compensation of source plasma donors has had an enviable safety record for the last 15 years because many additional controls have been put in place. The viral reduction and inactivation

treatment of the final product provide additional safety. Thus, the layers of protection operate differently in source plasma programs than in the volunteer blood programs, but are still highly effective in preventing infectious units from entering plasma pools and in ensuring the safety of the final product.<sup>62</sup>

## Blood Donor Adverse Events

### Donor Reactions

Blood and plasma donor reactions are monitored by collection agencies to ensure that donation does not pose a risk to the donor's health. Adverse responses to donation or reactions can be either 1) acute, ie, immediate or delayed after a single donation or 2) chronic, ie, in response to long-term donation.

Variables affecting donor reactions are listed in Table 62-1. Acute reactions most frequently arise from anxiety about painful venipuncture or susceptibility to the blood volume deficit during or after donation. Increased rates of reactions are seen with increased volumes removed, first-time donation, younger age, weight less than 120 pounds, and female gender. In a single study in which multivariate analysis was used, all of these factors were independent predictors of donor reaction with the strongest odds ratios for first-time donation and female gender.<sup>63</sup>

The most common type of reactions is a vasodepressor reaction, associated with changes in pulse and blood pressure. When mild, they are characterized by pallor, diaphoresis, and nausea. More severe reactions include syncope or movements that resemble seizures, and can include unconsciousness. Recovery can take 45 minutes or longer. These often resemble vasovagal reactions

seen in other situations (lowered blood pressure and slow pulse), and peripheral baroreceptor activity is thought to play a major role.<sup>19,64-67</sup> Syncope-related falls are not uncommon and may cause injuries.

Vasovagal reactions occur in 2% to 5 % of blood donors, with 0.8% to 0.34% of donations progressing to syncope. One study reported serious reactions in 0.6 per 1000 donations. They are less frequently seen with plateletpheresis procedures, presumably because of a slower blood removal and return of red cells.<sup>67</sup> In a 1-year study<sup>68</sup> in an urban blood center, the incidence of syncope was 0.09%. Younger donors and female donors had increased rates of vasovagal reactions. The reaction occurred before donation (1%), during or immediately after donation (26%), at the refreshment table (61%), and offsite (12%), and usually within 1 hour. The five most common clinical findings were pallor (87%), dizziness (67%), diaphoresis (49%), hyperventilation (49%), and nausea (25%). Six percent of all whole blood donors with syncope had emesis and 46% of the reactions included clonic movements, tetany, or twitching, and 5% had incontinence (usually urinary). Blood pressure and pulse reduction (hallmarks of vasovagal reactions) were actually minimal in this large series.<sup>68</sup> Fourteen percent had a traumatic injury as a result of the reaction. Six percent of the donors with reactions visited an emergency room, but none were hospitalized. First-time donors are known to have a higher risk of these reactions than repeat donors. In one study of high school donors<sup>69</sup> it was 9.4% vs 3.6%. Low weight adds to the risk. First-time donors weighing less than 59 kg had a rate of 13.6% and females at that weight had a rate of 16.4%.

Adequate hydration before donation along with nutritional intake is considered an important preventive measure by many. A study of high school donors receiving a 16-ounce drink before donation showed a modest 21% reduction in reactions; the mechanism is thought to be gastric distension increasing sympathetic activation.<sup>35</sup> Other methods of reducing donor reactions such as a muscle tensing technique are promising based on both distraction of the donor and maintenance of blood pressure.<sup>36</sup>

Autologous donation is associated with increased and more severe reactions.<sup>70</sup> Studies in autologous donors have demonstrated decreased cardiac output associated with donation (6.9 to 6.0 L/minute). Saline infusion during and after the donation limited the effect.<sup>70</sup> Studies in the well elderly showed surprising resistance to hemodynamic changes,<sup>19</sup> but postural hypotension can be seen in many donors as a normal consequence of donation. Increased heart rate occurs with loss of blood volume from removal, while a slowing of the heart rate generally indicates a vasovagal reaction that can be psychogenic in origin.<sup>19</sup>

Without more data, current measures to reduce reactions include adequate food and fluid intake before donation, reassurance, and distraction from an attentive staff, immediate attention to symptoms with cold packs, raising the lower extremities or lowering the head to promote blood return, saline replacement for apheresis donors, and a recovery period with snacks for donors before departure. Screening measures to ensure healthy

**Table 62-1.** Factors Associated with Donor Reactions\*

Variables associated with increased donor reactions

- First-time donation
- Greater percentage of blood volume removed
- Admitted anxiety
- History of fainting
- Female gender
- History of prior reactions
- Age less than 30
- Tall/thin habitus
- Greater than 4 hours from last meal
- Mobile blood drive
- Low diastolic blood pressure

Variables associated with decreased donor reactions

- Increased number of prior blood donations
- Greater body surface area; increased height and weight
- Increased donor age
- African ethnicity
- Higher diastolic and systolic blood pressure
- Donation in spring season

\*These factors have been found in some studies to influence donor reaction frequency and severity. These data are primarily from studies of whole blood donation.

donors should lessen the problem. Special attention from staff and longer recovery periods for first-time donors are reasonable steps. In addition to concern for donor well being and risk reduction, attention to the reduction of reactions is key to an adequate supply of blood and plasma. In one study, 59% of donors having no reaction returned to donate within a year (334 days); for donors with mild reactions the return was reduced to 26% and more severe reactions, 14%.<sup>67</sup>

### Phlebotomy

Another set of adverse consequence relates to the needle puncture, including hematoma, thrombosis, infection, and physical damage to anatomic structures, such as the median nerve. A hematoma can result at the venipuncture site. Causes include inadequate pressure on the site after donation, the needle going through the vein such that the pressure applied after the donation does not stop the leakage from the back side of the vein, adjustment of the needle, a bleeding tendency (for example in someone taking aspirin), anatomic variation, and vessel or tissue friability. Hematomas complicate 9% to 16% of donations, according to various surveys, but calls to randomly selected blood donors 3 weeks after donation revealed that 22.7% reported a hematoma.<sup>67</sup> Hematomas often go through a process of widespread extension along fascial planes with various discolorations that can be alarming to the donor. Treatment with ice immediately and periodically for 48 hours after the event will retard the bleeding and promote healing. Heat is often used later, but is only of symptomatic value.

Thrombosis can also develop in the phlebotomized vein and is seen in association with hematoma. In almost all cases, these are superficial venous thromboses often misdiagnosed as deep venous thrombosis in emergency rooms. In rare situations, the clot will travel into the deep venous circulation and anticoagulation or thrombolysis will be needed. A most serious combination is septic thrombophlebitis.

Rarely, a phlebotomy site can become infected, in the presence or absence of coincident hematoma. Cellulitis can develop that requires antibiotic treatment. Red streaks from the site, along with warmth, redness, and tenderness accompanied by lymphadenopathy in the axilla are suggestive. The individual is sometimes febrile. It is speculated that trauma to the vein is more common in frequent apheresis donors; however, these same problems are seen in the clinical laboratory setting after a single venipuncture with a small needle.

Acute reactions can also occur when other structures are punctured by the needle. Arterial puncture is a rare event noted when the blood removed is bright red and pulsating. The procedure must be stopped and firm pressure applied to the site for an extended period to ensure bleeding cessation (10 minutes or longer). A pseudoaneurysm is a rare complication.<sup>67</sup> Very rarely there are complaints of injuries to tendons or muscle.

A more common injury that has been studied in more detail is transection of a nerve, particularly the median nerve. A study at a large blood center<sup>71</sup> identified 66 cases during a 2-year period of 419,000 collections, with an incidence of 1 in 6300.

These generally present with numbness and tingling, excessive or radiating pain, with occasional loss of strength. Of the 56 donors who had follow-up, 22 recovered in less than 3 days, 17 in 4 to 29 days, 13 in 1 to 3 months, two in 3 to 6 months, and two in greater than 6 months. Four of the 56 complained of chronic problems that were mild. Because peripheral nerves can regenerate and heal, total recovery occurs in over 90% but it can take a prolonged time. This is probably an inherent problem that is not related to technique and is best treated with arm slings and reduced use whenever possible.<sup>71</sup>

Another complication is related to citrate toxicity. Citrate is the anticoagulant used in almost all apheresis collections. It is a ubiquitous compound found in human cells. Citrate is metabolized to bicarbonate and thus could cause metabolic alkalosis in excessive quantities or if renal disease is present. It acts as an anticoagulant by combining with calcium, which is needed for clotting to occur. Thus, if citrate is infused the ionized calcium level will fall. This leads to increased parathyroid hormone secretion. This in turn stimulates mobilization of calcium from bone and increases intestinal absorption and renal tubular reabsorption of calcium. Citrate does not cause toxicity in whole blood collections, because it is not reinfused. It has minimal effects in donor plasmapheresis because the citrate is mostly in the retained plasma. It is in plateletpheresis, large-volume leukapheresis, progenitor cell collection, and therapeutic plasma exchange with fresh frozen plasma that adverse sequelae resulting from citrate are most likely to be experienced. Symptoms of hypocalcemia seen are most commonly perioral and/or peripheral paresthesias. Symptoms seen less often include dysgeusia (unusual taste), nausea, lightheadedness, shivering, twitching, and tremors. More discussion of citrate reactions may be found in Chapter 42, about therapeutic plasma exchange.

Cardiac toxicity can also occur with citrate anticoagulation. The reduction in ionized calcium lengthens the plateau phase of myocardial depolarization, prolonging the QT interval. This has not been associated with clinical problems, but depressed myocardial contractility may rarely be seen. Although these rarely rise to the level of clinical concern, occasionally citrate toxicity cannot be differentiated from a cardiac event without a clinical evaluation.<sup>72</sup>

Attentive operators can reduce the citrate reaction rates by looking for early symptoms and slowing the outflow and reinfusion. Women and smaller individuals are more susceptible to reactions and thus warrant more careful observation. As new apheresis devices have been brought to market, citrate loads have been decreased and the symptoms have also been seen less frequently. Increased citrate infusion rates are clearly associated with more severe clinical reactions.<sup>73</sup> Various measures may be used to reduce citrate reactions. Administration of calcium gluconate effectively reduce the reactions, but requires careful monitoring.<sup>74</sup> Use of oral calcium supplements can be effective. For the most part the reactions are mild and well tolerated.

Allergic reactions are less common than others. In the past, reactions were seen to ethylene oxide used to sterilize disposable

sets, but this method of sterilization has been largely abandoned. Latex-related reactions are also possible if the environment is not latex free. Hives and minor reactions can be treated with antihistamines, but life-threatening anaphylactic reactions are treated with epinephrine.

Unusual reactions such as air embolism are theoretically possible during donor apheresis, but not reported using modern technology. This rare complication of apheresis is characterized by dyspnea, tachypnea, cyanosis, tachycardia, and hypotension after a large amount of air (typically over 200 mL) enters the venous circulation of the donor.<sup>75</sup>

With the increasing use of apheresis for blood collection—not only for platelets and progenitor cells, but also for red cells—the safety of the procedures is of concern. An analysis of 249,154 2-unit RBC apheresis collections, 40,870 single-unit RBC apheresis collections, and 90,082 plateletpheresis procedures compared with over one million whole blood collections confirmed the safety of the apheresis procedures.<sup>76</sup> Moderate and severe reactions were seen in 0.47% of whole blood donors, 0.37% of single-unit RBC apheresis donors, 0.15% of 2-unit RBC apheresis collections and plateletpheresis collections. These data confirm the favorable safety profile of standard apheresis procedures for collection of red cells and platelets.<sup>76</sup> Part of the lower reaction rate might be explained by the fact that apheresis donors are more likely to be experienced, regular donors than the whole blood donors. An older multi-institutional study<sup>77</sup> had shown a rate of acute reactions among apheresis donors of 2.18%, which is lower than reports of reactions among whole blood donors (11–21%) but higher than the newer larger study reported above. Differences probably relate both to definitions and fewer reactions with newer technology. The rate is higher among platelet donors (12%) than either plasma (5.9%) or granulocyte donors (9.4%). A single institution study<sup>78</sup> reported in 1999 found an overall reaction rate of 0.81% with two reactions out of 19,736 being serious enough to require hospitalization. Citrate reactions account for some of the differences. They are higher with plateletpheresis and with certain equipment.<sup>75</sup> Procedures collecting 2 RBC units at one time are growing in popularity. Studies have shown that, in donors who meet current selection criteria, the physiologic changes (heart rate, blood pressure, and exercise capacity) are not greater than with a whole blood donation except for a slightly greater decrease in  $\text{VO}_2$  max at 24 hours after donation. Cognitive functions have also been assessed and not found to differ significantly. There is a proportionate increase in marrow erythropoiesis, as expected. Thus, automated red cell collection of 2 units appears to be as safe as whole blood donation. The saline replacement and longer draw time probably provide a protective benefit.<sup>67</sup>

### Long-Term Effects of Donation

Long-term effects of donation are limited to those donors who donate frequently over an extended period. Among whole blood donors, the major concern is iron depletion, leading to anemia. Among plasma donors, the major concern is protein depletion (decreased immunoglobulins).

Over 200 mg of iron is lost with each whole blood donation; thus, screening for an adequate hemoglobin level is part of routine donor assessment. An additional measure to protect donors from iron deficiency is the requirement for an 8-week interval between donations. But these measures are not completely effective and iron depletion is frequent among regular whole blood or red cell apheresis donors. In one study,<sup>79</sup> 6% of first-time female donors were found to be iron deficient, while 22% who gave 2 or more units over a 4-year period had low ferritin levels. Corresponding percentages for first-time and repeat male donors were 0% and 9%, respectively.<sup>79</sup> In another study,<sup>80</sup> 0% and 12% of male and female first-time donors were iron deficient, and 16% of women who gave 2 units/year were iron deficient. Only 2% of males who gave this amount were iron deficient, but 19% of males who donated every 8 weeks were iron deficient. Low ferritin levels were frequently found in menstruating women, and menstruating women taking iron supplements had higher ferritin levels than those who did not. The degree of iron deficiency relates to the frequency of donation.<sup>80</sup> Although postmenopausal women have a lower risk, a study of elderly blood donors showed iron deficiency was frequent in those donating approximately four times per year. Male donors need 14  $\mu\text{g/kg/day}$  from dietary sources for physiologic loss and women require 24  $\mu\text{g/kg/day}$  to make up the additional iron loss from menses. Donation three times a year adds another 25  $\mu\text{g/kg/day}$  to this requirement. Dietary iron alone usually cannot make up this loss.<sup>81</sup>

Studies have shown that iron supplementation of menstruating female blood donors can compensate for the loss and allow this group to contribute to the blood supply.<sup>80</sup> But many blood donation organizations have not been willing to institute such a practice, because iron may be used inappropriately.<sup>82</sup> Complicating the problem have been reports of reduced cardiovascular mortality in individuals who are iron deficient, suggesting that this iron depletion might be beneficial to the health of the donor. Countering this are data that iron depletion alone affects mitochondrial metabolism, resulting in cognitive and physiologic impairment (fatigue, decreased work productivity, decreased physical endurance). Restless leg syndrome has also been found with iron deficiency. Iron deficiency anemia results in a clinical condition associated with symptoms when sufficiently severe, and this may be problematic in those 50 years of age and older as it might mask blood loss caused by gastrointestinal malignancy. The current whole blood collection paradigm has a hemoglobin cut-off slightly above the low end of normal in women and below the low end of normal in men.<sup>83,84</sup>

Risks of iron supplementation include masking of bleeding from occult gastrointestinal cancer in an older person, accidental poisoning in children, aggravation of hemochromatosis (if long term), gastrointestinal side effects, interaction with foods and other drugs, rare allergic reactions, and possible aggravation of atherosclerotic tendencies. The positive side would be to allow more women to donate. Newman<sup>83</sup> has proposed introducing short-term iron therapy after donation and simultaneously reducing the hemoglobin acceptance standard. This is particularly important for women of African ethnicity who have lower

normal hemoglobin than women of European ancestry. At the same time, Newman believes the standard should be increased for males, so that they are not accepted when they meet the definition of clinical anemia. These recent recommendations have not yet changed practice. Therefore, frequent donation may lead to iron deficiency and iron deficiency anemia. Many donors will leave the donor pool after being deferred for a low hematocrit or on instruction from their physician who diagnoses the problem.<sup>83,84</sup>

In platelet- and plasmapheresis donors, red cell removal is minimal so that neither iron depletion nor anemia is a problem. The hemoglobin check is simply to ensure the donor is in good health. Plateletpheresis donors at current frequencies do not face issues with either platelet or plasma protein changes.<sup>75</sup>

In contrast, serial plasmapheresis donors are known to be affected by the plasma protein removal at each donation and may not fully recover between donations. Dedicated frequent donors typically have lower serum protein, globulin, and IgG levels than nondonors. Albumin levels are less significantly affected and CD19+ B cells increase and suppressor T (CD8/CD11b) cells and natural killer cells are reduced.<sup>85</sup> In one study, 20% of normal source plasma donors and 42% of primarily female anti-D specialty donors who were very committed to the twice weekly donation had IgG levels below the normal range.<sup>85</sup> However, no clinical consequences were found in an industry-supported study<sup>86</sup> of donors who dropped out of plasmapheresis programs. Medical problems were not associated with their decision to end donation nor were they found on follow-up. Serum protein levels were higher than they had been when the donors were in the program, indicating the ability of the proteins to regenerate.<sup>86</sup>

The current regulations for protection of serial plasmapheresis donors in the United States require measurement of total serum protein at each donation and a protein electrophoresis upon first donation and at 4-month intervals. In German centers, IgG levels are measured at regular intervals instead of the protein electrophoresis. When donors fall below acceptable levels, they cannot donate and must have a repeat measurement in the acceptable range before resuming donations. General experience is that a rest of 1 or 2 weeks from donation permits the proteins to rise again to acceptable levels. One issue is that the refractometer (point of care) measurements of plasma protein give less accurate than the laboratory measurements, but no other method for measurement at each donation is currently available.<sup>85</sup> In addition, the protein electrophoresis measurement does not assess for specific IgG levels that could be reduced affecting immune surveillance. However, in the absence of any associated clinical problems in the donor population, the current FDA donor eligibility requirements have not been changed. In some other countries, lower acceptable frequencies and maximum annual total liters drawn by plasmapheresis are felt to provide additional protection.

Immune suppression is not a problem in whole blood donors or plateletpheresis donors. Thrombocytopenia has not proven to be an issue with long-term platelet donation. Altered bone metabolism and osteopenia has been noted in long-term

platelet donors because of citrate, but these findings are preliminary and not currently considered an issue. Long-term granulocyte or progenitor cell donation could result in lasting effects from the steroids and growth factors used to stimulate increased cells for collection, but this has not been a clinical problem.<sup>75</sup>

In summary, the adverse consequences of donation are generally well understood such that donors can be adequately protected. Efforts to reduce reactions will be rewarded because donors who have reactions or suffer long-term consequences such as anemia or reduced serum protein are less likely to return.<sup>87</sup> Current standards and practices appear adequate to protect the donor's health and safety, but continued vigilance is appropriate, just as it is with transfusion risk.

---

## Conclusion

The recruitment and screening of donors and the collection, processing, and testing of blood has developed dramatically over the past half-century. It is a highly regulated and technology-rich field. Much of the blood worldwide is collected by blood collection agencies that may differ greatly in structure and organization. Systems that are very different may still be successful in collecting and delivering a beneficial, life-saving product to patients when they need it. At the same time, the disparity between resources used in highly industrialized countries and other countries for procurement of safe blood is perhaps greater than in any other area of health care.

Blood transfusions present a paradox. They are believed to be safer than ever before. Yet, there has been no reduction in the number of legal controversies relating to blood. In part, this is because both the government and the general public have a low tolerance for risk in this area. The Food and Drug Administration (FDA) has mandated deferrals and tests whose utility, in many instances, has been questioned. For example, according to one academic estimate, nucleic acid amplification testing (NAT) costs between \$4.7 and \$11.2 million per quality-adjusted life-year (QALY) gained.<sup>1</sup> Indeed, the academic literature has acknowledged that blood safety measures are judged by a different standard than most health-care interventions.<sup>2</sup> The FDA may simply be mirroring public attitudes, as surveys have reported that many people erroneously believe AIDS can be contracted from donating blood.<sup>3,4</sup>

Another consideration is scientific and technological progress. Advances in cord blood and tissue transplantation, for example, have raised new ethical questions. Additionally, privacy concerns have taken on added weight in our society.

Given this delicate legal landscape, legal issues continue to surface in transfusion medicine. This chapter focuses on the following five areas:

- Classic blood transfusion injury claims.
- Donor injury claims.
- Tissue.
- Cord blood.
- Patient privacy.

## Blood Transfusion Injury Claims

Although technological advances have largely eliminated the most serious recognized infectious disease threats to the blood supply, such as human immunodeficiency virus (HIV) and hepatitis

C virus (HCV), lawsuits are still filed in the rare instances where transfusion recipients develop blood-borne diseases or suffer adverse reactions.

## Blood Shield Laws

Forty-nine of the 50 American state legislatures have enacted blood shield laws. Each of these laws deems blood to be a “service” rather than a “product.” As a result, a transfusion recipient generally must prove negligent “service” on the part of the blood center, the hospital, or the ordering physician—not merely that he or she received a defective “product.” As a practical matter, these blood shield laws have eliminated strict liability claims or breach of implied warranty claims against blood providers. In addition, even though New Jersey, the District of Columbia, and Puerto Rico lack formal blood shield laws, each of these jurisdictions has court precedents requiring negligence to be proved when a claim is brought against a blood supplier.<sup>5</sup> Negligence is thus the dominant legal standard.

The precise terms of blood shield laws vary considerably from state to state. For example, a few blood shield laws cover blood only, and not tissue.<sup>6</sup> Thus, while the general effect of blood shield laws is to eliminate non-fault-based claims, the exact wording of the state statute should be reviewed in the event of litigation.

State law should be consulted for two additional reasons. First, the transfusion injury claim may be governed by a health-care liability reform measure that has been adopted in that jurisdiction. Typically, such laws are drafted to benefit all “health-care providers.” In several instances, state legislatures have expressly included blood centers in the definition of “health-care provider”<sup>7</sup>—or courts have found that they should be implicitly included.<sup>8</sup> Second, special charitable immunity protections may apply to nonprofit hospitals and blood centers in that state.<sup>9</sup>

## Proving Negligence

Negligence typically requires the plaintiff to prove all of the following:

- A duty exists running from the defendant to the plaintiff.
- The defendant failed to meet the relevant standard of care.

- The defendant's failure to meet that standard of care proximately caused injury to the plaintiff.
- Damages were suffered by the plaintiff.

In transfusion injury litigation, "duty" is frequently at issue. For example, a number of claims against hospitals have been rejected on the ground that the attending physician, not the hospital, had the duty to warn about the risks of blood transfusion.<sup>10</sup> Conversely, some cases hold the transfusing hospital liable for the negligent actions of their physicians. "Duty" generally focuses on the relationship of the parties and whether the law recognizes an obligation on the part of the defendant to protect the plaintiff from the type of injury that occurred. Historically, a mere "bystander" does not have a legal duty to render aid to an injured party. However, as illustrated by one Ohio court, a community-based blood bank may owe a duty to provide blood to a person in a known life-and-death situation, even though it did not serve that hospital. The court emphasized the unique circumstances of the case.<sup>11</sup>

More frequently, liability depends upon how the issues of "standard of care" and "causation" are resolved—specifically on whether the defendant fell below the standard of care in some respect (such as by not deferring a specific donor, not rejecting a particular unit, or not using a certain assay) and on whether the failure to meet the standard of care *probably* caused the plaintiff's illness.

At the theoretical level, negligence is supposed to involve a cost-benefit calculation where the overall costs of a precaution are taken into account. Only if anticipated benefits of a safety measure exceed anticipated costs is the defendant deemed to have acted "negligently" by not implementing that measure. As one well-known judge put it: "[I]f the probability be called P; the injury, L; and the burden, B; liability depends upon whether B is less than L multiplied by P: ie, whether  $B < PL$ ."<sup>12</sup> However, public tolerance for risk in the blood area appears to be very low. As a practical matter, a blood center or hospital that does not follow the "state of the art" may be at legal risk if a transfusion-related injury occurs.

Additionally, in recent years, plaintiffs and their attorneys have become increasingly creative in fashioning theories of negligence. One such theory is that the transfusion recipient should have been given the opportunity to arrange for directed or autologous donations.<sup>13</sup> In light of the number of cases that have arisen in this area, it makes sense from a legal standpoint for a health-care provider to offer this opportunity when it is practical to do so and when the standard of care in the relevant community follows the practice, even though the value of both autologous and directed donations has been challenged. In another fairly recent case, a jury awarded \$6 million to the widow of a transfusion recipient who had allegedly wanted only autologous transfusions, although this verdict was reversed on appeal.<sup>14</sup>

Another example of legal creativity and innovation was a lawsuit brought against a Florida blood center when a young patient died after contracting West Nile virus (WNV) from a transfusion. No test available at the time would have detected the presence of the virus in the donor's blood, and the donor was completely asymptomatic. Nevertheless, the plaintiff maintained that the donor, an American citizen residing in Puerto Rico, did not speak English well enough to have been capable of responding accurately to donor

history questions. Although the plaintiff never showed that the blood center's alleged negligence (ie, failing to screen out this donor based on his allegedly limited understanding of English) was more than fortuitously connected to the harm that actually occurred (because even if the donor had understood English perfectly, he still would have been allowed to donate and would have passed along WNV), the trial court allowed the case to proceed. The jury then awarded over \$8 million.<sup>15</sup> In October 2007, an appellate court reversed this verdict, ruling that the claim was covered by a recent amendment to the Florida health-care liability reform legislation, and that the plaintiff had failed to comply with its provisions by not providing a presuit notice to the blood bank.<sup>16</sup> At this writing, the case is being considered by the Florida Supreme Court.

Bacterial contamination claims also appear to be increasing in transfusion litigation, because it can be more readily detected than in the past. Typically, the plaintiff names both the blood collector and the hospital when bringing a lawsuit, arguing that the delivery and transfusion of a contaminated unit could have been prevented at either stage.<sup>17</sup>

## Defining the Standard of Care

Because of the public's low tolerance for risk in blood transfusions, the key issue in a transfusion injury case often is whether the plaintiff can convince a judge to allow his or her case to go to trial. Once a case proceeds to a jury trial, the blood provider risks an adverse outcome. Thus, a defendant's goal often is to defeat the claim *before* trial through the pretrial device of "summary judgment." Summary judgment can be granted by the judge when he or she believes that the case is not supported by sufficient evidence to warrant jury submission.

In this regard, several questions need to be considered:

- Does the plaintiff need to establish a breach of the standard of care through testimony by a qualified expert?
- If so, who is considered to be a "qualified" expert?
- Regardless of what an expert says, does the blood provider have a complete defense if its conduct met prevailing industry standards?

These are critical questions because 1) the absence of expert testimony, 2) the absence of "qualified" expert testimony, and 3) the satisfaction of prevailing professional/industry standards are all potential defenses that may allow a claim to be disposed of on summary judgment.

## The Need for Expert Testimony

The prevailing view is that blood centers, like physicians, are entitled to be judged according to a professional standard of care. As a practical matter, this means that the plaintiff often must have an expert to support his or her lawsuit because a layperson cannot testify about a professional standard of care. As one Ohio court has said, "Because the operations and tasks of hospitals and blood banks are not within the purview of common knowledge, plaintiffs' negligence claims... require expert testimony."<sup>18</sup> A Nevada court made a similar point, acknowledging the clear and growing consensus of jurisdictions that view the production and safeguarding of the nation's blood supply as a professional activity,

entitled to a professional standard of care: “We are convinced that determinations concerning the testing of donated blood and the exclusion of categories of donors are better suited to professionally trained members of the industry rather than laypersons. Such determinations require professional expertise in adopting procedures necessary for securing healthy blood and blood products without dangerously impacting the availability of adequate blood supplies.”<sup>19</sup> Thus, without supporting expert testimony, the typical transfusion-related lawsuit will not be allowed to go forward.

### The Expert’s Qualifications and Opinions

Over the last 15 years, courts have subjected experts’ qualifications and opinions to much tighter scrutiny. In 1993, the US Supreme Court decided *Daubert v. Merrell Dow Pharmaceuticals, Inc.*,<sup>20</sup> which has ushered in an era of greater court skepticism about experts. In that famous case, involving a challenge to expert testimony on whether the morning sickness drug Bendectin caused birth defects, the Supreme Court adopted a four-factor test on whether expert testimony should be admitted: 1) whether the theory/technique issue can be tested; 2) whether it has been subjected to peer review and publication; 3) the known or potential rate of error; and 4) whether it has been generally accepted within the scientific community. Although these factors are not absolute prerequisites, *Daubert* on the whole has encouraged trial courts to look more closely at whether the scientific community would accept a particular expert’s testimony before allowing a jury to hear it.

Although *Daubert* is technically binding only on federal, not state, courts, it has influenced state court attitudes toward experts as well. Furthermore, since the early 1990s, a large percentage of blood transfusion claims have been litigated in federal court, because the Supreme Court ruled in 1992 that the Red Cross defendant in transfusion-related cases could compel any case in which it was named as a defendant to be tried in federal court.<sup>21</sup>

A Colorado case illustrates this trend toward increased judicial scrutiny of experts. There, a patient received a 1993 transfusion that was HIV positive because the donor had given blood during the so-called “window period.” The plaintiff’s expert argued that the blood center should have followed a procedure of freezing and quarantining blood donations for at least 6 months, and then retesting its donors, before releasing the blood. The court found that this approach was not sufficiently accepted within the scientific community and refused to allow the case to proceed to trial.<sup>22</sup> In another application of the *Daubert* case, the Texas Supreme Court decided that a trial court acted properly in excluding the plaintiffs’ expert and dismissing their case when it discovered the expert had no medical degree and had obtained his PhD by correspondence course from an unaccredited university.<sup>23</sup> In a Delaware case, a trial judge was reversed for questioning the credibility of a plaintiff’s expert excessively in the presence of the jury, although here again the court affirmed that the *Daubert* prerequisites apply to expert testimony.<sup>24</sup>

### The Relevance of Prevailing Standards

It is well-settled that governmental requirements alone generally do not define the standard of care in a blood transfusion

case. Thus, mere compliance with current statutory/regulatory requirements is typically not a complete defense for a hospital or center. At the same time, failing to follow FDA regulations can establish a breach of the standard of care. Thus, legal requirements are a kind of one-way street: they can serve as a basis for liability but do not necessarily exonerate a blood provider.<sup>25</sup>

Less clear is the weight to be accorded industry standards in a blood transfusion case. In a medical malpractice case, the plaintiff typically must show that the defendant physician failed to meet the prevailing standards of his or her profession. Without proof that the defendant’s conduct fell below the applicable standard of care in his or her community, the plaintiff’s lawsuit will usually fail.

Applying that analogy to blood collection and transfusion, a number of courts have decided that the plaintiff cannot pursue his or her case unless there is evidence that the defendant fell below the *prevailing* standard of care. Thus, for example, in Alabama, California, Ohio, and South Carolina, courts have indicated the blood bank can defend a case completely by showing it met the prevailing standard of care.<sup>26</sup> Elsewhere, as for example in Colorado, the District of Columbia, and Illinois, the prevailing standard is not a complete defense: The plaintiff is entitled to demonstrate that the industry standard was deficient.<sup>27</sup>

This debate is likely to continue into the future. However, where a state has passed a medical liability reform statute that includes blood establishments, as is the case in a number of jurisdictions, the blood bank ought to be able to argue persuasively that it should be treated no differently than a traditional health-care provider and, therefore, that meeting the prevailing industry standard is sufficient. In Arizona, Florida, and Indiana, for example, the statutory definition of “health-care provider” in their medical liability reform laws expressly includes blood banks.<sup>28</sup>

Even when a blood provider is legally entitled to rely on the prevailing industry standard, there may be disagreement as to what that standard is. One difficult area is the situation where a precaution is available but has not been generally adopted. Has it become an industry standard or not? As the costs of new assays and new procedures increase, this situation may become more common. For example, blood centers have followed divergent practices in leukocyte reduction, in testing for Chagas’ disease, and in responding to transfusion-related acute lung injury (TRALI). Where some blood collectors or transfusion centers follow a procedure, a center that does not follow the procedure may be at legal risk *if* the failure to follow the practice can be proved to result in injury. For example, a TRALI claim that failed, based on the consensus in the blood banking community as of the date of the transfusion,<sup>29</sup> might succeed at a future time.

### Causation

As noted above, the plaintiff in a transfusion injury case also must prove causation, namely, that the violation of the standard of care was responsible for his or her injuries. The more cutting-edge theories, such as failure to perform surrogate or single-donor (as opposed to pooled) testing, can pose difficult causation questions. For example, in one HCV case involving surrogate testing, the court specifically held that a lawsuit could

not proceed to trial based on insufficient evidence of causation. The court emphasized that the plaintiff had not presented evidence that the unperformed alanine aminotransferase test “more likely than not” would have screened out the donor carrying the hepatitis C virus.<sup>30</sup> This “more likely than not” rule is reflective of traditional tort doctrine that a plaintiff must prove each element of his or her case to a greater than 50-50 probability.

### **Lack of Informed Consent and Related Theories**

Although more sophisticated and up-to-date consent processes and forms have made it more difficult to pursue transfusion-related claims based on the patient’s lack of consent, these claims continue to be asserted in some circumstances. For example, if the recipient consent process does not include an explanation of a material risk or alternatives, defined as a risk that a “reasonable” person would have considered significant, this may give rise to a claim of medical negligence. Transfusion recipients or their representatives have alleged in some cases that the consent process was incomplete because it did not mention alternatives such as directed donations.<sup>31</sup> Or, the family may contend that either no transfusion or a transfusion from directed donations had been promised or requested, giving rise potentially to a breach of contract claim where the promise was not kept.<sup>32</sup>

### **Standard-Setting Claims**

Plaintiffs have also—on a few occasions and with mixed success—sued the entities that promulgate blood collection and transfusion standards. Thus, in a few jurisdictions, courts have allowed claims against the AABB to proceed for “negligent promulgation of standards.”<sup>33</sup> Those claims have not been uniformly permitted, however, causing a chilling effect on standard-setting organizations.<sup>34</sup> Allowance of those claims seems to go against the grain of American tort law, which normally requires the defendant to have been involved in delivering some product or service used by the plaintiff. Otherwise, the defendant is typically said to have had no duty to the plaintiff.

---

## **Donor Injury Claims**

Donor injury claims appear to be increasing. The most prevalent donor injury claims fall into two categories: 1) needle-related injuries<sup>35</sup> and 2) donor reaction claims—ie, allegations that the donor fainted or fell after the donation process because of the loss of blood.<sup>36</sup>

In most jurisdictions, for a plaintiff to bring a successful donor injury claim, he or she must prove not merely that the defendant’s conduct caused injury, but also that the defendant’s conduct fell below the applicable standard of care. If, for example, a donor suffers a nerve injury that was simply a rare, unfortunate, and unavoidable accident, then the blood center should not be held liable.<sup>37</sup> One court recently concluded that a plasmapheresis donor who alleged the injection of blood components into her arm tissue caused reflex sympathetic dystrophy could not rely on the legal doctrine of res

ipsa loquitur.<sup>38</sup> Res ipsa loquitur (“the thing speaks for itself”) is a legal shortcut that allows a plaintiff to forgo the need for direct proof of causation and a breach of the standard of care, based on a presumption that this kind of injury would have not occurred in the absence of negligence. Although res ipsa loquitur has been invoked successfully in donor injury cases,<sup>39</sup> the recent trend appears to be against its use and to require independent proof of negligence.

It is not entirely clear why donor injury claims seem to be increasing. Blood centers generally have sophisticated risk-management programs. Recognizing that a volunteer blood donor makes for a very sympathetic claimant, centers have generally followed the prudent policy that the “donor is always right.” The frequency of donor injury claims may reflect the fact that, from an attorney’s standpoint, these claims are relatively easy and inexpensive to bring. Unlike the case with a transfusion claim, the plaintiff’s attorney does not have to overcome difficult questions of tracing causation and what level of testing was considered the relevant standard of care. Also, in some instances, donor injury claims have been found to fall outside the scope of medical malpractice reform laws, which require plaintiffs to submit their claims to medical liability review panels and to support their claims with expert medical testimony.<sup>40</sup>

Thus, while the plaintiff must prove negligence in a donor injury case, it may be possible to establish negligence without even the need for expert testimony—or with only limited expert testimony. For example, a plaintiff may allege that he or she should have been escorted from the donation table and was not,<sup>41</sup> or that the defendant was negligent in hiring and training a particular phlebotomist.<sup>42</sup>

---

## **Legal Issues Relating to Cord Blood**

The high quality of hematopoietic stem cells in umbilical cord blood has led to an increase in the number of cord blood transplants since the first transplant in 1988<sup>43</sup> to over 1,964 in 2007.<sup>44</sup> Medical techniques to harvest cord blood have improved and physicians are steadily expanding cord blood use to combat a broader variety of diseases.<sup>45</sup> Governmental efforts have recognized the potential of cord blood and have taken steps to enhance its usage. Separately, the promise of cellular therapy derived from cell lines found in cord blood has resulted in a growing business of storing cord blood for potential self use in the future. As a result, both in the United States and internationally, health-care professionals, governmental units, academic institutions, for-profit and not-for-profit corporations are involved in activities that give rise to a variety of new and complex legal issues. Those involved with cord blood transplants must thoughtfully address changing legislation and legal issues or run the risk of serious consequences.

### **Informed Consent**

As with any medical procedure, informed consent is crucial. In the context of cord blood collection, consent is required when

the blood is collected and stored for potential use in future transplantation.<sup>46</sup> The American Academy of Pediatrics (AAP) has published recommendations for physicians consulted by prospective parents about cord blood banking and guidance for organizations involved in cord blood banking.<sup>47</sup> These recommendations place the burden of obtaining proper consent and educating prospective parents about the cord blood collection process on the physician.<sup>48</sup> The consent process has even been written into federal law in the Stem Cell Therapeutic and Research Act of 2005 (The Federal Act) for cord blood collected under the program.<sup>49</sup> Several states have placed the burden of obtaining consent largely upon the hospitals and physicians.<sup>50</sup>

Materials provided to the mother should contain at a minimum a family medical history questionnaire, information pertaining to what tests are to be performed on the cord blood, an explanation of how the parents will be informed should the test results be abnormal,<sup>46,51</sup> and the range of banking opportunities.<sup>49,50</sup> The consent must be given in writing and before labor begins.<sup>46,47,52</sup> In the event human research is involved, an institutional review board (IRB) must approve the consent form and approve all research protocols.<sup>53</sup> Few cord blood banks obtain both maternal and paternal consent because of the difficulty in obtaining consent within the short time available for successful processing. A report by the Institute of Medicine (IOM) recommended that a plan to address paternal objection to cord blood donation be developed.<sup>52</sup>

### The Medical Procedure

A sufficient quantity of cord blood is critical to a successful collection and future transplantation. Uniformly in the public banking arena and often in the private banking arena, unless the quantity collected meets certain standards,<sup>54</sup> the collection will be deemed inadequate for future use. An interesting and productive effort to address this quantity issue has been the increase in the use of multiple cord blood units for a single transplant procedure. Several medical centers are performing clinical trials to evaluate the use of multiple cord units to enhance engraftment.<sup>55</sup>

After birth, umbilical cord blood is collected by an obstetrician, nurse-midwife, or designated collector.<sup>56</sup> The collection procedure involves clamping the umbilical cord soon after the birth of the child.<sup>57</sup>

There is a risk to the child and thus potential legal exposure to the physician and possibly others if the clamping of the umbilical cord is not timed appropriately. Early cord clamping has been associated with anemia in the child and has led some practitioners to delay clamping for several minutes. Other practitioners believe that delayed umbilical cord clamping may be harmful because of increased blood volume to the child, which may increase the likelihood of future medical complications.<sup>58</sup> Earlier clamping of the umbilical cord increases the proportion of infant blood retained in the placenta and thus the volume of cord blood available for banking. The results of a 2007 study indicated that delaying clamping of the umbilical cord for at least 2 minutes after birth consistently improved both short- and long-term hematologic and iron status of infants.<sup>58</sup>

The AAP and the IOM have both indicated that the cord blood collection program should not alter routine practice for the timing of umbilical cord clamping.<sup>47,56</sup> Furthermore, in the event of a complicated delivery, cord blood collections should not be performed.<sup>47,56</sup>

### Private and Public Banks

There are both “private” or “family” banks (referred to here as private banks), and “public” cord blood banks. Private cord blood banks store cord blood for the future use of the donor or the donor’s family.<sup>56,57</sup> The private banks generally charge a fee for the collection, processing, and storage of cord blood. A contract or service agreement is entered into between the private cord blood bank and the family. Numerous states have enacted legislation specifically recognizing the importance of regulating cord blood donation programs and providing standard, objective information to explain the differences between public and private donation.<sup>50</sup> Recommendations by the AAP discourage private cord blood donation as “biological insurance” for a child.<sup>47</sup> Cord blood can rarely be used for the child from whom it was obtained.<sup>59</sup> A majority of the diseases that have been successfully treated by stem cell transplantation require the use of stem cells obtained from a different individual. The range of estimates that a child will need his or her own privately stored cord blood cells is from 1 in 1000 to 1 in 200,000.<sup>59</sup> Private cord blood banking is recommended for families with an older child with a genetic immune deficiency or similar disorder that may be successfully treated by hematopoietic stem cell transplantation (HSCT).<sup>48</sup>

Public cord blood banks store cord blood for public usage by unrelated donors.<sup>47</sup> There are an estimated 175,000 to 200,000 units of cord blood in public banks.<sup>56</sup> Public banks do not charge the donating family or hospitals a fee for processing, testing, or storing donated cord blood. A fee of approximately \$25,000 is typically charged by the cord blood bank to the transplant center when a unit is provided for transplantation. This fee is usually passed on to the patient and is frequently covered by health insurance.<sup>56</sup> As part of the consent process, physicians are encouraged to inform prospective parents that cord blood donated to a public bank will be available to any patient in need of transplant and will likely not be accessible for the family’s private use.<sup>47</sup>

### Standards and Accreditation of Banks

Increasingly, cord blood banks are accredited in accordance with national standards developed by the AABB or the Foundation for the Accreditation of Cellular Therapy (FACT). Additional standards are maintained by the National Marrow Donor Program (NMDP). All cord blood banks collecting cells for HSCT are required to register with the US FDA.

### Privacy and Cord Blood

In addition to the traditional privacy issues involved in blood-related procedures, the use of cord blood comes with special

privacy requirements. In defining what is a qualified cord blood bank for the purposes of receiving federal funds, the law states that such a bank must have “established a system of strict confidentiality to protect the identity and privacy of patients and donors in accordance with existing Federal and State law; . . . and . . . a system to confidentially maintain linkage between a cord blood unit and a maternal donor.”<sup>49</sup> In regard to patient privacy and cord blood donor records, the IOM recommends that “[s]ecure links between the medical records of the donor and the banked cord blood unit be established to ensure the safety of transplantable products and the patients receiving transplants.”<sup>52</sup>

## Selecting the Cord Blood Unit

The Federal Act, and actions of the US Department of Health and Human Services (DHHS), have resulted in significant efforts to facilitate more cord blood collection and usage. Pursuant to contracts with DHHS, the NMDP maintains a registry of publicly available cord blood units. This registry is to function as a single point of access for patients seeking a transplant.<sup>49,60</sup> Several states have also enacted laws regarding the collection of cord blood that have affected the selection process.<sup>50</sup>

Cord blood is also available directly from some cord blood banks or through registries established by other countries or groups of cord blood banks such as the International NetCord Foundation or AsiaCord, each having created a network that promotes access to units stored by its members.

## Storing, Shipping, and Selling

When cord blood has been properly collected and tested, it must be frozen and stored by a cord blood bank. These actions give rise to potential liability issues. A cord blood bank compensated for its storage services will in all likelihood be labeled a “bailee” under court-defined common law. A bailee has the legal duty to exercise “ordinary care” when dealing with the property of the bailor. Although courts have addressed primarily the duty of ordinary care as applied to private blood banks, a similar duty extends to cord blood banks. A violation of the duty of ordinary care occurs when the bailee “[does] something blood bankers of ordinary care, skill, and diligence would not have done under similar circumstances.”<sup>61</sup> The meaning of ordinary care may also be derived from approved industry customs or practices.<sup>57</sup> In addition, the FDA has promulgated regulations governing storage, which require all blood and tissue manufacturers, including cord blood storage companies, to follow current good tissue practice (cGTP) regulations.<sup>62</sup> The FDA has indicated its intent to require public cord blood banks to meet current good manufacturing practice (cGMP) regulations as well.<sup>63</sup>

Labeling is also regulated by the FDA<sup>64</sup> and the labeling process is closely scrutinized by accreditation groups. In the unlikely event a mislabeled unit got through the required multiple check system and was actually used in a transplant, serious liability issues by would face all involved.

The applicability of blood shield statutes,<sup>65</sup> express and implied warranties of fitness for a particular purpose, and merchantabil-

ity of cord blood under the Uniform Commercial Code (UCC) also need to be considered.<sup>66</sup> In the sale and transfer of significant quantities of cord blood such as on the closing or merger of cord blood banks, the validity of security interests under the UCC should be reviewed.<sup>67</sup> Standard forms (which were probably designed before cord blood was ever sold or shipped) should be carefully reviewed by counsel before being used in a cord blood transaction.

The act of shipping cord blood from a cord blood bank to a transplant center or other location may give rise to additional novel legal issues. If shipping is international, the applicability of custom inspections and air carrier regulations may come into play. Efforts are under way to make these international requirements uniform and make cord blood readily available for transplantation anywhere in the world. However, the international nature of many transplant procedures still raises potential legal issues for the various contracts, agreements, bills of lading, etc that are frequently involved. Cord blood bank licensing requirements also differ from country to country.

## Ownership

The question of “ownership” of cord blood presents another area that has no clear legal answer. Both mother and father may logically claim some interest in the collection. It has also been suggested that a newborn has not legally abandoned his or her property rights to his or her own cord blood.<sup>68</sup> This raises the potential question of whether an individual, upon reaching the age of majority, acquires an interest in his or her own cord blood being held in private storage. Moreover, private banks may also claim an ownership interest in a unit if an individual whose cord blood is banked should die or default on collection or storage fees.<sup>69</sup> In the case of public banks, the donation is quite clearly made by the parents for use by the public; therefore, a strong argument can be made that neither the family nor the child have a unique interest in the unit. As noted below, the terms of the relevant consent documents and the extent of disclosure of information to the parents are likely to play a factor if and when courts face this issue.

No cases have yet addressed directly the property rights of umbilical cord blood, but cases related to human cells, tissue, and organs provide some guidance. In the context of analyzing the validity of a patent and whether private cord blood banking was a service, the US Court of Appeals for the Federal Circuit found that cord blood remained property of the family for the period in which the defendant private cord blood bank stored the unit.<sup>70</sup> The landmark case of *Moore v. Regents of the University of California*<sup>71</sup> held that a person does not possess property rights in his or her own cells or tissue or any profit made therefrom. This case involved a physician and other defendants obtaining patent rights to the creation of a cell line through the use of the plaintiff’s blood and marrow. Based on the reasoning of this case, at least one commentator has written that “*Moore* should not control in identifying property rights in privately stored cord blood.”<sup>72</sup> Certain other case law supports the notion that the storage of human cells creates a property right in the owner of the cord blood unit.<sup>73</sup>

## The Future

Millions of dollars are being invested in research and infrastructure to assist patients in need of a cord blood transplant and to provide a return on these investments in both human and dollar terms. It is difficult to draft appropriate and workable documents to obtain consent, protect privacy, and comply with regulations and accreditation standards. Unresolved issues must be managed. Science, medicine, and law all intersect, each with their own methods and time lines. Cord blood transplantation presents a challenging opportunity for professionals to creatively combine scientific, medical, ethical, and legal concepts to help save lives throughout the world.

---

## Legal Issues in Tissue Banking

Medical science has long recognized the clinical and humanitarian value of donating and transplanting conventional human tissues—musculoskeletal, cardiovascular, and skin—to enhance and save lives. This history what has become known as “tissue banking,” traces the roots to 1949 and the establishment of the first tissue bank, the United States Navy Tissue Bank. The Navy’s program developed many of the fundamental clinical standards, practices, methods and techniques that are still in use.<sup>74</sup>

The Navy Tissue Bank led to the creation of the American Association of Tissue Banks (AATB) in 1976. More than 30 years later, the importance, widespread application, and growth of tissue transplantation are evidenced by the 103 tissue banks accredited by the AATB. This exponential growth in tissue banking and tissue transplantation has been fueled by the development of precision musculoskeletal grafts and novel tissue-based products for an ever-increasing assortment of clinical applications to treat a continually expanding list of medical conditions. Today, AATB-accredited facilities retrieve, process, store, and distribute annually more than two million tissue grafts from 30,000 to 40,000 donors in the United States (AATB, unpublished data).

## Legal and Regulatory Oversight

The legal oversight of human tissue is governed by statutes and regulations at both the federal and state levels. The regulations are supplemented by detailed industry standards and private accreditation programs. Established case law is sparse and focuses on issues of ownership.

### Federal Laws

The principal federal regulatory jurisdiction of tissue lies with the FDA and is based on Section 361 of the Public Health Service (PHS) Act.<sup>75</sup> The PHS Act authorizes the FDA “to make and enforce such regulations as . . . are necessary to prevent the introduction, transmission, or spread of communicable diseases” and “to provide for such inspection. . . as in (the agency’s) judgment may be necessary.” A tissue bank that refuses to allow FDA inspection may be prosecuted.<sup>76</sup>

Another major federal statute that touches tissue banks is Title III of the National Organ Transplant Act (NOTA), Public

Law 98-507, approved October 19, 1984, and amended in 1988 and 1990.<sup>77</sup> This law forbids the sale for “valuable consideration” of human organs, which also includes most human tissues. However, the Act also provides an important exception:

“The term ‘valuable consideration’ does not include the reasonable payments associated with the removal, transportation, implantation, processing, preservation, quality control, and storage of a human organ or the expenses of travel, housing, and lost wages incurred by the donor of a human organ in connection with the donation of the organ.”

### Federal Regulation

Human tissue intended for transplantation has been regulated by the FDA since the agency issued interim requirements in the Code of Federal Regulations (CFR) that became effective on December 14, 1993.<sup>78</sup> This initial regulation (21 CFR 1270) required certain infectious disease testing, donor screening, and record-keeping to prevent the transmission of HIV and the hepatitis viruses from human tissue used in transplantation.

On July 29, 1997, the FDA issued its final regulations (21 CFR 1270) that were broader in scope. The final rule required facilities that are engaged in recovery, screening, testing, processing, storage, or distribution of human tissues to ensure that specified minimum required medical screening and infectious disease testing have been performed and are documented.<sup>79</sup> The regulations also contain provisions for inspecting tissue facilities and for retaining, recalling, or destroying human tissue for which appropriate documentation is not available.

Also in 1997, the FDA announced a new, tiered, risk-based approach for regulating human cells, tissues, and cellular and tissue-based products (HCT/Ps).<sup>80</sup> This proposed regulatory scheme involved three new regulations that replaced the previous approach. The new regulations require establishment registration and product listing; donor eligibility requirements; and GTP.

The first of these, the “Establishment Registration and Listing for Manufacturers of Human Cellular and Tissue-Based Products” final rule, was published on January 19, 2001.<sup>81</sup> This rule requires that facilities participating in the recovery, screening, testing, processing, storage, or distribution of human tissue for transplantation must register with the FDA. These rules extend to all human tissues, imported and domestic, but hospitals or other clinical facilities that only receive and store human tissue for transplantation within their same facility are exempt.

The second set of regulations, “Eligibility Determination for Donors of Human Cells, Tissues, and Cellular and Tissue-Based Products,” was published on May 25, 2004, and became effective that day.<sup>82</sup> These regulations established screening and testing requirements relating to “cell and tissue donors for risk factors for, and clinical evidence of, relevant communicable disease agents and diseases.”

The culmination of the FDA’s new regulatory approach to tissue banking came on November 24, 2004, with the publication of its third and final rule, “Current Good Tissue Practice for Human Cell, Tissue, and Cellular and Tissue-Based Product

Establishments: Inspection and Enforcement.”<sup>83</sup> Similar to FDA’s cGMP regulations for pharmaceutical products<sup>84</sup> and medical devices,<sup>85</sup> the cGTP regulations require that every entity in the manufacturing process establish a quality program that addresses all the core cGTP requirements. These requirements are spelled out in 20 different sections.<sup>86</sup> In addition, the FDA has issued 10 guidance documents to supplement and interpret its regulatory requirements.

### State Laws and Regulations

Before 1968, no federal laws existed governing organ or tissue donation, and what state laws did exist varied considerably from state to state. In that year, to devise a system for donation of human tissue and organs, the National Conference of Commissioners on Uniform State Laws drafted and promulgated the Uniform Anatomical Gift Act (UAGA).

The UAGA is a model law for the states to adopt individually. The 1968 UAGA was enacted in all 50 states within 4 years. Almost 20 years later in 1987, a new version of the UAGA was drafted to address advances in transplant medicine and important issues that had developed, but it was enacted in only 26 states. A 2006 revision has been approved in approximately 30 states, as of June 2008.

The fundamental provisions of the UAGA govern the donor’s rights and the process for making a donation. It incorporates the NOTA prohibitions against buying and selling organs and deals with a multitude of other issues involved with donation.

In addition to following each state’s Anatomical Gift Act, tissue banks should also be aware of specific state laws or regulations. For example, the states of New York<sup>87</sup> and Florida<sup>88</sup> are the only two states that license and inspect tissue banks throughout the country. The oversight includes tissue procurement, donor screening and testing, processing, tracking practices, emergency procedures, labeling, facilities, and disposition of unused tissue. The states of California, Delaware, Georgia, Illinois, Maryland, and Oklahoma require tissue banks to register or be licensed by the state, or to have a permit. Of these, California and Maryland perform inspections to maintain licensure; however, they inspect only those tissue banks that are located within their state.

Many of these state laws and regulations are largely based on AATB *Standards for Tissue Banking*.<sup>89</sup> In fact, more than 20 states specifically reference or incorporate AATB accreditation or AATB *Standards* in their state laws or regulations. Six states (Illinois, Ohio, Oklahoma, South Carolina, Texas, and Virginia) and the District of Columbia require tissue banks operating in their jurisdictions to be AATB accredited.

### Industry Standards

What constitutes the appropriate standard of care is a question of law. Whether the defendant has met the standard of care is a question of fact that the jury determines. Over the years, trade associations and others have published standards or practice guidelines for their respective industries. These standards are developed to protect the public health and welfare and to serve

as a code of conduct for an organization’s members. Widely accepted, industry-created standards are evidence of the standard of care.

In tissue banking, apart from federal and state statutes and regulations, the principal source for determining the standard of care in tissue banking is the AATB’s *Standards for Tissue Banking*. These *Standards* are universally accepted and address virtually all aspects of tissue banking, including for example: institutional requirements; records; the consent process; donor eligibility; retrieval; processing; containers; storage; labeling; distribution; packaging; recalls; standard operating procedures; staff; facilities; equipment; quality assurance; quality control; testing; and release. In addition, the AATB has also published four guidance documents to supplement the *Standards*.

Because blood centers and transfusion services may store and provide tissue, the AABB *Standards for Blood Banks and Transfusion Services*<sup>90</sup> includes requirements for managing tissue. Those requirements are found primarily in the general quality standards, the storage and transportation standards, and record retention standards. Efforts have been made to harmonize AABB tissue standards with those of AATB. AABB also provides guidelines and a handbook on tissue management by hospitals, rather than collection facilities.

### Legal Issues

Legal issues relating to tissue donation and transplantation are very similar to those of blood banking and transfusion medicine. Both involve the transfusion or transplantation from a donor to a recipient. Both are regulated health-care industries where industry standards play a major role. Claims involving the negligent infliction of injury to a donor or a recipient are common to both settings, as are issues involving consent, violation of standards and accreditation, and even issues surrounding antitrust and patient privacy.

In addition, several states have enacted the tissue equivalent of blood shield statutes.<sup>91</sup> These laws deem tissue banking to be the provision of a “service” and not the sale of a “product.” As such, they provide statutory immunity from claims for “strict liability” or “breach of an implied warranty of merchantability or fitness for a particular purpose.”<sup>92</sup>

As medical science has uncovered more uses for donated human tissue and as new tissue-engineered products enter the health-care arena, the issue of ownership has surfaced.<sup>93</sup> As described above, in the case of *Moore v. Regents of University of California*,<sup>71</sup> the California Supreme Court determined that a person has no property interest in his or her cells after they have been removed from his or her body. The court noted that California laws bestow no property rights on patients for their tissue that has been surgically removed. In addition, the court found that the cell line was “both factually and legally distinct from the cells taken from (the plaintiff’s) body.” Perhaps more significantly, the court stated that:

“The extension of conversion law into this area will hinder research by restricting access to the necessary raw materials [and]

destroy the economic incentive to conduct important medical research.”

In *Greenberg v. Miami Children's Research Institute*,<sup>94</sup> the plaintiffs were families suffering from Canavan disease, a degenerative affliction of the central nervous system. They created a patient registry and engaged a physician to conduct research. The physician successfully identified the gene and developed tests for the disease. He also obtained a patent for the relevant genetic sequence for his institutional employer so that it controlled genetic testing for this disease. The plaintiffs sued, claiming that they had not provided resources for the economic benefit of the defendants.

Much like the California Supreme Court's ruling in *Moore*, the Florida trial court failed “to find a property interest in body tissue and genetic information voluntarily given to defendants.”<sup>94</sup> The judge also determined that there was no liability for conversion because the samples, used only for medical research, were distinct from the patented genetic sequence. Finally, the court also voiced a concern that finding for the plaintiff would “cripple medical research.”

A variation on a theme occurred in a recent decision involving a prostate cancer researcher who moved from Washington University in St. Louis to Northwestern University in Chicago and wanted to take his tissue samples with him. In *Washington University v. Catalona*,<sup>95</sup> the university sued to retain the samples. Testimony revealed that the researcher in question sent letters to the patients asking them to sign a second consent form releasing their samples to his new institution.

Based on the holdings in *Moore* and *Greenberg*, the court remarked that a person retains no rights in his or her tissue once it is removed from their body. It is a gift, and the issue was to whom these patients gave their tissue samples. The court decided that the gift of tissue was made to Washington University and not to the researcher—a finding that was upheld on appeal.

The rapid growth of tissue activities is bound to give rise to novel legal issues, with the technical requirements differing from those applicable in the blood banking and transfusion medicine arena. Nonetheless, case law relating to the legal requirements for defining when a duty arises and the applicable standard of care are likely to be influenced by those areas.

## Legal Considerations for HIPAA Privacy Rule Compliance

Blood/tissue collection and transfusion/transplantation services are subject to myriad regulatory schemes. Few produce as much confusion as the regulations governing patient privacy.

The Health Insurance Portability and Accountability Act of 1996 (HIPAA) authorized the DHHS to promulgate patient privacy standards.<sup>96</sup> In December 2000, the DHHS Secretary issued the first national privacy standards to protect individually identifiable health information (the Privacy Rule)<sup>97</sup> intended to accomplish three goals:

1. To protect and enhance the rights of consumers by providing them access to their health information and controlling the inappropriate use of that information.
2. To improve the quality of health care in the United States by restoring trust in the health-care system among consumers, health-care professionals, and the multitude of organizations and individuals committed to the delivery of care.
3. To improve the efficiency and effectiveness of health-care delivery by creating a national framework for health privacy protection that builds on efforts by states, health systems, and individual organizations and individuals.

The privacy rule creates a variety of affirmative obligations for covered entities and subjects covered entities to potential civil and criminal liability for violations.

Although this regulatory framework has broad subject matter coverage, Congress and the DHHS have excluded certain transactions from HIPAA and its regulatory progeny. Furthermore, when it adopted the final rule in December 2000, DHHS removed language that would have defined the procurement and banking of blood and tissue as a “health-care” activity.<sup>97</sup> This has resulted in many challenging legal issues unique to the field of blood/tissue collection and transfusion/transplantation services. Therefore, practitioners in this field must make individualized assessments of who they are and what precisely they do to determine HIPAA applicability and the scope of their obligations under HIPAA.

### Determining HIPAA Coverage

HIPAA applies only to individuals or organizations that conduct certain specified transactions. Organizations first must evaluate whether HIPAA applies before introducing or modifying their privacy policies. Because there are several exceptions to coverage, determining HIPAA applicability is complex.

### Who or What Is a “Covered Entity”?

Covered entities are divided into three groups: health plans, health-care clearinghouses, and health-care providers.<sup>98</sup> Each group has separate organizational obligations and restrictions under the privacy rule.<sup>99</sup> Coverage of health-care providers is the broadest category of coverage and applies equally to individuals and organizations. If an organization or person in the blood/tissue collection and transfusion/transplantation field qualifies as a covered entity, it will likely fall within this category.

To evaluate whether an individual or organization is a covered entity, one must determine: 1) whether he/she/it falls within the definition of health-care provider; 2) whether he/she/it transmits health information in electronic format; and 3) whether the information transmitted relates to a covered transaction.

The term “health-care provider” includes specific types of providers, specific types of services, and a catch-all that extends coverage to any person or organization who furnishes, bills, or makes payments for health care in the normal course of business.<sup>98</sup> A blood bank that does not provide patient-related services (such as therapeutic apheresis) would not normally fit

within the definition of a health-care provider. An organization that provides blood transfusions or tissue transplantation services or dialysis treatment or dialysis supplies and equipment, however, likely would meet the health-care provider definition.

A health-care provider is not covered by HIPAA unless the provider transmits personal health information (PHI) in electronic form or stores information electronically. An organization probably would still be covered even if it used only printed documents, because many third-party payers require the electronic submission of documents.

The last element to determine covered entity status requires PHI to be related to a covered transaction. Covered transactions applicable to blood banks include: health-care claims or equivalent encounter information; health-care payment and remittance advice; coordination of benefits; health-care claim status; eligibility for a health plan; health plan premium payouts; or referral certification and authorization.<sup>98</sup>

Although many organizations and practitioners in the collection and transfusion industry might seem to be covered entities, there are some exceptions built into the health-care provider definition.

### What Is the Procurement Exclusion?

As noted above, during the regulatory process, the DHHS regulations implemented a “procurement exclusion,” which applies directly to blood/tissue collection:

[T]he procurement or banking of organs, blood (including autologous blood) sperm, eyes, or any other tissue or human product is not considered to be health care under this rule and the organizations that perform such activities would not be considered health-care providers when conducting these functions.<sup>97</sup>

Because procurement is not intended for the health care of the donor, HIPAA is inapplicable. Therefore, if an organization is in the business of collection only, it is not considered a health-care provider and the HIPAA privacy rule does not apply.

Some commentators argue blood/tissue collection centers are always covered health-care providers. The view is premised on an overly broad reading of HIPAA that contends that coverage is extended automatically by virtue of handling PHI. This reasoning constructs an implied purpose that does not comport with the careful limitations on the HIPAA provisions as drafted.

Blood/tissue collection centers that perform patient-related support services, such as transfusions, diagnostic testing or therapeutic phlebotomy, in addition to procurement, may be covered entities as described below.

### How Does HIPAA Apply to Organizations with Mixed Transactions?

If an organization provides both covered services and noncovered services, such as procurement, it may choose either to comply with the HIPAA privacy rules all the time, or to self-designate as a “hybrid entity” and observe HIPAA regulations only when engaging in covered transactions.<sup>98</sup>

Some organizations and practitioners have decided to comply fully with HIPAA privacy regulations all the time regardless of HIPAA’s applicability to all their transactions. They choose this option, among other reasons, to prevent internal separation of functions or any administrative restraints on the free-flow of information internally.

Blood/tissue collection services should not be classified as covered entities unless they chose this classification because the broader organization performs covered transactions and the overall organization chooses to be HIPAA-compliant across the board. If an organization chooses to classify itself as a covered entity, the entity is subject in its entirety to the privacy rule obligations.

By contrast, a hybrid entity may limit its compliance to only covered transactions.<sup>97</sup> This method of compartmentalized compliance is known as the health care component approach. This approach grants flexibility to organizations that provide both covered and noncovered functions, by creating modified compliance obligations. For example, a blood bank that also provides therapeutic apheresis services may comply with HIPAA in providing just those services, while ignoring HIPAA for noncovered functions, such as procurement.

Overall, evaluating whether an organization meets the covered entity definitions requires a detailed, fact-specific analysis of its business functions. It also requires an organization to assess the particular benefits, if any, of operating as a hybrid entity. Because of the complexity of HIPAA compliance implementation for hybrid organizations, there will be unique legal concerns for each entity to consider. Therefore, it is prudent to consult counsel when assessing coverage and the scope of an organization’s HIPAA obligations.

### HIPAA Privacy Rule Protections

The privacy rule entitles health-care patients to certain rights and requires covered entities to protect the disclosure and use of individually identifiable health information.

### What Information Is Protected?

Individually identifiable health information maintained, created, transmitted, or received by a covered entity is protected by the privacy rule. Under HIPAA, the information is protected when: 1) the information is created or received by a covered entity; 2) the information relates to the past, present, or future physical or mental health of an individual; the provision of health care to an individual; or the past, present, or future payment for the provision of health care to an individual; and 3) the information individually identifies the recipient of care or contains sufficient information that a person reasonably believes can be used to identify the individual.<sup>98</sup>

The privacy rule is triggered only when an organization is a covered entity or a business associate of a covered entity. For example, a health assessment survey completed by a donor in the course of blood donation is not considered PHI, *if* the blood bank is not a covered entity or has not agreed to be a business associate of a covered entity.<sup>100</sup> Where the transaction is procurement only, the HIPAA privacy rule protections do not attach, unless the blood/tissue bank has opted to comply with HIPAA as described above.

In addition, the privacy regulations protect covered entities who de-identify or strip PHI of individually identifiable information. The privacy rule creates a safe harbor when a covered entity divulges PHI, if the individually identifiable information has been properly removed. The protection of this process, known as “de-identification,” can be obtained in one of two ways: 1) preliminarily obtaining the opinion of a qualified statistician that the risk of identification of an individual is small<sup>101</sup> or 2) removing the statutorily specified identifiers that could potentially give rise to identification.<sup>101</sup> Absent de-identification, PHI remains protected and may subject a covered entity to liability upon improper use or disclosure.

### What Protections Are Afforded PHI?

The privacy rule imposes a general prohibition on the use or disclosure of PHI by covered entities, except as expressly authorized or required by statute. The terms “use” and “disclosure” are separately defined. Use applies to protected health information when it is shared, applied, analyzed, examined, or utilized *within* a covered entity, whereas disclosure applies when the information is released, transferred, divulged, provided to, or accessed from *outside* the entity.<sup>98</sup> A covered entity should differentiate between the terms to evaluate its duties and limitations.

The privacy rule expressly establishes circumstances for permissible use and disclosure. Within these parameters, most decisions to use or disclose PHI are at the discretion of the covered entity. There are two exceptions, however, both of which impose an obligation to disclose: 1) upon request by the individual who is the subject of the protected health information, or 2) to the DHHS during an investigation for regulatory enforcement.<sup>102</sup>

Generally, the conditions on use and disclosure are restrictive and vary depending on the recipient, the purpose, and other attendant circumstances. Some uses and/or disclosures may be authorized absent an individual’s consent, some require the individual’s permission, while other instances require the covered entity to provide notice and opportunity for the individual to object. Instances where authorization is not required deal primarily with treatment, payment and health-care operations,<sup>103</sup> or statutorily designated public priority purposes.<sup>104</sup>

These provisions are intended to restore control of PHI to the patient by granting the individual the authority to authorize or request greater or lesser privacy protections. Any disclosure not mandated or permitted by the regulations requires individual authorization.<sup>105</sup> Therefore, a covered entity should always have a sample authorization at its disposal. The authorization must be written in plain language, identify the information to be used or disclosed, identify the entity or person disclosing and receiving the information, contain an expiration date or event, and describe how an individual may revoke authorization. However, a covered entity may implement more restrictive policies on use and disclosures if it wishes, such as requiring authorization for transactions where it would not otherwise be required. Similarly, a patient is entitled to request more comprehensive restrictions, even though a covered entity is not bound to agree.

The privacy rule also grants patients new rights not otherwise available under federal law. An individual now has the right to access his or her PHI. This creates an obligation for a covered entity to facilitate a right of inspection or a right to copy the health information.<sup>106</sup> A covered entity may deny that request in the statutorily proscribed manner and situations, but the covered entity is often required to provide reasons for that denial to the individual.<sup>106</sup> In addition, the individual now has a right to amend his or her PHI.<sup>107</sup> Also, the individual is entitled to receive notice of the covered entity’s privacy practices<sup>108</sup> and an accounting of disclosures upon request.<sup>109</sup> As a result, covered entities must implement a “privacy policy,” place their patients on notice, and maintain a history of disclosures.

### How Does a Covered Entity Implement Its Privacy Policy?

A comprehensive privacy policy addresses each of the situations where disclosure and use of PHI is possible and develops and implements adequate procedures to prevent noncompliance. The policies and procedures at a minimum should cover use and disclosure requirements for PHI the covered entity creates, maintains, receives, or transfers. The policy should also address procedures for analyzing and acting on requests for uses and disclosures, and for managing an individual’s invocation of his or her privacy rights. A covered entity has a continuing obligation to ensure compliance. By performing periodic assessments or audits of all information collected, maintained, and received by the organization, the entity can better minimize risk of liability.

A covered entity must provide notice of its privacy policy<sup>110</sup> and include therein certain additional administrative requirements. Thus, a covered entity must designate a “privacy official,” who is responsible for developing and implementing policies and procedures, receiving complaints, and providing individuals with notice of the privacy policy.<sup>110</sup> Also, the privacy official or a designated contact person must document all complaints and implement a procedure for receiving and addressing those complaints.<sup>110</sup> A covered entity must also ensure and keep a record that its workforce, including employees, volunteers, trainees, and interns, are appropriately trained on the policies and procedures governing PHI to carry out their respective functions.<sup>111</sup> A consultant or law firm can facilitate the training for the entity, or the covered entity may choose to conduct the training in-house.

Additionally, a covered entity’s privacy policy must take into consideration state law. Because HIPAA authorizes states to enact legislation that provides for greater protections of the use or disclosure of PHI and perhaps more expansive individual rights, an organization should always consult with counsel to determine what additional requirements or restrictions, if any, are applicable.

### HIPAA PHI Safeguards

Reasonable safeguards are necessary to ensure that PHI is protected from intentional or unintentional disclosure.<sup>112</sup> Although the privacy rule does not require a covered entity to ensure the elimination of *all* risks of incidental use or disclosure, a covered

entity is expected to develop and implement minimum necessary policies and risk management strategies.

### What Is the Minimum Necessary Standard?

The minimum necessary standard, under the privacy rule, limits the amount of PHI that may be used, disclosed, or requested.<sup>113</sup> The covered entity must make reasonable efforts to limit the information to the minimum amount necessary to accomplish the intended purpose of the use or disclosure.<sup>113</sup> A covered entity is not required to perform individualized assessments of each use and disclosure. Instead, the covered entity must implement plans and policies that ensure the minimum necessary standard will be met. For example, covered entities should implement access policies on a “need to know” basis for their personnel by identifying persons or classes of persons within the organization and limiting their access to PHI to only the information necessary in the performance of their job duties.<sup>114</sup> However, the minimum necessary standard excludes disclosures intended for the purposes of treatment.

### How to Implement a Risk Management Plan

HIPAA provisions also require covered entities to implement a risk management plan. An appropriate risk management plan should implement a variety of administrative, technical, and physical measures to protect the use or disclosure of PHI in contravention of the privacy policy.<sup>112</sup> Traditional measures such as speaking quietly with a patient, avoiding the use of names, and isolating or locking file cabinets and record rooms are common practices. In addition, HIPAA requires covered entities to implement electronic security measures, such as password protection, limiting access, both on-site and remotely, enacting provisions governing portable electronic storage devices (laptops, CDs, and external hard drives), and installing fire walls and virus protection software.<sup>115</sup> A comprehensive risk management plan should address all facets of information flow, including access, storage, and transmission of PHI.

A covered entity should consider including mitigation provisions in the privacy policy. Should the disclosure of PHI occur, unintentionally or intentionally, the privacy rule requires a covered entity to mitigate, to the extent practicable, any harmful effect that is known of a use or disclosure of PHI in violation of its policies.<sup>116</sup> A covered entity should also consider implementing deterrence measures, such as sanctions against its workforce, for those who fail to comply with the privacy policies and procedures.<sup>117</sup>

### What Additional Safeguards Do Hybrid Entities Require?

Hybrid entities have further obligations to ensure security of PHI within the entity. HIPAA prohibits the disclosure of PHI by the health-care component to a noncovered component of the covered entity, in accordance with the privacy rule.<sup>118</sup> Moreover, a covered entity’s employees or persons within its workforce must not disclose PHI created or received in the course of work for the health-care component during their employment in a different

component.<sup>118</sup> Accordingly, the covered health-care component should develop appropriate privacy policies and procedures to minimize risk of internal disclosure.

### Business Associate Agreements

Even if a blood collection service does not meet the definitional requirements of a covered entity, HIPAA may still apply based on requirements relating business associate agreements.

### What Are Business Associates and Business Associate Agreements?

A business associate is not a member of the covered entity’s workforce, but performs or assists a covered entity in the performance of a function or activity involving the use or disclosure of PHI.<sup>98</sup> For instance, covered entities, such as hospitals, may require that a collection service enter into a business associate agreement before entering into contractual arrangements for the supply of blood and tissue or related services. Whether such an agreement is necessary turns on an examination of what the collection service is asked to do for the covered entity.

A business associate agreement is required only when an organization engages in activities involving the use or disclosure of individually identifiable health information. Those activities include, but are not limited to, claims processing or administration; data analysis, processing, or administration; utilization review; quality assurance; billing; benefit management; practice management, and repricing.<sup>98</sup> Because the procurement exclusion expressly exempts collections of blood and tissue from HIPAA, supply alone should not result in the exchange of protected health information. To accurately evaluate whether a business associate agreement is required, the parties should examine the extent of the services provided and the content of the information exchanged.

If an organization in the field of blood or tissue procurement and transfusion services designates itself as a covered entity, the organization has the added obligation to require business associate agreements. Business associate agreements govern the use or disclosure of PHI and are designed to ensure that business associates use PHI only for the purposes that they are engaged to perform or as otherwise required by law. Business associates must safeguard the information from impermissible uses and disclosures, report any such disclosures to the covered entity, and otherwise assist the covered entity in complying with HIPAA requirements.

### Are Third Party Business Services Covered?

A business entity may also provide business-related services, such as legal, actuarial, accounting, consulting, data aggregation, management, administrative, or financial services to or for a covered entity that do not involve health care but may involve access to PHI.<sup>98</sup> A covered entity should negotiate a business associate agreement with any third parties that provide these types of services, such as a certified public accounting firm that provides accounting or auditing services or an attorney whose legal services involve access or review of PHI.

In addition, HIPAA specifically includes accreditation as a covered service that gives rise to a business associate relationship. Therefore, covered entities or health-care components must ensure that PHI shared during the accreditation process is similarly protected from unlawful use or disclosure through a business associate agreement between the covered entity and the accreditation authority.

A covered entity has a continuing obligation to ensure its business associates comply with the terms of the agreement. A covered entity may be liable for actual knowledge of noncompliance. When instances of noncompliance do arise, the covered entity should consider appropriate actions to mitigate noncompliance or even consider terminating the relationship. In some instances, the covered entity must report the noncompliance to the DHHS.

### Privacy Implications for Research

Business associate agreements are not necessary for researchers. HIPAA creates an entirely different set of requirements for researchers and covered entities who elect to use PHI in their research. Traditionally, research involving human subjects has been governed by the DHHS Protection of Human Subjects Regulations<sup>119</sup> and/or the FDA human subject protection regulations, depending upon the source of funding for the research.<sup>120</sup> Now, HIPAA contains additional provisions for researchers.

### What Research Is Covered by HIPAA?

HIPAA extends the protections of the privacy rule to research groups that are covered entities and to research conducted by covered entities. Certain types of research, such as quality improvement research, may fall within the category of conducting patient care and subject the research to HIPAA in its entirety. In contrast, research performed that does not include the use of PHI may not meet HIPAA's threshold standard for coverage. As a result, organizations should preliminarily determine whether they will be subjected to HIPAA's privacy regulations before authorizing or conducting research.

### What Research Use or Disclosure Is Permitted

#### Absent Consent?

HIPAA establishes guidelines for research use and/or disclosure of PHI without authorization or consent. A covered entity is permitted to disclose PHI to a researcher solely to prepare a research protocol or for research involving only PHI of decedents.<sup>121</sup> All other PHI uses and/or disclosures require: 1) approval of alteration or waiver by an IRB or privacy board, 2) a limited data set agreement, or 3) individual authorization.

#### Privacy Board

A privacy board is an additional review body formed with the limited authority to evaluate requests for waivers of PHI. Board members should possess varying backgrounds of professional competency to review the effect of the research protocol on the

individual's privacy interests.<sup>121</sup> No member participating on the board can have a conflict of interest, and at least one member must not have affiliations with the covered entity or the entity sponsoring or conducting the research or its affiliates.<sup>121</sup>

A covered entity may use or disclose PHI only when it obtains a valid, documented waiver from the IRB or privacy board. The waiver should identify the board, the date of approval, the PHI needed, and a statement of review and approval procedures.<sup>122</sup> The researcher requesting the waiver must show that the research practically could not be conducted without the waiver or approved alteration.<sup>122</sup> In addition, the researcher must show that the use or disclosure will not involve more than a minimal risk to the individual's privacy. The burden to protect individual privacy requires the researcher to implement a risk management plan to protect PHI from improper use and disclosure, to destroy PHI at the earliest opportunity, and to provide adequate written assurance that PHI will not be reused or disclosed to any other person or entity.

### Limited Data Set Agreement

A researcher may also enter into a limited data set agreement with a covered entity. This allows the covered entity to disclose a limited set of PHI without individual authorization. Although the PHI is not de-identified, portions must be removed, such as names, street address, social security numbers, and account numbers.<sup>123</sup> Additionally, the research agreement must contain provisions that limit the use of the data set for particular purposes given, establish who is permitted to use and receive the data, ensure the security of the data, report any unauthorized uses or disclosures, ensure that agents and subcontractors agree to the same restrictions and conditions that apply to the recipient and not identify the information or use it to contact any individual.<sup>123</sup>

### Individual Authorization

A researcher may also use or disclose PHI when a research participant provides individual authorization. The researcher must first ensure, however, that the authorization meets specific HIPAA provisions governing authorizations.

HIPAA authorizations should not be confused with the separate legal requirement of informed consent. A researcher may decide to use one single form, known as a compound authorization, that contains both the provisions for consent and the authorization pursuant to HIPAA, or two separate documents, a "stand-alone" HIPAA authorization and a consent document. If a researcher decides to use a compound authorization, this document must undergo IRB review, given the element of consent. Otherwise, a HIPAA stand-alone authorization does not require review.

Additionally, a covered entity must determine when an authorization is required. For instance, when a tissue sample is used for clinical research *outside* of the tissue repository, HIPAA documentation must be obtained. It is not as clear, however, whether the de-identification of this tissue sample avoids HIPAA coverage.

Because HIPAA provisions authorize a covered entity to identify specimens according to a code format, de-identification of the sample should be possible. As long as the code is not related

to information about the donor, arguably tissue and/or blood samples may be unlinked from donor information. In these situations, researchers are struggling with the applicability of informed consent. Is consent necessary in this situation? Is the donor's privacy adequately protected by the safeguards in place? Does the de-identification safeguard use or disclosure in accordance with HIPAA? Will one-time consents be honored? Legal challenges certainly exist and the regulations governing research of tissue and blood will continue to be shaped in the upcoming years.

## Donor Privacy Protections Under State Law

In addition, blood donor confidentiality is generally mandated by *state* law, regardless of HIPAA's applicability to a specific case. Several states have statutes or regulations expressly requiring the safeguarding of donor confidentiality.<sup>124</sup> In some instances, courts have found such a right to be footed in the state constitution.<sup>125</sup> Other courts have identified a privacy right based on public policy.<sup>126</sup> Because the specifics of these privacy protections vary from state to state, it is important to be acquainted with the relevant state law in a particular case.

One effect of these provisions has been to restrict the discovery that can be taken from blood donors in transfusion litigation. In one California case, the court prohibited the plaintiffs from conducting even "veiled" depositions of blood donors, who would have remained unidentified behind a screen, because the court felt that this would have violated the strict state law on donor confidentiality.<sup>127</sup> More commonly, courts will permit an anonymous deposition or a deposition upon written questions of a blood donor to be taken where the donor has been identified as a source of an infectious agent and the deposition is not simply a "fishing expedition."<sup>128</sup>

## HIPAA Summary

Understanding HIPAA imposes difficult challenges on blood/tissue banks and transfusion/transplantation centers, or any organization or person procuring, supplying, or studying human cell, tissue, and cellular and tissue-based products. Procurement activities alone should not be enough to trigger HIPAA coverage. Hybrid entities are complicated to manage, however, and collection centers may be required to enter into business associate agreements with hospitals and other covered entities. All practitioners in this area should seek advice and guidance when facing uncertainties in HIPAA compliance.

**P. Ann Hoppe<sup>1</sup> & Sheryl A. Kochman<sup>2</sup>**<sup>1</sup> President, Hoppe Regulatory Consultants, LLC, Decatur, Georgia, USA<sup>2</sup> Chief, Devices Review Branch, Division of Blood Applications, Office of Blood Research and Review, Center for Biologics Evaluation and Research, Food and Drug Administration, Rockville, Maryland, USA

With the emergence of AIDS during the early 1980s, the interest of the public as well as regulatory authorities in the safety of the blood supply increased dramatically and has remained a top priority. The vast majority of blood and blood components for transfusion in the United States are supplied by free-standing blood centers that collect blood from donors or process blood and blood components for transfusion. Some blood is collected in hospital-based blood banks located in a hospital laboratory with a transfusion service. The current good manufacturing practice (cGMP) concepts apply equally to both blood establishment types. The high level of regulatory oversight has been due, in part, to the public's low tolerance for risk, especially risk associated with blood transfusions. It also has been difficult for the public to accept that resources are limited and that reducing the risks of transfusions further will require trade-offs for risk reduction in other parts of the health-care system.<sup>1</sup> Finally, because biologic systems are imperfect, reduction of transfusion risks to zero is not possible, regardless of the resources dedicated to achieve such a goal. In addition, despite increasingly effective safeguards in process control, human error can still defeat even the most stringent control devices.

Compliance with the provisions of Title 21 of the Code of Federal Regulations (CFR) specifying cGMP requirements that outline production process control for the pharmaceutical industry continues to be the focus of inspections and guidelines by the Food and Drug Administration (FDA). Although guidelines do not exert the force of regulations, they provide establishments with the FDA's current thinking regarding the systems in blood centers to control production processes. Further, compliance minimizes the probability that ineligible donors will be accepted or that unsuitable blood components will be made available for transfusion. This is an even more restrictive concept than that used by the FDA to define reportable errors in which quality is

defined as "... never releasing an unsuitable unit for transfusion or further manufacture."<sup>2</sup>

Current good manufacturing practice principles embrace industrial rather than medical concepts. The subspecialty of transfusion medicine has been carved from other medical disciplines over the last three decades.<sup>3</sup> Because blood center operations traditionally have been viewed as medical rather than industrial enterprises, the need to implement cGMP in blood centers was not immediately obvious and the benefits were only slowly recognized. Further, implementation of cGMP has been resisted by some blood banking professionals because they believed implementation would be detrimental to transfusion medicine as a medical discipline.<sup>4,5</sup> Finally, it has been observed that health-care organizations are not ideally suited for modern industrial management.<sup>6</sup> Thus, blood centers have been required to separate operationally medical functions, such as providing consultations and patient care, from manufacturing activities, such as the manufacturing of blood components. The prevailing standards of medical care largely define the practice of the former, whereas cGMP regulations govern the latter.

This chapter opens with the history and the elements of cGMP and an introduction to blood center supplementation of cGMP with statistical process controls and process innovation. A synopsis of additional regulatory criteria to be met by facilities in the United States selling plasma for fractionation is described (as reflected by the guidance documents issued by the Pharmaceutical Inspection Convention/Pharmaceutical Inspection Cooperation Scheme known as PIC/S). In addition, the application of recent scientific advances such as molecular approaches will be addressed.

---

**Historical Perspective**

The development and implementation of laws and regulations regarding drugs, biologic products, and medical devices are exceedingly complex. In the simplest terms, Congress passes broad enabling legislation and operational regulations are then

promulgated by regulatory agencies, primarily the FDA and Centers for Medicare and Medicaid Services (CMS) in the case of blood centers.

## Beginnings

Biologic products initially were regulated when Congress passed the Biologics Control Act in 1902.<sup>7,8</sup> Many provisions of this act established practices that remain part of current FDA law, more than 100 years later. Among these provisions is the requirement that a biologic product obtain premarket approval (ie, a license) for the article to be shipped in interstate commerce. Historically, all food and drug manufacturers were required to register their firms and products with the FDA. In order to ship biologic products in interstate commerce, however, both establishment and product licenses were required. A product license would not be issued in the absence of an establishment license nor an establishment license granted unless the firm manufactured at least one licensed product. In that scheme, a *responsible head* (under current terminology, an authorized official, see below) served as the contact between the firm and the FDA.

## Licensing Products and Establishments

Current regulations require that a firm file only a biologics license application (BLA) to ship blood products in interstate commerce.<sup>9,10</sup> In addition, the term *responsible head* was replaced by *authorized official*, and the responsibility for regulatory compliance rests with this person or persons designated to represent the firm. Firms that already held approved establishment licenses and product licenses were issued a new biologics license when the FDA received the first supplement to a firm's existing approved license. The approved product license along with the portion of the approved establishment license relevant to the requirements of the new regulation are deemed to constitute a biologics license under section 351 of the US Public Health Service (PHS) Act.<sup>11</sup> Although "user fees" do not apply to blood components at this time, the FDA has committed to work with sponsors to speed the process of biologics license regulatory review<sup>12</sup> and target timelines are applied to the review process despite the lack of a mandate. Guidance for industry about submissions is available from the FDA.<sup>13,14</sup>

The form used to apply for a license to market a new drug or biologic or to supplement an existing biologics license [Form FDA 356(h)], contains a certification section in which the applicant agrees, among other things, to comply with the cGMP provisions of the CFR. This certification clearly reinforces the emphasis by the FDA on cGMP.

The FDA has provided many guidance documents to ensure compliance with the requirements for BLA submissions.<sup>15</sup> This guidance partially echoes the scheme for interacting with the FDA about license changes as described in 21 CFR 601.12, which establishes reporting requirements.<sup>16</sup> The extent of FDA notification about a change is now categorized according to the significance of the change. Major changes, defined as presenting "... a substantial potential to have an adverse effect on the safety or

effectiveness of the product ..." require a supplement submission and approval (Prior-Approval Supplement/PAS) before distribution of a blood product in interstate commerce. Examples of changes (provided by the FDA) requiring this most stringent level of regulation include implementation of a new production process for a blood component or a change in contractor to perform a portion of the manufacturing process, including infectious disease testing of blood donors.

Moderate changes that present a "... moderate potential to have an adverse effect on the safety or effectiveness of the product ..." require notification of the agency (Changes Being Effected/CBE-30) at least 30 days before the distribution of a product affected by the changes. Included in this moderate category are changes such as implementation of a computer-assisted donor health history process or a change in manufacturer of automated donor apheresis equipment.

Moderate changes requiring supplemental submissions before distribution of a product affected by the change can also be made without waiting the 30 days (CBE). Labeling the application Supplemental Changes Being Effected (CBE) at the time of submission is required for this regulatory treatment. Examples of these changes provided by the FDA include the use of an FDA-approved standard operating procedure (SOP) of another licensed facility.

Minor changes are placed in the least stringent regulatory category. Such changes need only be included in the annual report. Examples of minor changes as outlined by the FDA might include modification of quality control procedures that are consistent with the manufacturer's instructions, changes in radiation equipment used by the applicant or a contractor, selection of a different leukocyte reduction filter or minor facility renovations.

From a practical standpoint, the changes brought by the single-license BLA have little impact on the day-to-day regulatory environment within which blood centers and transfusion services operate. The legal obligations with regard to cGMP remain unchanged, and the applicability of the cGMP elements described in greater detail below continues to expand. The FDA has encouraged licensees to communicate uncertainties about changes, including seeking guidance before implementing them.<sup>16</sup> It also encourages cover letters with submissions to improve communications between the agency and a blood establishment. As noted, the "authorized official" has assumed the previous vital role of the responsible head in such interactions, but the new terminology permits more flexibility in communication with the FDA because alternate authorized officials are acceptable.

## Recalls and FDA Enforcement Activities

Recall authority of the FDA essentially remains unchanged by the licensing process modifications (21 CFR 7.40-7.59) and applies equally to drugs, biologics, and medical devices. All products manufactured in violation of FDA requirements are subject to recall. Following revocation or suspension of a license, the FDA may also order a recall of products already distributed by the firm. In 1902 and 1903, the PHS, then the enforcer of the act, focused

on suspension and revocation of licenses as the basic enforcement mechanisms for biological products, with unannounced inspections occurring at least every 2 years. This compliance approach continues to dominate current FDA enforcement philosophy in dealing with biological firms it views as noncompliant.

### Safety Initiatives

In 1905 Upton Sinclair published *The Jungle*, which described horribly unsafe and filthy practices in Chicago slaughterhouses.<sup>17</sup> The book is widely regarded as providing part of the impetus for the passage of the Pure Food and Drug Act of 1906. That law addressed the purity of food and drugs but neither their safety nor efficacy. In 1909, at a time when inspections of biologic establishments were conducted by the Marine Hospital Service, the concept of responsible head was developed. This person acted as a single point of interaction between the FDA and an establishment.

Between 1909 and 1919 additional regulatory requirements were formulated to supplement the Biologics Control Act of 1902 (Table 64-1). Many of these provisions, such as training, production records, control records, and lot release requirements, remain part of the regulations today. These provisions are key elements of cGMP.

In 1938, over 100 people died from a pharmaceutical company's elixir containing a toxic alcohol. Simple toxicity tests would have demonstrated that the formulation was unsafe, but such tests were neither required nor performed. The Federal Food, Drug, and Cosmetic (FD&C) Act passed shortly thereafter required that the sponsor of a product subject to licensure or new drug approval prove its safety as well as its purity.

In response to the severe congenital defects caused by thalidomide in the late 1950s, the FD&C Act was amended significantly in 1962 (Kefauver-Harris amendments). For the first time drugs were also required to be proven effective, and this proof could be obtained only by clinical trials approved by the FDA before their initiation. Unapproved drugs could not be distributed and given to patients until an investigational new drug (IND) exemption for the candidate drug was reviewed and accepted by the agency. These amendments completed the well-known approval or licensure triad: safety, purity, and efficacy.

### Short Supply—A Unique Form of Oversight

An unusual provision of the Code of Federal Regulations provides an additional pathway to ensure compliance with the regulations but at the same time relieves the FDA of many burdensome inspections. Title 21 CFR Section 601.22 permits

unlicensed biologic products, such as Recovered Plasma, to be shipped for further manufacture while transferring the inspection responsibility from the FDA to the buyer of products declared to be in short supply. This provision applies particularly to unlicensed facilities because it permits any registered establishment to ship unlicensed Recovered Plasma (separated from Whole Blood), but not Source Plasma (obtained by apheresis), in interstate or international commerce under Section 601.22, provided the buyer has documented that the product is in compliance with the provisions of the CFR and the source material specifications for the final, FDA-approved product.

In applying the requirements of cGMP to a firm, the distinction between licensure and registration is more technical than real. Licensure is required to ship products subject to license in interstate commerce or internationally. Registration is required for all blood and tissue establishments, including those located in hospitals, that manufacture (collect, store, process, or distribute) blood components for transfusion or further manufacture. Registration requirements for blood are outlined in 21 CFR, Part 607; license requirements are in 21 CFR, Part 601. Tissue for transplantation (including progenitor cells) requirements are found in 21 CFR Parts 1270 and 1271.

### Enforcement Options

A major regulatory action available to the FDA for enforcement includes injunctions and consent decrees. In the early 1990s, regulatory letters sent to some blood centers cited failure to comply with provisions of Title 21 CFR Section 211. Through these letters the FDA gave all the blood centers notice that they would be required to comply, not only with the cGMP portions of the Title 21 CFR 600 series (although technically parts, they are often referred to as series), but also with the provisions of the 200 series. This application of the more strict regulations by the agency was reinforced in many Form FDA 483s (the reports of observations by individual investigators left with blood centers following an FDA inspection). Frequently these observations suggested that the investigator(s) did not believe the establishment was in compliance with regulations of the agency, including cGMP.

A pattern emerged in which blood centers gradually were being regulated as pharmaceutical manufacturers. Section 210.2(a) clearly states that the CFR 600 and 200 series supplement one another. Only when there is a conflict does one take precedence, and in that case the more specific applies.

In 1991, the FDA published a memorandum that outlined the more common deficiencies of blood establishments.<sup>18</sup> Deficiencies were most frequently found in the areas of donor deferral, viral testing, SOPs, and computer systems operations. Through this memorandum, the agency gave blood centers additional notice of its regulatory intent; this intent continues to be reinforced by current actions of the agency.

In 1991, the FDA also published the first draft of proposed "Quality Assurance Guidelines for Blood Establishments" and held a workshop to receive input from the regulated establishments.<sup>19</sup> It became very clear at this workshop that cGMP

**Figure 64-1.** The detection model of quality control. Note the negative consequences of failed inspections.

**Figure 64-2.** The prevention model of quality control. Note the similarity of this process with that of error management as diagrammed in Fig 64-4.

included quality systems and formed the cornerstone for FDA's intensified regulatory approach. It was reemphasized that blood centers producing blood and blood components are pharmaceutical manufacturers and would be regulated as such.

## Current Good Manufacturing Practice Rationale

As noted, cGMP is an industrial concept and, as such, its principles are rooted in industrial quality models.<sup>20</sup> In the traditional detection model for quality (Fig 64-1), testing of final product is used to discover production defects and weed out unsuitable products. Products are shipped with the knowledge that some percentage has undetected defects. It is left to the purchaser to discover a defective product and seek replacement. Detection has been the quality model generally used by health-care facilities.<sup>21</sup> But Deming, as well as others, emphasized that testing final products cannot improve manufacturing quality—it can only describe it.<sup>22</sup> The basis for this belief lies in the calculus of errors. Even a small variance in each process can result in major product variation if numerous production steps are required. Thus, the detection model is no longer viewed as ideal for controlling biomedical manufacturing establishments. Product testing as the primary means of controlling quality in blood centers is particularly unsuitable because the quality of the raw materials—blood given by volunteer donors—cannot be completely controlled. Furthermore, because each donation becomes a “lot” in the traditional pharmaceutical production sense, it is not feasible to perform additional tests on all products manufactured from each donation, that is, each lot. Finally, a blood product defect, such as contamination by an infectious agent that could have been intercepted by laboratory testing,

**Table 64-2.** Elements of Current Good Manufacturing Practice

may be discovered in a transfusion recipient only after disastrous consequences have ensued many months later.

In contrast to the detection model, the prevention model (Fig 64-2) seeks to obviate manufacturing variation by rigidly controlling manufacturing processes. In this model, it is assumed that employees will have lapses but that the design of the manufacturing systems will prevent such lapses from resulting in the release of components unsuitable for transfusion. This model is particularly apropos for blood centers because, as noted, the quality of the raw materials cannot be predicted or completely controlled; likewise, each lot (a component) cannot be exhaustively tested. However, the manufacturing processes can be controlled with the objective of reducing lot-to-lot variation. The cGMP concepts provide a roadmap for production controls and, as such, have been embraced by blood centers. The power of the elements of cGMP rests in their simplicity and universality. As described below, each element can be applied to any manufacturing function, or skill box. In the context of this chapter, skill box refers to the smallest discrete step in a production process that can be described, characterized by the FDA, and controlled. The elements of cGMP are listed in Table 64-2. This division into elements is arbitrary but is based on an analysis of commonality of the requirements of Title 21 CFR as they apply to all aspects of blood center operations. Thus, it is irrelevant whether they are applied to blood collection or to infectious disease testing; each element is applicable for each discrete blood center operation. The principle driving the elements rests in flow charts of operational production processes. In Fig 64-3 the general flow diagram of the production of platelets is shown. Optimally, cGMP elements are applied to each skill box in the manufacturing process. However, the cGMP elements should be viewed in the context of a blood center's entire production system. The safety of the blood supply is protected only by their application to the total system. The levels of protection (Table 64-3) of the blood supply create a safety system with intentionally designed redundancies.

### Standard Operating Procedures [§§211.100(a) and 211.22; §606.100(b)]

Management of standard operating procedures lies at the heart of quality manufacturing and cGMP compliance. For the purposes of this chapter, quality is narrowly defined as never

releasing a product unsuitable for transfusion or further manufacture. Because blood and plasma centers are required to follow their own SOPs, each SOP creates unique regulatory requirements for that center. From a regulatory standpoint, this concept is significant in that compliance standards and regulatory requirements are created by individual center SOPs. Procedures for documentation control are essential to ensure that all SOPs, including any changes, are reviewed and approved by the quality unit. Any deviation from established procedures should be documented and investigated. Such investigation should determine whether the deviation had an impact on quality. The results of such investigation should be reviewed and approved by the quality unit. A list of responsibilities of the quality unit is found in Table 64-4.

Current good manufacturing practice describes both the production methods used by blood centers to manufacture components and the manufacturing process controls in place. Section 211.22 requires approval of all SOPs by the quality control unit. As defined by the FDA, the quality control unit is an

**Table 64-4.** Quality Unit Responsibilities<sup>24</sup>

**Attributes of the Required Quality Unit**

- Responsibilities are described in writing.
- Is independent of production.
- Is involved in all quality-related matters.
- Reviews and approves all quality-related issues.
- Has adequate analytic control facilities at its disposal.

**Quality Unit Responsibilities Should Include, But Not Be Limited to, the Following**

- Approve specifications.
- Approve test procedures, including process controls.
- Approve validation plans, protocols, or equipment.
- Review changes in product, process, or equipment and determine if revalidation is required.
- Approve specification changes, sampling plans, and test procedures.
- Approve sampling procedures.
- Approve reference standards.
- Conduct analytic investigations and evaluate results.
- Approve testing materials.
- Provide analytical reports.
- Approve or reject intermediates and active pharmaceutical ingredients manufactured, processed, packed, or held under contract by another establishment.
- Gather data to support retest dates (stability testing).
- Evaluate and approve contractors.
- Review batch records.
- Review complaints.
- Dispose of materials not meeting specifications.
- Dispose of materials returned to the establishment.
- Perform internal and external audits.
- Perform periodic assessments of procedures, policies, and responsibilities within the establishment's manufacturing and control operations.

organizational entity with defined responsibilities and authority for controlling, through checking or testing, that specifications are met and quality systems are maintained. The FDA has explained that the quality control unit cited in 21 CFR 211 is equivalent to what is now called a quality program, quality system, or quality assurance department. However, the principle of having a single “head” responsible for quality issues remains extant, without regard to what designations appear on an organizational chart. All matters that relate to quality should funnel to a single person or group with broad knowledge of the entire blood center operation and access to the information necessary to assess the impact of proposed changes. These principles emphasize the importance with which the FDA views both the quality unit and SOPs.

Consensus has not developed about the level of detail that should be contained in blood center SOPs. It is generally agreed that they should be sufficiently explicit that a qualified technical person could, with minimal training, perform the described procedure and manufacture products that meet all requirements. Highly detailed SOPs require more frequent revision and are much more likely to be violated by center personnel, a failing that makes blood centers vulnerable during inspections, particularly when inspectors actually observe performance of procedures.

Every provision of a center’s SOPs must reflect the manufacturers’ instructions for licensed or approved systems used in the center. It is strongly recommended that planned deviations from a manufacturer’s instructions occur only after submission to the FDA of the proposed alternative; however, it should be noted that FDA does not generally look favorably on such changes as evidenced by the requirement at 21 CFR 606.65(e) for following the manufacturer’s directions for use. Difficulties associated with following a manufacturer’s directions for use should first be addressed with the manufacturer. Further, 21 CFR 211.100 requires that all deviations from SOPs, whether planned or inadvertent, must be documented. Change control of SOPs remains one of the more difficult issues for blood center management. Standard operating procedures to manage procedural changes are critical when implementing new and revised processes. Both meticulous change control and periodic review of SOPs during audits are essential to prevent “drift” in manufacturing processes.

A reference resource manual of SOPs of member centers maintained by America’s Blood Centers has proven to be a useful resource for supplying benchmarks for blood centers.

### **Record-Keeping (§§606.160, 606.170, and 211.180 through 211.198)**

Of the cGMP elements, record-keeping is perhaps one of the most important, particularly from the perspective of preparing for inspections or defending a center’s actions if legal issues arise. During an inspection, it is assumed that an activity not documented was not performed. In general, the record-keeping requirements of the 21 CFR 200 series are more detailed and rigorous than those of the 600 series. However, the provisions of both series require concurrent, legible, indelible documentation of each production step (linked to the operator by

dated signature or initials) and an audit trail for any changes subsequently made to records. These requirements apply to both paper records and electronic records but additional requirements for electronic records exist and are discussed below. Records for every lot must permit traceability and trackability of a product by both the manufacturer and the FDA during inspections and recalls. The latter may require reconstruction of manufacturing (including labeling) of a product that has been linked to an adverse reaction or other problem. Both the 21 CFR 200 and 600 series require that records of adverse reactions, deviations, and complaints be maintained. These records may be scrutinized during inspections because they may indicate weaknesses in the manufacturing controls of an establishment. It is essential that the records of these events include an evaluation of the problem to determine if a root cause analysis is warranted. If an investigation is performed, maintaining a detailed description of the process is critical. The records should document who made the decisions concerning whether the events also required a deviation report to FDA, whether look-back notifications or recalls are necessary, and, if a device failure was involved, whether a medical device report (MDR) was required in accordance with 21 CFR 803.<sup>25</sup> Likewise, if an investigation is not conducted, the rationale for not doing so and the identification of the individual responsible for that decision should be documented.

It is essential that the records extend to the training and competency of the personnel responsible for these decisions; that is, it is a cGMP requirement that only trained personnel be allowed to make these judgments. Important assignments such as these reporting functions should be identified in the position descriptions for the personnel. Meticulous records of compliance with cGMP elements are required to assure both upper management and the FDA that an establishment is in control. Control, in this context, can be defined as compliance in every respect with all of the establishment manufacturing SOPs and FDA requirements. It is worth emphasizing that if a firm’s SOPs are more stringent than FDA requirements, it is not acceptable to deviate from the SOP, even if the FDA requirement is met, unless appropriate change control and reporting to FDA are carried out before the deviation. During inspections of blood centers, whether by the private sector or regulatory bodies such as the FDA, the overriding investigational concern is whether an establishment is in control. Records should be designed to document control of manufacturing systems.

Record-keeping is greatly facilitated by blood center computerization. Increasingly, information management and technology are being used to maintain batch records, document process control, and similar record-keeping activities. Validation (see below) of computer systems used to maintain blood center records is the subject for extensive and detailed guidelines published by the FDA.<sup>26-31</sup> Further, the FDA notified vendors of blood establishment computer software that these programs are medical devices subject to regulation [including 510(k) clearance processes], and blood centers must ensure that software used for control functions is a properly validated, 510(k)-cleared device, or equivalent.<sup>32-36</sup> In the final section of this chapter, the

application of information technology to improve process control through process innovation is discussed further.

### Medical Devices (§820)

The Center for Biologics Evaluation and Research (CBER) maintains a list of all blood establishment computer software (BECS) it has cleared (<http://www.fda.gov/cber/products/510ksoft.htm>). Although this list is a valuable resource for blood establishments that are adopting their first or a new BECS, it should not be the only resource used. Newly cleared BECS are continually added to the list, but those that are obsolete are not removed from the list. Furthermore, although the list includes the version of the software that was reviewed and cleared, it does not necessarily reflect the most current version available. Not all changes to a device, including software, require submission to and clearance by the FDA; thus newer versions not appearing on the list may be legally available. Most important, the limitations of the 510(k) clearance process must be recognized.

The 510(k) review process was implemented in 1976 as part of the Medical Device Amendments to the FD&C Act. In general, before 1976, as long as a device was not associated with adverse events it was allowed to remain on the market. Those that were associated with adverse events could be ordered off of the market and if they remained on the market were considered illegal. When the Medical Device Amendments were enacted, rather than call for submissions to the FDA for the countless number of devices already on the market, it was determined that any device that was legally on the market was safe by the virtue of the fact that it had not been ordered off of the market.

However, the Amendments required that these devices be classified so approximately 1700 different generic types of devices were identified and grouped into 19 medical specialties. The devices were classified into three classes based on the level of control thought necessary to ensure device safety and effectiveness. Class I devices are those that FDA determined needed the lowest level of control to ensure safety and effectiveness. Class II devices are those that FDA determined need to conform to performance standards in order to ensure safety and effectiveness. Class III devices are those that FDA determined need the highest level of regulation to ensure safety and effectiveness.

Two processes for bringing new devices to market were developed; the premarket *notification* submission as described in Section 510(k) of the Act and a premarket *application* as described in Section 515. The premarket notification submission became known as a 510(k), whereas the premarket approval application became known as a PMA.

Under a 510(k), the submitter is required to show substantial equivalence to a legally marketed device. A legally marketed device is one that was legally on the market before 1976 (a pre-amendment device) or has been shown to be substantially equivalent to another device that has been cleared through the 510(k) process. These legally marketed devices are known as the “predicate.” Under a PMA, the submitter is required to provide a reasonable assurance of safety and effectiveness.

BECS is reviewed under the 510(k) process and thus the review focuses on a determination of substantial equivalence. A substantial equivalence determination is based on the similarity of devices to one another but does not require that a new device be exactly the same as the predicate. This is an important concept for users to understand; all BECS do not have the same features and perform the same functions. It is the user’s responsibility to determine what the requirements are and to determine which device or devices meet those requirements.

Another important aspect of the 510(k) review process is the fact that it does not consider compliance of a device manufacturer or a device with other parts of the regulations. For example, except in a few cases, it does not consider whether the manufacturer is in compliance with the medical device quality system regulation (21 CFR Part 820), MDR requirements (21 CFR Part 803), electronic records and signatures (21 CFR Part 11), etc. All of these can have an impact on the ability of the product to meet the users’ needs and requirements but FDA has not reviewed them as part of the premarket submission.

With this understanding of what the 510(k) review process is and is not, the user needs to take an active role in the identification and selection of a BECS. As mentioned earlier in this section, the list of cleared BECS is additive and obsolete versions of software are not removed from the list. Thus, the mere presence of a particular BECS or version of a BECS on the list does not mean that it is available or that it will meet current user requirements. Likewise, the absence of a particular version of a BECS does not mean that it is illegal for the vendor to market it. If the version number being offered for sale is only incrementally larger than one on the FDA’s list, it is likely that the changes were minor and did not trigger the need for a new 510(k). To determine if the product is marketed under 21 CFR 820, the user can look into the manufacturer’s inspection history. Although the FDA does not post a list of those manufacturers with an acceptable compliance history, it does post information about manufacturers who have compliance issues (<http://www.fda.gov/ora/>). Other information that may be related to device performance is available in the enforcement report (<http://www.fda.gov/opacom/Enforce.html>) for recalls and at <http://www.fda.gov/cdrh/databases.html> for MDR reports. However, all of this up-front research does not eliminate the need for the user to perform adequate validation of the software before putting it into actual use.

Why is validation necessary if the manufacturer has performed validation studies and the FDA has cleared a device? Validation is required because the manufacturer cannot anticipate every configuration in which its device may be used and thus cannot test every configuration. Nor can the manufacturer anticipate and test every data entry error that may result in an unintended consequence. Likewise, the environment in which the software will be used will vary from location to location. Proximity of other equipment and wireless systems will not have a direct impact on the software, but can have an impact on the hardware the software is used with. Therefore, the user must validate the software in the context of the complete system, ie, in its

operating environment. Thus, as with any validation project, the software validation must be performed on-site with the users' hardware and other equipment, personnel, SOPs, etc. In fact, 21 CFR 211.68 includes computers as equipment needing validation. It is important to note that if the manufacturer indicates that the software is compliant with 21 CFR Part 11, the user needs to include validation of this aspect as well.

### Electronic Records (Part 11)

Part 11 was promulgated to describe the criteria under which the FDA would consider electronic records, electronic signatures, and handwritten signatures executed to electronic records to be trustworthy, reliable, and generally equivalent to paper records and handwritten signatures executed on paper. Where electronic signatures and their associated electronic records meet the requirements of Part 11, the agency will consider the electronic signatures to be equivalent to full handwritten signatures, initials, and other general signings that the regulations require. Electronic records that meet the requirements of Part 11 may be used in lieu of paper records, in accordance with 21 CFR 11.2, unless paper records are specifically required. As one would expect, the computer systems (including hardware and software), controls, and attendant documentation maintained under Part 11 are subject to FDA inspection and must be readily available.

There are many aspects to Part 11 and an establishment can choose which records are going to be kept electronically. There are important distinctions regarding open vs closed systems and the various types of records and signatures required. Thus, when a facility is considering use of electronic records or signatures it is particularly important for the definitions in 21 CFR 11.3 to be understood.

Other software products, such as programs used for logging and analyzing data trends from quality system activities or from complaint and MDR systems, are available for use in blood establishments. Although these other types of software are not medical devices, they can be considered equipment and should still be validated for their intended use because they can have an indirect impact on product manufacturing. As an example, one facility had a calibration scheduling program that calculated the date of the next calibration in a manner different from that in the firm's SOP. This resulted in the calibration expiring before the recalibration date calculated by the software. The firm was deemed to be manufacturing outside of the SOPs and using equipment that was not calibrated.

### Personnel and Training (§§606.20, 211.22 through 211.34)

The requirements of the personnel regulations are designed to ensure that people engaged in the manufacture of biologics and drugs have sufficient education, training, and experience to perform their assigned functions. Section 211.22 also requires that employees be trained in cGMP by qualified individuals. Although these provisions present only the most general requirements, it is recognized that several key components must be included as part

of a personnel training program that complies with cGMP and that ensures SOPs are correctly implemented by all staff.

### Training

Training should be performed formally by personnel with documented credentials attesting to their qualifications, and the records of training should include clearly defined objectives and course content. Training in general systems (eg, computers, incident reporting, safety) are as important as technical training specific for an employee's tasks. Pre- and post-training examinations are one acceptable way of documenting the attendance of the employee and the effectiveness of the training. Refresher courses must be offered at predetermined appropriate frequencies and whenever a manufacturing or process control is changed. It is also critical that experience, education, and competency of staff and contractors be documented, without regard to whether they perform maintenance and repairs, training, auditing, or other staff functions, and particularly if they are expected to perform with little additional training after hire. In the absence of this training documentation and certification of credentials, it is critical that tasks performed be directly supervised; for example, records of laboratory equipment repair should be countersigned by the laboratory staff before the repair technician leaves the premises. It must be understood that the blood center remains responsible for all work performed on its behalf and the countersignature represents an assessment not only that the technician was present on a given day but that the work listed on the work order was in fact performed.

### Competency Testing

In addition to evaluations demonstrating effectiveness (pre- and post-training testing) accompanying formal training, personnel should demonstrate continued competency by periodic examination, review of records they generate, and actual task performance. The results of these assessments should be retained by the quality unit as well as part of employee training records. Personnel records should be subdivided to permit easy access to the training portions (and the corrective action relative to errors, if applicable) without divulging any confidential portion of the personnel record. If a weakness is detected, retraining and reevaluation become critical corrective actions. An employee who fails a competency evaluation (or makes a serious error in performance of duties) must not continue to perform that task without documented supervision until retraining and a satisfactory evaluation is recorded. The content of the assessment exercises is also a required record. It is not acceptable practice to discard the tests and maintain only the scores; however, maintaining a single master file copy of the test (rather than every employee's copy) is acceptable as long as scores can be related to the appropriate test instrument.

Some employees may feel threatened by these activities; however, they can be approached constructively. Proper training improves the performances of all employees and they should be taught that they are better prepared to comply with cGMP through training. Employee acceptance can be improved by

**Table 64-5.** Calibration Deficiencies: Synopsis of Warning Letter Citations

- 
- Written procedures for record keeping and equipment calibration are not followed.
  - Calibration logs, travel tickets, and donor files contained illegible corrections.
  - No documentation was available showing calibration of all equipment such as the donor scale, refrigerator alarm system, trip-scale temperature gauges, and thermometers used to monitor the incubator and freezer.
  - Records maintained for the incubator, freezer, and hematocrit analyzer revealed several instances of the equipment temperatures or calibration being outside acceptable ranges; no documentation was available to show that deviations were investigated or that corrective actions were implemented.
  - Equipment was not calibrated as prescribed in the standard operating procedures (SOPs) (21 CFR 606.60) in that the rpm calibration and timer check of the centrifuge was not performed every 60 days as required in the written procedure and operator's manual; vital signs monitor was not calibrated every 6 months as required.
  - An employee failed to enter the reference pipette calibration constant as required by the firm's SOP.
  - The SOP for microliter pipette calibration does not require a time frame for review of the calibration records; as a result, review of records did not occur until 6 to 14 months later.
  - The apheresis department does not have an SOP requiring a time-frame for review of equipment maintenance and calibration.
  - No document is available to show calibration and maintenance of the recording thermometers.
  - Quality control checks on other laboratory equipment are not being performed in accordance with established written procedures.
  - Numerous records reviewed during the inspection contained illegible corrections, and there is no documentation that these records were reviewed by a supervisor.
  - Staff failed to calibrate the stopwatch used in the calibration of the Hematastat's timer, the tachometer used to calibrate the Hematastat's rpms, and the sphygmomanometers.
  - Established written procedures for apheresis equipment calibration, monthly maintenance, and cleaning to avoid possible cross-contamination are not being followed.
  - There are no quality control and calibration records for the Diatek donor thermometer and the blood pressure cuff.
  - There are no quality control and calibration records, nor is there a written procedure for the quality control and calibration, for the scale used for collecting blood.
  - There were incomplete records of the quarterly performance testing of automatic cell washers and quarterly calibration checks of the Coulter counter instrument as required by the blood bank's written SOPs.
  - Records showed deficiencies related to the secondary review of analytic and calibration data.
- 

CFR = Code of Federal Regulations; rpm = revolutions per minute.

emphasizing that the performance of each employee is critical to the organization's success in complying with cGMP to ensure safe products, and that cGMP compliance is vital to the overall quality and regulatory compliance of blood center operations.

### Retraining

Ad hoc training of employees who have experienced lapses and made errors forms a vital step in continuous improvement programs (see below). When there is a documented event that requires retraining, such as an error that is detected after a product has been released or an employee who has failed a competency evaluation or proficiency testing, the retraining and its effectiveness must be documented as with other forms of training. However, citing retraining as the primary corrective action for an error raises additional questions. If this person's competency evaluation had inaccurately predicted the ability to perform, are there others failing to perform? Was the original training adequate or does the basic training need revision? What products may have been affected by inadequately trained staff? Is supervision of the employee adequate if the deficient performance was not detected until an error was made?

### Calibration (§§606.60 and 211.68)

Calibration has been defined as the comparison of a firm's measurement systems with known standards. An example may be helpful in describing calibration requirements. A centrifuge used to manufacture platelets has multiple process points that can be calibrated. Among these are the centrifugation timer, its tachometer,

and its brake timing. Subpart H (Laboratory Controls) of 21 CFR 606 outlines calibration requirements for several common devices used in blood collection, processing, and testing. Section 211.160(b)(4) outlines specific calibration provisions, requiring that all "instruments, apparatus, gauges, and recording devices must be calibrated under established protocols that specify periodicity." These provisions are applied to blood centers, and there is increasing evidence that FDA will apply all requirements stringently. Examples of deficiency citations that relate to calibration issues are found in Table 64-5. Other areas that some centers fail to address are the qualification of the equipment that will be used in calibration and the qualification of procedures and staff used by contractors performing calibration services. Blood centers retain full responsibility for ensuring that work will meet FDA requirements, whether it is done in-house or contracted.

In the 21 CFR 600 series, under Subpart D (Equipment), it is required that all production equipment be calibrated "... on a regularly scheduled basis as prescribed in the Standard Operating Procedures Manual." In Section 606.60 the calibration requirements of common blood bank equipment are provided in tabular form. This table is incomplete, however, and many of the automated systems currently used in blood centers are not listed. Guidance then must be sought in Section 211.68 and the manufacturer's instructions for the item.<sup>37</sup>

As noted, blood centers must have a calibration SOP that specifies the center's policies regarding this requirement. Traditionally, blood centers have delegated responsibility for equipment calibration to the section in which the equipment is used. A more

comprehensive approach is frequently used in the pharmaceutical industry in which a metrology unit is responsible for calibrating all equipment in the establishment. Scheduling can be computerized and can be integrated with process innovation system designs (see below). Centralized calibration of blood center measurement equipment provides several advantages, whether the metrology functions are provided by full- or part-time personnel, and is the preferred organizational approach. Management can easily review the calibration efforts of the establishment by consulting with one unit and one computer printout, centralized file, or set of records.

### Validation (§211.68)

Validation has been defined as documented evidence that provides a high degree of assurance that a specific process (or product) will consistently produce an outcome that meets established quality and performance specifications. Despite the lack of detailed validation requirements in either the 21 CFR 200 or 600 series, the FDA has focused on validation (especially of computer/software systems) during center inspections, at workshops, and in guidelines and memoranda.<sup>19,26-31</sup> It is clear that as blood bank systems continue to increase in complexity, validation of these systems will continue to be an important element of cGMP. During cGMP training, calibration frequently is confused with validation. Calibration deals with the assurance that critical measurement instruments for specific pieces of equipment used in the manufacture of blood components measure accurately.

Several aspects of validation are recognized as critical: system descriptions (including validation plans and protocols with established criteria for pass and fail), a defined process for review and acceptance of data including procedures for tracking and resolving all discrepancies, allocation of responsibility for the go ahead or no go decisions, assessment of impact on operations and revalidation requirements.

### System Description

Validation of a system cannot be achieved without an accurate description of the process that is to be validated. The description of the system should contain identification of all major pieces of equipment, software, hardware, and flow diagrams, as well as verbal characterizations of the systems or processes. Acceptance/rejection criteria should be described whenever appropriate. This aspect of validation is of particular importance for computer systems for which, as noted, specific validation guidelines have been published by the FDA.<sup>26-31,38</sup>

### Validation Protocol

A key component of validation, whether retrospective or prospective, rests in developing and executing a validation protocol and planning its integration with operational systems. This protocol should prospectively specify the manner and documentation of system or process validation, the testing to be performed (including stress or boundary testing), and acceptable statistical outcomes. Test protocols should address all operational situations and all equipment or hardware that will be used, all sites, minimal and maximal

load conditions, stress, interference, boundary conditions, etc, that can reasonably be anticipated. The protocol should include the validation of the physical environment of the system (installation qualification, or IQ), the testing of the equipment as installed (operational qualification, or OQ), and the plan to follow up on the actual operation of the system by trained staff after integration in routine usage (performance qualification, or PQ).<sup>29,38</sup> It should be noted that although retrospective validation may provide valuable information and some level of confidence in the object being validated, it should not be used in lieu of adequate prospective validation.

### Revalidation Requirements

Protocols should specify when system and process revalidation should be undertaken. Revalidation is integrally linked to both process control (see below) and change control. The latter should be governed by change control SOPs.

Historically, validation requirements for blood centers developed bidirectionally. Blood centers explored what was doable for their legacy systems, and the FDA defined best methods for validation of blood center systems in general, enforcing validation requirements when failure to validate resulted in operational errors. The private sector offered language that would extensively revise the proposed language but not change its effectiveness,<sup>39</sup> and the FDA to date has not finalized their draft guidance on blood bank systems, but relies on guidance issued for validation of computer systems for all FDA-related purposes.<sup>31</sup> On the other hand, the International Society of Blood Transfusion (ISBT) has issued guidance on validation of automated systems in blood banking.<sup>40</sup>

### Labeling (§§211.122–211.130; §606.120)

An important aspect of labeling of blood components lies in the definition of a lot or batch. In the 21 CFR 600 series, a lot is defined as "... having been thoroughly mixed in a single vessel." Clearly this definition relates only imprecisely to the production of blood components by blood centers and limits a *lot* to products from a single donor. Therefore, the term *batch* has more meaning in relation to release of products, and in the blood arena *batch* is usually defined as a group of products for which the laboratory tests were performed at the same time. Essentially, a batch release has the same meaning for blood centers as what the FDA has called a lot release. One of the difficulties created by these definitions rests in the inability to test each lot completely. This inability dictates that manufacturing controls must be in place to regulate product quality precisely, because only limited testing of the final product is practical. In many blood centers, labeling is used as a control point or final check that a unit, or lot, is suitable for transfusion or further manufacture, and that other required work, such as testing for viral markers, has been performed on the batch. Each component is checked, usually by a computer, to ensure that all of the testing and record checking has been completed and that no disqualifying information appears in the past or current records of either the donor or the donated unit. If the product is stored for any period after the initial release, there must be procedures to ensure that receipt of any postdonation information or

seroconversion of a donor results in appropriate interdiction of the products collected earlier, regardless of where they are stored.

It is essential that labels be recognized as a critical control element requiring strict procedures for inventory, archives, and change control, as well as appropriate checks of their acceptability for use (release to inventory) and approval of all changes. It is noteworthy that the recall provisions of 21 CFR 7.40-7.50 require a copy of reconstructed label(s) of the product being recalled to be provided to the FDA, regardless of the amount of time elapsed since the product was issued.

Increasingly, blood centers are installing automated label printers that make on-demand custom labels for components only after an electronic record review has found each suitable for release. These systems also permit electronic label reconciliation to approach label accountability requirements of 21 CFR Section 211.120. If duplicate labels can be printed, strict controls are required to avoid a mislabeling. Product release systems may include automated checks as additional safeguards at the time the shipments are packed. Two-dimensional barcoding permits encrypting a great deal of information about the unit on the label. The FDA has strongly encouraged transition to these systems through its support of the ISBT 128 barcodes and publication of guidance regarding its recognition of the standard. The agency has also cleared for marketing (<http://www.fda.gov/cber/efoi/510k.htm>) several transfusion safety management systems that use the barcode on the blood component unit in conjunction with a barcode on the recipient's wristband to ensure that the right unit is given to the right patient.<sup>41</sup> On-demand label printing should be validated to ensure that peculiarities of the printer(s) and labels used do not have an adverse effect on the final product labels. Printer technology has vastly improved, but the limitations of some printers, particularly dot matrix printers, make printing of labels difficult. In some cases, text is nearly impossible to read and does not allow for some of the font characteristics required in blood establishments. The most notable situation was related to the printing of reports rather than labels. Because the device printed only in capital letters, anti-C could not be differentiated from anti-c. This situation emphasizes the importance of validation of printers.

The FDA requires blood to have machine-readable labels in a format approved by the FDA [21 CFR 606.121(c)].<sup>13</sup> The information on the label that must be machine-readable includes:

- A unique facility identifier.
- Lot number relating to the donor ("unit number").
- Product code.
- ABO/Rh.

ISBT 128 is an international standard for the transfer of information pertaining to blood, tissue, and cellular therapy products that is already in use in many countries. It uses internationally agreed-upon terminology and label formats to ensure clear, unambiguous labeling. Use of common databases to interpret barcodes allows users to overcome language barriers when products are shipped internationally. Scanning of barcodes can serve to "translate" the language on the label. Features of ISBT 128 include:

- Donation identification numbers that are unique worldwide for a period of 100 years.

- A detailed product code database for blood, tissue, and cellular therapy products that is readily expandable.
- An international facility identification database.
- Improved process control capabilities through the use of standardized data identifiers, keyboard entry check characters, and concatenation of barcodes.

Information on ISBT 128 is available from the International Council for Commonality in Blood Bank Automation (ICCBBA), the organization that manages the standard (<http://www.iccbba.org>). The FDA provides guidance on barcode label requirements (<http://www.fda.gov/cber/gdlns/barcode.htm>).

### Error Management [21 CFR 211, §§606.160(b)(7)(iii) and 606.171 and 606.100(c)]

Other than the obligation to report adverse reactions as provided in 21 CFR Section 606.170 and the investigation of errors with documentation of corrective action as provided in Section 606.100(c), an integrated error management system is not specifically required by the provisions of Title 21, although the rules in 21 CFR 606.171 mandate the reporting within 45 days of all biologic product deviations on released products. Table 64-6 provides a summary of the reporting criteria and examples of reportable and nonreportable events. Traditionally, 21 CFR 600.14 has always required licensed facilities to report promptly any error that may affect the safety, purity, or potency of the product, and it was understood that a system was needed for capturing these events consistently. The FDA has recognized the importance of this cGMP element in a memorandum and regulations issued in 2001 (21 CFR 606.171). The rules are more broadly applicable to blood establishments than any preceding policies, although they are narrowly directed.<sup>42,43</sup>

The investigation and follow-up of deviations is critical to the successful improvement of blood center quality. Appropriate management of errors and accidents (or deviations in the current FDA terminology) forms the centerpiece of continuous improvement. Each blood center deviation should be treated as a "jewel" to be used as a case study for the staff to improve center processes. All facilities must develop SOPs for reporting, managing, and correcting errors and deviations. These SOPs should form the centerpiece of both blood center staff training and continuous improvement. Error management efforts and results should be documented in the records of the quality unit. Monitoring corrective action outcomes to ensure effectiveness is an essential part of the system for addressing corrections. Figure 64-4 illustrates a process diagram of error management; the similarity to the diagram of the prevention model of quality control (Fig 64-2) is evident.

Although error management systems are not defined in Title 21, some attributes of good systems have emerged both in blood centers and in industrial manufacturing establishments.

1. Employees at all levels in the organization are encouraged to report errors. Punitive policies discourage reporting and hence opportunities for systems improvements may be lost.
2. Employees involved in the process in which an error was made should be involved with the investigation and resolution of the error and process change. It is essential that the investigation

**Table 64-6.** Synopsis of Final Rule, on Reporting Biological Product Deviations<sup>2</sup>

- The rule applies to all establishments: donor centers, blood banks, transfusion services.
- Reporting time is not to exceed 45 days.
- Report by mail: Director, Office of Compliance and Biologics Quality, 1401 Rockville Pike, 200N (HFM-600), Rockville, MD 20853-1448; electronically: CBER's Web site: [www.fda.gov/cber/biodev/biodev.htm](http://www.fda.gov/cber/biodev/biodev.htm).
- If the answers to the questions below are affirmative, the event is **reportable**:  
 Was the event associated with manufacturing?  
 Did the deviation affect safety, purity, or potency?  
 Did it occur in a licensee's or a contract facility?  
 Did the facility have control over the product when the deviation occurred?  
 Was the product distributed?

**Reportable Biologic Product Deviations**

- An event occurs that may affect product purity, safety, or potency.
- Postdonation information is received that potentially affects safety.
- Compatibility sample was collected from the wrong patient.
- Collection or processing materials did not meet specifications.
- FDA requirements were not met on donor deferral and screening.
- Current or subsequent viral marker test was positive.
- Donor screening (history, arm inspection, etc) was not recorded.
- Both confidential unit exclusion stickers were not applied to unit.
- Donor deferral lists were incorrectly checked.
- Bag used for collection was outdated.
- Donor sample of unit was clotted or hemolyzed.
- SOPs for collections were inadequate or not followed.
- Collection time was not documented or extended.
- Time frame for collection or processing was incorrect.
- Use of special procedures was inappropriate.
- Testing was not performed in accordance with instructions.
- Unsuitable samples were used for testing.
- Mislabeling of ABO and the like occurred.
- Storage or shipping temperatures were incorrect.
- Unsuitable units were not quarantined.
- Special orders were not filled (for example, cytomegalovirus-negative).

**Examples of Nonreportable Biologic Product Deviations**

- Transfusion errors occurred outside the blood facility.
- An error was corrected before distribution and safety was not affected.
- Look-back, retrieval, or notification procedures were not followed.
- Donor protective measures were not met (age, colds, flu, etc).
- Previous donation records were not checked.
- Labeling errors occurred that did not affect safety (short expiration, etc).
- Shipping paperwork contained errors.
- Units were returned because of temperature deviations.

FDA = Food and Drug Administration; SOPs = standard operating procedures.

**Figure 64-4.** Error management process. Note similarity to the prevention model of quality control diagrammed in Fig 64-2.

be sufficient to determine the underlying root cause for the error rather than identifying mere “symptoms” of the root cause. The FDA also requires that staff be educated concerning the effect their errors have or potentially have on product quality; that is, it is required that they understand how their responsibilities have an effect on ensuring that only safe products are released.

3. Confirmation of the effectiveness of the corrective action is vital to ensure that the improved process continues to yield the expected results. Post-change monitoring is essential and long-term evaluation should be undertaken at appropriate intervals, eg, 3 or 6 months after a process improvement is completed.

**Quality Control Unit and Internal Audits [§§600.10, 606.20, 211.22, 211.192, 211.180(e)]**

Meeting the quality system provisions of Title 21 facilitates compliance with cGMP. As noted, Section 600.10 provides that an authorized official must be appointed to exercise control over all matters relating to compliance. Further, this designee must understand the scientific principles of manufacture. No similar provision is found in the 21 CFR 200 series, although the designated “official correspondent” is probably an equivalent function. A licensed establishment must tell the FDA who has been designated as its authorized official(s) and must report any changes. Similarly, an unlicensed registered facility must identify a reporting official on FDA Form 2830 as part of its annual blood establishment registration. The rationale for these provisions rests on the need for the agency to be able to deal with a responsible contact person in an establishment. Although the FDA permits the designation of alternative authorized officials, it takes no responsibility for the communication that must occur within a company. If a firm designates multiple authorized officials, the FDA may communicate with any one of them and the company must ensure that the information is disseminated appropriately. The authorized official can commit the establishment to certain courses of action, such as recalls and market withdrawals. Case law holds that upper management cannot avoid adverse consequences of noncompliance with regulatory requirements because a lower-ranking employee is designated the authorized official.<sup>44</sup> Some experts believe that the chief executive officer should be the responsible head (authorized official) to indicate the commitment of senior management to the principles of cGMP.<sup>45</sup> The Guideline for Quality Assurance in Blood Establishments states that, “A QC/QA Unit should report to management or its designee. In licensed firms, this unit should report to the Responsible Head who is the individual designated in the establishment license application to represent the firm in its regulatory activities with CBER [See 21 CFR 600.10(a) . . . ].”<sup>19</sup> However, this reporting structure is not wise unless regulatory compliance is a genuine part of the direct responsibilities and focus of this individual.

Section 211.22 states that an establishment must have a quality control unit [QC unit, quality program, or quality assurance (QA) staff] with several responsibilities designated in the CFR. Table 64-4 lists the responsibilities of the unit, including the authority to approve or reject all components and the approval

**Table 64-7.** Key Elements of a Blood Center Audit Program

|                                                                                                                                                                                                                                                                                                                                                                                           |

| <ul style="list-style-type: none"><li>• Written audit protocols.</li><li>• Audits of defined scope and purpose.</li><li>• Knowledgeable audit team members.</li><li>• Review of audit reports by authorized official.</li><li>• Referral of adverse finding for error management.</li><li>• Audit teams independent from production.</li><li>• Scheduled follow-up and reaudit.</li></ul> |
|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

of all written procedures used in the establishment. Although not required by the CFR, it is generally held that the QC unit should organizationally be distinct from manufacturing to ensure its independence, and this de facto requirement appears in FDA guidelines.<sup>19,46</sup> In many blood centers the director of the QA unit reports to the chief executive officer.

Although internal audits are also not specifically required by regulations, procedures to detect problems are required and internal audits are important to ensure that processes remain in control (see Production and Process Controls). Audits are included in the quality control guidelines and reference is made to Section 211.180(e), which requires written procedures for evaluation of manufacturing records. Audits, whether performed by the facility staff, by customers, or by contracted third parties, can serve a more substantive role in detecting manufacturing problems. The key elements of an audit program are listed in Table 64-7. Integration of audits with error management offers an opportunity to augment continuous improvement efforts of blood centers proactively, the result of searching for errors and defects.

The quality control guidelines in effect since 1995 (and very similar to the 1991 and 1993 versions) suggest that audits focus on the adequacy of the critical control points outlined in the guidelines.<sup>19</sup> One useful approach employs audits to assess the completeness of compliance with a cGMP element throughout the facility. For example, training and competency records could be reviewed in each unit throughout the center. In a second approach, a specific process can be audited and each skill box evaluated for compliance with all of the cGMP elements. Centers should develop audit procedures adaptable to their own operations.

Internal audits are considered confidential by the FDA and not available to FDA investigators unless fraud is suspected or there appears to be an imminent threat to public health. This policy is in place because if audit reports were reviewable by the FDA, reporting of audit findings might be discouraged. The FDA also respects supplier audits as confidential internal audit information. However, it is critical that the center have readily available SOPs for audits, schedules demonstrating that all elements of operations are reviewed regularly (at least annually), processes for ensuring and documenting corrective and preventive action and follow-up, and formal closure notices to complete the records. It is also essential that any deviations discovered in the course of audits be properly documented in records that are available to FDA investigators.

Quality units can be deployed to enhance the quality of blood center operations in a variety of ways. They can assume

responsibility for personnel training, especially in cGMP, maintain calibration and validation records, design validation protocols, identify trends through statistical analysis, etc. A well-directed quality unit can be of enormous value to both the authorized officials and the staff of the facilities in which it is established. However, quality unit staff are not the ideal staff to write SOPs, because they need to be the final approval authority and their objectivity cannot be ensured when reviewing their own work.

**Facilities and Equipment (Multiple Sections of Both the 600 and 200 Series)**

Most of the provisions in both the 200 and 600 series deal with sufficient space and work flow design to prevent mix-ups and, in the case of interviewing blood donors, ensure privacy. Written procedures, schedules, and methods for maintenance and cleaning are also addressed. To meet cGMP requirements, the contracts for cleaning, pest control, and maintenance must specify the materials to be used, the schedules, and the procedures, and must show evidence of review and acceptance by the contracting facility. Such records must be reviewed by the firm periodically, and should meet cGMP documentation standards with dates and initials, no cross-outs, etc. Signature logs should show inclusive dates of employment. Training documentation for all of the tasks performed, including avoidance of biohazards, cGMP and documentation practices must be available and show evidence of review by the quality unit staff.

The segregation of unrelated activities and the preservation of clean and dirty pathways for both in-process materials and staff are basic cGMP principles. Section 606.40 emphasizes quarantine facilities, because it is critical to physically separate components unsuitable for release from those suitable for transfusion or further manufacture. Sterile supplies should be protected from inadvertent exposure to dirty conditions or biohazard waste. Incoming goods must be physically separated from released-for-use inventory, and supplies with specific temperature requirements during storage (eg, copper sulfate and plastic blood containers) must go promptly to monitored areas. All records must be protected against inadvertent loss or alteration, which translates to well-organized, locked storage or restricted-access areas. The FDA has defined prompt retrieval of records to mean “availability within a few hours.” Off-site storage of blood products by licensed facilities requires pre-approval (license supplement) by the FDA and close oversight by the blood center to fulfill its responsibility to ensure that all FDA requirements will be met. Schedules of performance checks, as well as calibration, are provided in a table in Section 606.60, but as with calibration requirements, much of the equipment used today is not specified in this table. Centers must develop their own schedules. In Section 606.65 frequency of serologic reagent checks is specified.

**Process and Production Controls [§§606.100, 606.140, 211.100, 211.101(c)]**

In a sense, all of the cGMP elements are embodied in production and process controls. The requirements for SOPs, calibration, etc, are outlined in these provisions, as are a variety of quality control

procedures. The FDA accepts SOPs as provided by manuals of the AABB and the American Red Cross [§606.100(d)]. However, when these are referenced, it is important that the facility identify exactly which parts apply and determine that there is no conflict with manufacturer's directions or other FDA requirements. As previously emphasized, the determination that an establishment is in control is the most important attribute in the preservation of an establishment license.

With respect to validation testing, the reagents themselves are not being validated but rather the test *system* is being validated. Users should validate any new test before using it to test actual samples and should revalidate anytime a significant change to the system occurs. The underlying concepts for validating a test system are the same as for process and product validations. The components of the system should be listed and adequately described. Validation should address factors within the user's control at both the minimum and maximum criteria. For example, if the package insert for a reagent gives a range for incubation temperature, incubation time, centrifugation time, centrifugation speed, etc, the test system should be evaluated using both the minimum and maximum parameters. Likewise, if a test kit can be used with different brands or models of instruments, validation should be conducted for each instrument in the facility.

With regard to acceptance testing and routine QC testing, these tests are needed because once the reagent leaves the manufacturer's storage, it is no longer in its control. Although the FDA does require stability studies and shipping studies, among others, in support of licensure, the manufacturer cannot anticipate all of the adverse circumstances the reagent may be exposed to in shipping, use, and subsequent storage and therefore cannot test under them. The fact that most reagents used in blood establishments are derived from biological materials, which are labile and sensitive to many external factors, further complicates the issue of performance and acceptability.

Thus, the purpose of acceptance testing is not to test the manufacturer's ability to ensure lot-to-lot consistency but rather to determine if the reagent was exposed to and affected by adverse shipping conditions such as extreme heat or cold.

Once the reagent performance has been deemed acceptable for putting the reagent into use, it must be subjected to QC testing throughout its use. Quality control testing serves to evaluate the use and storage of the reagent. Most of the reagents are multi-use products opened and entered repeatedly over a period of days or even months. Testing should be directed at detecting product deterioration caused by contamination with other reagents or microbes, improper storage and use temperatures, excessive mixing or vibration, etc. It can also serve as a means of monitoring equipment function and user proficiency. For some reagents (eg, immunohematology reagents), minimum criteria for performance of QC are described in Title 21. For reagents for which there are no QC requirements in Title 21, the QC testing described in the manufacturer's package insert must be followed. In laboratories where clinical samples are tested, Clinical Laboratory Improvement Amendments (CLIA) requirements for QC, listed at 42 CFR 493, must also be followed.

Not all reagents used in blood establishments need to be licensed. Title 21 CFR 610.40 requires the use of FDA-approved test kits for the performance of tests for communicable disease agents. The agency provides a list of currently licensed human immunodeficiency virus (HIV) and hepatitis test kits (<http://www.fda.gov/cber/products/testkits.htm>). Title 21 CFR 640.5 requires licensed "or equivalent" anti-A, anti-B, and anti-D for blood typing but the regulations do not require that other immunohematology reagents be licensed. The expectation is that if licensed reagents are available, blood establishments will use them. If a licensed reagent is not available, reagents and tests developed in-house (eg, home-brew reagents), or expired licensed reagents may be used providing appropriate controls and labeling are in place. One example is when source material for a particular blood grouping reagent is no longer available or of sufficient reactivity to use as a reagent. In these cases, blood establishments may choose to use expired reagents with appropriate controls or serum from patients or donors known to contain the subject antibody. The blood establishment should use only those expired reagents or sera/plasma in an emergency with the approval of the medical director, and only when appropriately tested with positive and negative control cells. Also, if the blood establishment uses unlicensed sera/plasma to type a patient, it should retype the patient with licensed reagents when they are available. If the blood establishment uses unlicensed sera/plasma routinely, it must meet the requirements in 21 CFR 660.25 and 660.26. The facility must have an adequate QC program to monitor such sera/plasma. If the blood establishment uses unlicensed sera/plasma to type donor units, it should notify the consignee by attaching a label to the unit with the statement "Tested and found negative for XX-antigen using unlicensed typing reagents" or an equivalent statement. The establishment may use a tie-tag attached to the unit for the additional labeling. The FDA "Compliance Program Guidance Manual; Chapter 42 - Blood and Blood Products; Inspection of Licensed and Unlicensed Blood Banks, Brokers, Reference Laboratories, and Contractors 7342.001," provides more information on controls and labeling.

Most recently, some of the larger blood establishments have developed or are developing molecular methods for in-house use. These facilities generally have developed test methods to help them provide Red Blood Cell units with extended red cell typing for transfusion to patients with multiple antibodies or to reduce exposure to foreign antigens in transfusion-dependent patients. Although molecular tests have been available in some countries for many years, there are currently no licensed/approved/cleared molecular tests for blood typing available in the United States. It is expected that once methods are developed that allow for high throughput in a short period, there will be more interest in this technology and products will be submitted to the FDA for premarket clearance or approval. In anticipation of these future submissions, the FDA cosponsored a workshop with the National Institutes of Health.<sup>47</sup> In the meantime, several protocols are available for other medical disciplines that might be of interest (<http://www.clsi.org/>).

**Figure 64-5.** Platelet yield distribution. (Used with permission from Zuck.<sup>50</sup>)

## Current Good Manufacturing Practice Violations

The FDA periodically publishes common violations of cGMP. The classification of deficiencies cited on FDA 483 forms from routine blood center inspections indicate that many of these violations fell into four broad categories.<sup>18</sup>

- 1. Donor deferral.** Deferral records were incomplete and multiple reasons for deferral were not recognized. Incomplete or inaccurate donor identification was noted as a recurring problem.
- 2. Viral testing and review of testing records.** A variety of failures were outlined, including poor sample identification, failure to follow manufacturer's instructions, improperly qualified equipment, and samples tested numerous times without proper initial test invalidation (so-called *testing into compliance*).
- 3. Computer systems.** Failure to validate computer systems and lack of documentation of computer training and validation of change procedures were cited frequently.
- 4. Standard operating procedures and control of operations.** Citations included lack of adequately detailed SOPs for all steps in manufacture and/or failure to follow the SOPs.

A more recent and comprehensive "top 10" list released by the agency reflects all types of FDA-regulated facilities and is shown in Appendix 64-1.

## Process Control Imperative

Complying with cGMP and correcting deficiencies only begin to meet the public expectations for quality performance in manufacturing and distributing the nation's blood supply. Blood and plasma centers are developing quality improvement programs

based on principles of continuous improvement, statistical process controls (SPC), and process innovation. The objective of these efforts is to reduce lot-to-lot variation in blood component manufacture and the risks of blood transfusion to as low as reasonably achievable, a concept that originated in the reduction of risks associated with exposure to ionizing radiation.<sup>48</sup>

Continuous improvement initiatives are centered on error management by redesigning processes to prevent an error from recurring. They also embrace the prevention model of quality management that is rooted in SPC. As represented in Fig 64-2, this model monitors the various steps in manufacturing in an effort to determine which steps are, and which are not, in control. The many tools available to assist in these activities are beyond the scope of this chapter. However, several of the more important ones relate directly to cGMP compliance—frequency histograms (Pareto charts), Shewhart control charts (also called  $\bar{x}$ ,  $r$  charts), and process capability studies.<sup>49</sup>

Histograms are useful in plotting the results of individual process outcomes and to prioritize corrective action. Figure 64-5 illustrates a histogram describing results of platelet concentrate manufacturing at one center. The Gaussian distribution of this histogram, provided it is similarly contoured and placed as on prior charts, suggests that the manufacturing processes are in control. A kurtotic or skewed distribution or a shift in the mean count to the right or left would suggest that processes may not be in control.

Shewhart or control charts are regarded as a singularly important tool of SPC to detect drift and variation in manufacturing processes.<sup>49</sup> They permit identification of process weaknesses that result in lot-to-lot variation. When identified, process redesign can be undertaken to improve manufacturing and product quality.

Pareto charts offer another tool for blood center quality improvement.<sup>49</sup> The frequency of cGMP problems discovered by audits or error management are charted on a histogram and give management the option of addressing first those problems that have both the most frequent occurrence and the highest likelihood of causing release of blood components unsuitable for transfusion. One of the difficulties of the current FDA inspection approach lies in its inability to differentiate a major from a minor infraction. For example, on Form FDA 483, failure to perform specific gravity of a copper sulfate solution may appear as a cGMP violation of equal importance to performing faulty HIV donor screening. In the United Kingdom, inspectional findings of blood centers are graded from critical (those that pose an imminent health hazard) to other (those of low probability of causing damage). This strategy permits both the inspected establishment and the public to assess the seriousness of the findings. The FDA has established grades of license change applications, and favors risk-based assessment of the threat to public health posed by deficiencies. Blood center personnel are encouraged to focus on those deficiencies most likely to affect the public health. Meanwhile, Pareto charting as a tool to determine priorities for error management within a blood center will partially compensate for inspection and recall policies that may not reflect the seriousness of deficiencies.

## Future Initiatives

### Process Innovation

Implementing cGMP represents only the initial effort to improve the safety of the blood supply by strengthening process controls in blood centers. Process innovation presents another opportunity for centers to improve significantly the safety of the blood supply.<sup>51</sup> To oversimplify, process innovation employs information technology (IT) to control manufacturing processes.<sup>23,51</sup> Recent initiatives have included work known as process and analytical technology (PAT), which is defined as systems for analysis and control of manufacturing processes based on timely measurements, during processing, of critical quality parameters and performance attributes to ensure an acceptable end product. This work is based on the premise that all products have critical quality attributes, and process variables can be controlled to maintain the critical quality attributes within acceptable limits. PATs are applied to achieve both understanding and control of process variables that are causally linked to product quality attributes.

Initiated in industry to improve productivity, process innovation is being instituted in blood centers to improve quality and is defined in this chapter as the prevention of the release of units unsuitable for transfusion. Integrating computer control of manufacturing processes offers a significant advance to reduce further the risk of infectious disease transmission by blood transfusions. A few examples may illustrate the power of this strategy. Currently, blood center computer systems can be configured to prevent recruitment of deferred donors. Because deferred donors have been excluded from the rolls presented to telerecruitment

**Figure 64-6.** Theoretic process innovation in blood centers.

departments, they cannot be recruited. This principle can be extended. Figure 64-6 illustrates the capability of IT to control manufacturing processes. Personnel records can be linked with production records to prevent unsuitable employees from using their access codes to create batch records. Similarly, a centrifuge in need of calibration on a certain date could be precluded from use beyond the calibration expiration date. The power of linking IT with process controls lies in preventing the manufacture of components unsuitable for transfusion. Components not manufactured cannot be released. Other examples of process innovation designed to increase the safety of the blood supply can be envisioned. More advanced systems will emerge as this technology is implemented in blood centers throughout the country. As discussed previously, definitive guidance on electronic signatures and electronic records has been issued and will support the move to process innovation.<sup>52</sup>

### Harmonization with International Standards (PIC/S)

Blood centers that sell Recovered Plasma in the international market are increasingly subjected to the European interpretation of cGMP. Although there are many similarities between US and European requirements, there are also some striking differences. Awareness of the criteria reflected in the guidance documents issued by the PIC/S will be beneficial in ensuring that inspections by foreign authorities go smoothly.<sup>53-55</sup> Because there have been relatively few inspections carried out by the foreign national authorities, it is not clear how rigidly inspectors will apply the stated requirements summarized below. Different plasma fractionators may have different requirements based on where the end products will be marketed.

### Potential Issues

The QA system must be assessed for effectiveness by management at regular intervals. There must be written delegation of responsibility for hygiene and lot release (lot release requires two senior staff). All records must be kept at least 10 years; donor eligibility and testing records are to be retained at least 30 years (for some fractionators, 33 years). The manual alternatives to automated systems must be exercised with a mock breakdown at least annually. Sterility certificates must be checked before sterile goods are released to inventory. A second person must document performance of a check of all numbers (tubes, product, record forms) after donation. Staff must also control the discard of all unused

numbers. Records storage areas must be locked and have restricted access. Donors may not touch their records except for filling out the initial form. The methods of transport for products and samples must be validated for every phase. Environmental monitoring is required for “clean” work areas. A physician or approved substitute, as well as QA staff, must be present during donor processing.

All manual computer entry must be verified. If samples are pooled for any kind of testing, equivalence study data must be available. Reagent qualification data are required for every lot received. A 2-year retention period is required for test samples. Leukocyte-reduced Red Blood Cells must be shown to have 40 g hemoglobin/unit and hemolysis must be less than 0.8% at the end of shelf life (US products are cleared by the FDA with 1% hemolysis at expiration). Platelets must have a pH of 6.4 to 7.4 at 22°C (vs automated testing at 37°C).

### **Donor Eligibility and Blood Collection**

The eligibility criteria for donors are based upon the Council of Europe “Guide to the Preparation, Use and Quality Assurance of Blood Components.”<sup>56</sup> Some of the differences from the usual US criteria include: donors over 65 years of age need annual physician clearance; males must have a hemoglobin of 13.5 g/dL or higher. Permanent deferral is required for a history of babesiosis, kala-azar, Chagas’ disease, corneal transplant, and convulsions or repeated syncope (or >3 years since last medication without recurrence). Donation is deferred for 6 months (or 4 months with negative NAT) following endoscopy and pregnancy. The donor’s address must be proven and a list of unacceptable addresses posted and periodically updated. The staff must check for a prior deferral and the deferral list details must be defined in writing. The donor’s social security or other identification number is required and donor identity must be confirmed/documented a minimum of twice per visit. The identification step must be repeated before phlebotomy even if the same staff person already identified the donor. Manual blood pressure tests can be performed only by a nurse or physician and all abnormalities are referred to a physician. Tattoos, piercings, branding, or scarification need location and date of procedure noted. Sterility documentation must be from an official source rather than the facility that performed the tattoo or piercing if the donor is accepted with less than a 6-month (for some fractionators, 12-month) wait. Softgoods cannot be set up in advance, including no removal from overwrap until hung. The arm disinfection must be completely dry AND include at least a 30-second wait. It is required to check the product container for defects after collection and to have an independent recheck that all tube, container, and record numbers match. The maximum time allowed between collection and processing must be defined and must be monitored. Complaints require statistical evaluation.

### **Facilities Issues**

The facility must be designed to minimize risk and preclude entry of persons not working in the area. Inspections will assess facility design and size for suitability of rooms and equipment. The collection areas must be suitable for the intended purpose, lack any

incompatible features, and have documentation of QA approval before use. Written assessment of mobile sites before use is required. Testing laboratories should not open to production or storage areas and should preclude donor or public access. Any scissors that are used must be disinfected between cuts of product tubing. Recently, the use of scissors has been banned entirely by some inspectors. Facility design must effectively bar insects and pests of any kind. Cleaning and pest control programs require validation and documentation that includes the products to be used, the areas involved, the methods used, and the schedules established. Segregation of unrelated activities, complete isolation of biohazards, and defined “clean/dirty” pathways are required. No food or drink is allowed in the donor room and all exterior doors are locked if not a defined reception area with continual staff presence. Donor privacy is required for screening and “white noise” is not allowed; there should be no passage way or waiting area next to interview booths. Restrooms should not be available to nondonors. Air flow must be known and be appropriate for clean areas. Walls, floors, and ceilings should all be smooth and cleanable; no carpets or uncleanable mats are permitted. No wooden pallets are permitted. There should be no right of way past biohazardous waste. The biohazardous waste storage area cannot have a re-circulated air supply, and cages are not sufficient isolation. In-use biowaste containers should be visibly clean, be covered or have a restricted opening, and must be emptied daily from the work area. Hand-washing instructions must be posted at each sink.

Freezer validation is critical and must include mapping. Freezing process validation is also required to determine the length of time required to reach a core temperature of –25°C or colder. The freezing process requirements at the time of this writing included that plasma be rapidly frozen at –30°C or colder. Products should be frozen in the coldest area and the alarm and recorder probes should be placed in the warmest spot possible. A difference of at least 2°C (4°C preferred) between the alarm set-point and the maximum freezer temperature is expected. Plasma must be stored and transported at –20°C or colder.

The recorder probe should be in a volume of fluid no larger than smallest product and the fluid should be changed at defined intervals. A back-up thermometer must be inside the freezer and be read daily by staff and documented. Even the defrost cycle cannot exceed the required temperature limit. A freezer map must be posted both inside and out and differentiate where each type of product is stored (untested, tested, quarantine, autologous, released, etc). If a flash freezer is used, staff must document the time required, as determined by study of minimum/maximum loads, etc. Records must include identification of the specific units in each batch as well as the temperature for that batch. Both optical and acoustic alarms are required for freezers. Any removal of product from the freezer must be documented not to exceed a period of 20 minutes at room temperature.

### **Documentation of Look-Back Investigations**

The expected time frames for receipt of viral marker test results must be defined. Notification must be received in less than 7 days

for repeat reactive results and less than 21 days for confirmatory tests. All look-back investigations must be performed within 2 working days. Customer confirmation is required for receipt of notice. Notice must include a period of at least 6 months before the last negative test or 5 years.

## Summary

In this chapter, the development of cGMP elements in the FDA regulation of the pharmaceutical industry and their more extensive application to blood establishments are reviewed. Vigorous application of cGMP principles to the production processes of blood and blood components has greatly reduced, but not completely eliminated, risks associated with the transfusion of blood components. Fortunately, the availability of industrial models broadly applicable to blood centers has facilitated cGMP implementation.

Current good manufacturing practice compliance now represents minimal performance standards for blood centers, and principles of continuous improvement and error rates as low as reasonably achievable have become the hallmarks of quality. Process innovation offers exciting mechanisms for extending the safety of an already exceedingly safe blood supply. Information technology will likely be featured prominently as an increasingly vital part of these innovations.

## Section VI

- 21 CFR 606.160(b) Failure to maintain [donor] [processing] [storage and distribution] [compatibility testing] [quality control] [general] records.
- 21 CFR 606.160(a)(1) Records are not concurrently maintained with the performance of each significant step in the [collection] [processing] [compatibility testing] [storage] [distribution] of each unit of blood and blood components so that all steps can be clearly traced.
- 21 CFR 606.20(b) The personnel responsible for the [collection] [processing] [compatibility testing] [storage] [distribution] of blood or blood components are not adequate in [number] [educational background] [training and experience, including professional training as necessary] to ensure competent performance of their assigned functions, and to ensure that the final product has the safety, purity, potency, identity, and effectiveness it purports or is represented to possess.
- 21 CFR 606.160(a)(1) Records fail to [identify the person performing the work] [include dates of the various entries] [show test results] [include interpretation of the results] [show the expiration date assigned to specific products] [be as detailed as necessary] so as to provide a complete history of the work performed.
- 21 CFR 606.171 Failure to submit a biological product deviation report [within 45 days from the date you acquired information suggesting that a reportable event occurred].
- 21 CFR 606.65(e) Failure to use supplies and reagents in a manner consistent with instructions provided by the manufacturer.

### Drug Citations

- 21 CFR 211.22(d) The responsibilities and procedures applicable to the quality control unit are not [in writing] [fully followed].
- 21 CFR 211.100(b) Written production and process control procedures are not [followed in the execution of production and process control functions] [documented at the time of performance].
- 21 CFR 211.110(a) Control procedures are not established which [monitor the output] [validate the performance] of those manufacturing processes that may be responsible for causing variability in the characteristics of in-process material and the drug product.
- 21 CFR 211.160(b) Laboratory controls do not include the establishment of scientifically sound and appropriate [specifications] [standards] [sampling plans] [test procedures] designed to ensure that [components] [drug product containers] [closures] [in-process materials] [labeling] [drug products] conform to appropriate standards of identity, strength, quality, and purity.
- 21 CFR 211.100(a) There are no written procedures for production and process controls designed to assure that the drug products have the identity, strength, quality, and purity they purport or are represented to possess.
- 21 CFR 211.165(a) Testing and release of drug product for distribution do not include appropriate laboratory determination of satisfactory conformance to the [final specifications] [identity and strength of each active ingredient] before release.
- 21 CFR 211.192 There is a failure to thoroughly review [any unexplained discrepancy] [the failure of a batch or any of its components to meet any of its specifications] whether or not the batch has been already distributed.
- 21 CFR 211.25(a) Employees are not given training in [the particular operations they perform as part of their function] [current good manufacturing practice] [written procedures required by current good manufacturing practice regulations].
- 21 CFR 211.188 Batch production and control records [are not prepared for each batch of drug product produced] [do not include complete information relating to the production and control of each batch].
- 21 CFR 211.67(b) Written procedures are not [established] [followed] for the cleaning and maintenance of equipment, including utensils, used in the manufacture, processing, packing or holding of a drug product.

### Bioresearch Monitoring Citations

- 21 CFR 312.60 An investigation was not conducted in accordance with the [signed statement of investigator] [investigational plan]. Specifically\*\*\*
- 21 CFR 312.62(b) Failure to prepare or maintain [adequate] [accurate] case histories with respect to [observations and data pertinent to the investigation] [informed consent].
- 21 CFR 312.62(a) Investigational drug disposition records are not adequate with respect to [dates] [quantity] [use by subjects].
- 21 CFR 56.115(a)(2) Minutes of IRB meetings have not been [prepared] [maintained] in sufficient detail to show [attendance at the meetings] [actions taken by the IRB] [the vote on actions, including the number of members voting for, against and abstaining] [the basis for requiring changes in or disapproving research] [a written summary of the discussion of controverted issues and their resolution].
- 21 CFR 312.60 Failure to obtain informed consent in accordance with 21 CFR Part 50 from each human subject before [drug administration] [conducting study-related tests] . Specifically\*\*\*
- 21 CFR 56.108(a)(1) The IRB [has no] [did not follow its] written procedure for conducting its [initial] [continuing] review of research.
- 21 CFR 312.66 Failure to report promptly to the IRB all unanticipated problems involving risk to human subjects or others.
- 21 CFR 50.27(a) Informed consent was not properly documented in that the written informed consent used in the study [was not approved by the IRB] [was not signed by the subject or the subject's legally authorized representative at the time of consent ] [was not dated by the subject or the subject's legally authorized representative at the time of consent].
- 21 CFR 56.108(c) For other than expedited reviews, the IRB does not always review proposed research at convened meetings at which a majority of the members of the IRB are present, including at least one member whose primary concerns are in nonscientific areas.

MDR = medical device report; SOP = standard operating procedure; IRB = institutional review board; HCT/P = human cells, tissues, and cellular and tissue-based products; cGTP = current good tissue practice.

# Transplant Organizations and Networks in the Regulation of Cellular Therapy Programs

**Dennis L. Confer**

Clinical Professor of Medicine, University of Minnesota, and Chief Medical Officer, National Marrow Donor Program, Minneapolis, Minnesota, USA

Worldwide, multiple governmental and nongovernmental organizations are involved in various aspects of cellular therapy. Understanding these organizations and their roles provides useful insights on the current and future directions in this field. Practically speaking, most of the existing structure has developed to support only one cellular therapy—namely, hematopoietic stem/progenitor cell transplantation (HSCT). As additional cellular therapies emerge, new entities might develop in support of these therapies or the existing organizations might enlarge their scope to embrace new aspects of the field. This type of evolution is particularly well illustrated by the development in recent years of umbilical cord blood (UCB) as a useful graft source for allogeneic HSCT. Several organizations with long-standing roles in traditional HSCT have expanded their activities to include UCB transplantation. At the same time, new organizations, eg, NetCord and Eurocord, have also emerged to play important roles in this developing field.

## Hematopoietic Stem/Progenitor Cell Transplantation

The therapeutic use of HSCT has been expanding for nearly 40 years.<sup>1</sup> Today, an estimated 60,000 HSCT procedures are performed annually, worldwide. Twenty-thousand of these are allogeneic transplants in which the stem cell graft has been procured from a living donor or from the placental/umbilical cord blood of a newborn. Marrow collected under general anesthesia from living donors was previously the sole graft source for HSCT, but today peripheral blood progenitor cells (PBPCs) are employed for virtually all autologous HSCTs and for more than 70% of allogeneic living donor HSCTs. The use of UCB units for HSCT continues to be more prevalent among recipients who are children or adolescents, where UCB units are used in 20% to 25% of allogeneic HSCTs.

The most common indications for allogeneic transplantation are hematologic malignancies, eg, acute myelogenous leukemia, acute lymphocytic leukemia, and myelodysplastic syndrome. Chronic myelogenous leukemia was previously the single most common allogeneic HSCT diagnosis, but transplants for this condition have declined with the development of tyrosine kinase inhibitors, especially imatinib.<sup>2-4</sup> Severe aplastic anemia and other marrow failure states are the most common nonmalignant conditions that are indications for allogeneic HSCT. Up to 40% of transplant procedures for children, however, are performed for nonmalignant conditions including congenital metabolic disorders and inherited and acquired immune system abnormalities.

HLA matching between the donor and recipient plays a critical role in the success of allogeneic HSCT.<sup>5-10</sup> The HLA Class I proteins, HLA-A, -B, and -C, are expressed on the surfaces of most cells in the human body. The Class II proteins, HLA-DR, -DQ, and -DP, are more restricted in their natural expression, but can be induced by various stimuli. HLA is fully discussed in Chapter 57.

The HLA proteins are encoded by genes that reside in a relatively small region on the short arm of chromosome 6. Because they are close together, the group of genes, termed a haplotype, tends to be inherited en bloc. Thus, in the absence of chromosome crossovers in the HLA region, which occur at a frequency of approximately 5%, all the offspring of a particular couple will demonstrate one of four HLA phenotypes. Therefore, each full sibling of an individual in need of allogeneic HSCT has a 25% chance of being an HLA match. There is a 50% chance the sibling, like the parents, will be half matched (haploidentical) and a 25% chance the sibling will share no HLA haplotypes with the HSCT candidate. In the United States, Canada, and Europe, family sizes are such (average of just over two children) that if one family member is an HSCT candidate, the likelihood of an HLA-matched sibling donor is about 30%. This fact alone has driven the worldwide development of large registries composed of HLA-typed adult volunteers who are willing to consider anonymous HSCT donation. The more recent development of allogeneic UCB banking also stems from the recognition that most

individuals who are candidates for HSCT lack suitably matched family-member donors.

## Donor Registries and Their Networks

### National Marrow Donor Program

The National Marrow Donor Program (NMDP) was established in 1986 to recruit adults between the ages of 18 and 60 to serve as marrow donors for unrelated HSCT.<sup>11-13</sup> Since that time, NMDP has grown to become the world's largest unrelated donor registry. The current NMDP file lists more than 7.1 million adult donors and 82,000 UCB units (Table 65-1). Twenty-one percent of the adult donors have HLA typing only at HLA-A and -B loci. If there are no suitable HLA-A, -B, and -DRB1 donors present on a patient search, selective DRB1 typing of matched HLA-A, -B-only donors may uncover a complete match. In practice this is uncommon because the HLA-A, -B-only pool of donors is composed largely of HLA-A, -B phenotypes that are common in those of European ancestry. In previous years, NMDP developed prospective DRB1 typing programs to scour the pool of HLA-A, -B-only donors and complete the typing on those likely to represent unique HLA phenotypes. All newly recruited donors and UCB units are HLA-typed at HLA-A, -B, and -DRB1 loci by highly accurate DNA-based methods.

NMDP has developed and maintains standards for participation in and operation of its network.<sup>14</sup> The network includes 171 transplant centers, which are HSCT programs within large tertiary care hospitals, many of them university medical centers. Adult donors are recruited and managed by one of 70 member donor centers. These donor centers are based at community blood centers, universities, or freestanding facilities. Donor centers are assisted in their recruitment activity by 11 recruitment groups, which are organizations focused upon recruitment within US racial and ethnic minority populations. When a donor is selected to provide PBPCs for transplantation, the collection occurs at one of 91 designated apheresis centers. Similarly, marrow is collected at one of 97 hospitals, which are designated as member collection centers. UCB units, the newest graft source for unrelated donor transplantation, are

collected and stored at 24 member cord blood banks. Many of the centers within the NMDP network are located outside the United States, including 43 transplant centers, six donor centers, nine apheresis centers, 16 collection centers, and three cord blood banks. Additional adult donors and UCB units can be accessed through formal agreements with 26 international cooperative registries.

The NMDP recruits about 350,000 new US adult donors annually. Almost all of these are recruited at community donor drives, which are held at numerous locations including shopping malls, blood centers, college campuses, community centers, and churches. More than 1000 drives are held each month. Prospective recruits are screened to confirm good health and the absence of high-risk behaviors,<sup>15</sup> after which informed consent is obtained. Blood samples for HLA typing have been largely replaced by swabs of the buccal mucosa. In the early years of the NMDP registry, donors were HLA typed by serologic methods, but these have been replaced by highly accurate DNA-based HLA typing methods. However, because of cost considerations, donors are not typed at the highest available resolution (allele-level), but are instead typed at an intermediate level of resolution. Once HLA typing is completed, the results, along with limited demographic information and the assigned donor identification number, are entered into the NMDP databases where they become available to searching patients.

The processes in place at cord blood banks are similar.<sup>16-20</sup> Each bank may work with one or more hospital-based obstetric programs. Expectant mothers are recruited through the obstetric program or through doctors' offices. Mothers complete a health questionnaire and provide consent for unit collection before delivery. UCB units that are deemed suitable undergo processing, testing, and cryopreservation at the cord blood bank. When the necessary criteria are met, the units are listed in the registry and made available for searching. Further details about umbilical cord blood are presented in Chapter 36.

Transplant centers manage searches for their patients who are prospective HSCT candidates. Several studies have shown that HLA matching is critical for the success of unrelated allogeneic transplantation. With adult donors, patient outcomes are best when the donor and recipient are allele-level matched at HLA-A, -B, -C, and -DRB1 loci.<sup>5-7,21,22</sup> UCB unit transplantation does not appear to require the same high level of HLA matching.<sup>23-26</sup> UCB units are typically matched by intermediate resolution at HLA-A and -B loci, and high resolution at HLA-DRB1 loci. UCB units should be matched to at least the 4 of 6 level, but 5 of 6 or 6 of 6 is preferred. Cell dose also plays a critical role in the success of UCB HSCT, so unit selection must consider both HLA match and cell dose.<sup>26-28</sup>

Internet-based computer software enables transplant centers to consider these complex factors and examine the NMDP registry of adult donors and UCB units. Because adult donors and UCB units are not HLA-typed at high resolution, a sophisticated computer algorithm, designated HapLogic, has been developed

**Table 65-1.** Composition of the NMDP Donor and Cord Blood Unit File (as of June 2008)

|                                | Total     | HLA-A, -B and -DR<br>Typed (% of Total) |
|--------------------------------|-----------|-----------------------------------------|
| NMDP US adult donors           | 4,869,783 | 4,148,350 (85)                          |
| NMDP international<br>donors   | 2,040,444 | 1,332,664 (65)                          |
| Cooperative registry<br>donors | 193,040   | 138,434 (72)                            |
| Total adult donors             | 7,103,267 | 5,619,448 (79)                          |
| UCB units                      | 82,562    | 82,562 (100)                            |

NMDP = National Marrow Donor Program; UCB = umbilical cord blood.

to predict the likelihood that any given donor or UCB unit is allele-level-matched with the prospective recipient. HapLogic narrows the donor selection process so the transplant center can select a few adult donors or UCB units for further evaluation, including high-resolution HLA typing. This stage of the search process is termed “confirmatory testing.” After confirmatory testing, a final donor selection is made. If a UCB unit is selected, the cord blood bank will transport the unit frozen in liquid nitrogen to the transplant center. If an adult donor is selected, the donor will be scheduled for a marrow or PBPC collection at a collection center or apheresis center, respectively, preferably near the donor’s residence. Fresh marrow and PBPC products are transported by trained couriers to the designated transplant center where the product is promptly administered to the waiting HSCT recipient.

Other registries and cord blood banking operations are organized similarly to the NMDP network. There are far too many such entities to discuss in detail, but several are listed in Table 65-2 and a few are specifically discussed below.

**Caitlin Raymond International Registry and Gift of Life Bone Marrow Registry**

Caitlin Raymond International Registry (CRIR) and Gift of Life Registry are two registries with headquarters in the United States. CRIR was founded in 1986 and has its offices at the University of Massachusetts Memorial Medical Center, Worcester, MA. The registry is named after the founder’s daughter, who had developed juvenile myelomonocytic leukemia and received a transplant from an unrelated donor. Approximately 75,000 adult donors are registered with CRIR. Gift of Life was founded 1991 to recruit primarily donors of Jewish ethnicity. The founder and current executive director was himself a leukemia patient in need of a transplant donor. He received his transplant in 1995 and has

continued to operate Gift of Life to benefit other patients. Gift of Life has recruited about 122,000 adult donors and has also recently established a UCB bank. Donors from both CRIR and Gift of Life are listed in the NMDP file as cooperative registry donors and are directly accessible.

**Anthony Nolan Bone Marrow Trust**

The Anthony Nolan Bone Marrow Trust (ANBMT) was established in London in 1974. Like the Caitlin Raymond Registry, this registry was named for a child in need of an unrelated donor transplant. Today the ANBMT maintains a file of more than 390,000 donors and has facilitated more than 8000 transplant procedures. In addition, ANBMT supports an extensive research program focused on the immunobiology of unrelated donor HSCT. Additional registries in the United Kingdom and Ireland include the British Bone Marrow Registry, the Welsh Bone Marrow Donor Registry, and the Irish Unrelated Bone Marrow Registry.

**German National Bone Marrow Donor Registry**

The most active registry in the world is the German National Bone Marrow Donor Registry [Zentrale Knochenmarkspender-Register für die Bundesrepublik Deutschland (ZKRD)]. ZKRD has more than 3.2 million adult donors distributed among 31 donor centers and has collected 6500 UCB units. In 2006, ZKRD provided 3058 adult donor and cord blood products for transplantation compared to 2681 products released by the NMDP. More than 60% of the products released by ZKRD in 2006 were exported to other nations, mostly in the European Union. The products not exported were distributed to 33 transplant centers located within Germany. The vast majority (83%) of adult donor products collected by ZKRD in 2006 were PBPCs (2491 PBPC units vs 548 marrow).

**Table 65-2.** Selected Registries of Adult Donors and Umbilical Cord Blood\*

| Name                                             | Country   | Adult Donors | Cord Blood Units |
|--------------------------------------------------|-----------|--------------|------------------|
| Caitlin Raymond International Registry           | US        | 75,484       | 11,030           |
| Gift of Life Bone Marrow Registry                | US        | 122,422      | 927              |

\* Except as noted, adult donor and cord blood unit inventories are from Bone Marrow Donors Worldwide (<http://www.bmdw.org>) as of June 2008.

†Cord Blood units are included in the NetCord inventory.

‡NL: Not listed with the registry as of 2006.

§As of October 2007.

## NetCord

NetCord was established in 1999 as an international organization of cord blood banks. A total of 25 cord blood banks are members of NetCord with a combined inventory in excess of 150,000 UCB units. As of October, 2007, NetCord banks had provided 6227 UCB units for transplantation. The majority of these units were used for children, but UCB unit transplantation for adults is continuing to increase. Since 2000, NetCord has partnered with the Foundation for the Accreditation of Cellular Therapy (FACT) to develop international standards for cord blood unit collection, processing, testing, storage, and release. The NetCord-FACT standards are currently in their third edition. NetCord and NMDP have also recently entered into a collaboration that allows the exchange of search information.

## World Marrow Donor Association

The World Marrow Donor Association (WMDA) is an organization of international registries and cord blood banks working together to promote international cooperation and the exchange of HSCT products.<sup>29,30</sup> WMDA was established in 1994 and maintains several working groups that address issues in quality assurance, registry operations, ethics, finances, and transplant program services.<sup>29-34</sup> WMDA has also established standards for the operation of unrelated donor registries and created an accreditation program for its members.<sup>35</sup> In 1999 WMDA added cord blood banks to its membership, which currently totals 67 adult donor registries and 48 cord blood banks.

The WMDA conducts an annual survey of its members. Sixty-seven registries and 47 cord blood banks responded to the most recent survey, which covered activities through the end of 2006.<sup>36</sup> The survey documented more than 11,800,000 potential adult HSCT donors and 292,000 UCB units worldwide. Virtually all of the UCB units and about 70% of the adult donors had been tissue typed for HLA-A, -B, and -DRB1.

Adult donor registries collected 8418 unrelated donor products in 2006. PBPC products dominated with 5416 (64% of total) compared to marrow (3002 products, 36% of total). Among the adult donor products collected, 7975 (95%) were first-time donations, but 443 represented products from donors who had previously donated for the same or a different HSCT recipient. The 47 cord blood banks in the survey reported releasing 2075 UCB units for transplantation in 2006. The exact number of UCB recipients is uncertain because of the popular rise in the frequency of double-unit UCB transplantation.<sup>37</sup>

It is important to emphasize the prominent international nature of unrelated donor HSCT activities. In 2006, 3269 (39%) adult products and 829 (40%) UCB units were shipped to transplant centers in other countries. This robust international activity is apparently driven by the need for HLA tissue matching and facilitated by electronic search engines, such as that of the NMDP, which provide rapid access to international inventories of adult donors and UCB units.

A very useful tool for initiating international searches is offered by Bone Marrow Donors Worldwide (BMDW).<sup>38</sup> Most WMDA

members list donor information in this database where it is accessible through the Internet. A BMDW search will quickly direct transplant teams to those registries and cord blood banks that are most likely to have suitable HLA matches. As of mid-2008, 12.2 million adult donors and 299,000 UCB units were listed in BMDW from 97 adult donor and cord blood programs in 45 countries.

---

## Outcomes Registries, Professional Associations, and Their Networks

### Center for International Blood and Marrow Transplant Research

The Center for International Blood and Marrow Transplant Research (CIBMTR) was established in 2004 through an affiliation of the International Bone Marrow Transplant Registry (IBMTR) and research programs of the NMDP. The affiliation brought together two organizations with a long histories and extensive experience in collection of data concerning the results of HSCT.<sup>12,39</sup> The IBMTR was established in 1972, shortly after the first successful allogeneic HSCT experiences were reported. The goal of IBMTR was to collect data about transplantation that could be used to analyze trends, evaluate efficacy, and conduct research concerning HSCT. IBMTR created an open structure of working committees focused on particular diseases and key topics affecting HSCT. The emergence of autologous HSCT led IBMTR to establish the companion Autologous Blood and Marrow Transplant Registry (ABMTR) with additional working committees. Membership in IBMTR/ABMTR and the submission of transplant outcome data were voluntary activities for transplant programs. In contrast, the submission of outcome data to NMDP for unrelated donor transplant recipients was a requirement of congressional legislation. Both organizations maintained computer databases, staff for auditing and data management, and research agendas. The complementary strengths of IBMTR and NMDP and the desire to reduce duplication of effort led to the merger of research activities and creation of CIBMTR.

Currently CIBMTR has participation from more than 400 transplant programs in 47 countries. Data have been accumulated on nearly one-quarter million autologous and allogeneic transplant procedures. CIBMTR has developed two levels of data reporting for its centers. The first level collects basic information about an HSCT procedure and its outcome. This is termed "transplant essential data" (TED) and is useful for monitoring trends and conducting basic analyses. The second level of data collection involves comprehensive, research-level data. These data are collected on selected patients based on diagnosis, type of donor, type of transplant procedure, and other factors.

The research structure of CIBMTR includes 17 scientific working committees, which receive, review, and prioritize research studies. A steering committee also oversees access to research blood samples from HSCT donors and recipients maintained in a repository operated by NMDP. In addition, CIBMTR has established another new program (Resource for Clinical Investigation in BMT), which is designed to facilitate multicenter, prospective

**Figure 65-1.** Data management system of the CIBMTR. Data are submitted by participating organizations to NMDP FormsNet 2.0. FormsNet communicates with the organizations submitting data, with components of the NMDP programs, and with the CIBMTR data systems. CIBMTR distributes SCTOD data and research datasets. AGNIS: A Growable Network Information System.

clinical trials. The annual research agenda of CIBMTR is largely established at its annual meeting, the BMT Tandem Meetings, held in partnership with the American Society for Blood and Marrow Transplantation (ASBMT) in February of each year.

In 2006, the CIBMTR was awarded a contract from the US government to develop and operate the Stem Cell Therapeutic Outcomes Database (SCTOD). The Stem Cell Therapeutic and Research Act of 2005 created the SCTOD with a mandate to collect HSCT outcomes data from every allogeneic HSCT procedure that involves a US recipient or donor.<sup>40</sup> The Act required, among other things, that data from the SCTOD would be used to evaluate the performance of individual transplant centers and that portions of the data would be made publicly available. In fulfillment of the SCTOD requirements, CIBMTR expanded the TED forms to collect sufficiently detailed data for the required analyses. Expansion of TED was pursued in collaboration with the European Group for Blood and Marrow Transplantation (EBMT) and the Asia-Pacific Blood and Marrow Transplant Group (APBMT), so that a new international standard for the minimal acceptable HSCT dataset was established. Subsequently, CIBMTR with support from the NMDP launched a new data collection and management program in December 2007 (Fig 65-1). The new program, which collects both SCTOD data (TED data) and comprehensive research-level data, employs a web-based data entry and validation system, FormsNet 2.0, as well as an emerging component, AGNIS, for automated messaging of data. AGNIS, which is the acronym

for A Growable Network Information System, was started with funding from the National Institutes of Health Roadmap Initiative and relies heavily on tools developed by the National Cancer Institute's cancer Biomedical Informatics Grid (caBIG) project. AGNIS seeks to reduce the data management burden for transplant teams by establishing a system of automated, authenticated, and secure transmission of HSCT outcomes data among designated, participating databases. To establish the semantic connection for AGNIS data, the acceptable common data elements are fully defined in the publicly available cancer Data Standards Repository (caDSR) managed by the NCI. AGNIS is open source software available for download (<http://www.agnis.net>).

### American Society for Blood and Marrow Transplantation

The ASBMT is a professional society whose members include transplant physicians and allied health-care personnel. ASBMT promotes the clinical and research interests of the HSCT community with its membership, the pharmaceutical industry, and national government. Through these efforts, ASBMT addresses research initiatives and funding, communication and education about HSCT activities, establishment of clinical standards, and reimbursement by payers. ASBMT publishes a peer-reviewed journal, *Biology of Blood and Marrow Transplantation*. Its annual meeting, the BMT Tandem Meetings, is held in partnership with the CIBMTR. Together with the International Society for Cellular Therapy, ASBMT established FACT.

## AABB

AABB was established in 1947 as professional organization in transfusion medicine. Its tag line—Advancing Transfusion and Cellular Therapies Worldwide—was adopted in recognition of its international presence and expanding role in cellular therapies beyond traditional blood transfusion. More than 2000 institutions and 8000 individuals are members of AABB. The organization sets standards and operates an accreditation program for transfusion services and cellular therapy processing programs. The *AABB Standards for Cellular Therapy Product Services* is currently in its 3rd edition.<sup>41</sup> AABB programs and services address regulatory and legal matters, promote education and communication, and publish electronic and print resources. AABB publishes a monthly peer-reviewed journal, *Transfusion*, and holds its annual meeting in the fall of each year.

## European Group for Blood and Marrow Transplantation

The EBMT functions as both a professional organization and as an HSCT outcomes registry. The organization combines features of both CIBMTR and ASBMT. EBMT was founded in 1974 to allow scientists and physicians involved in clinical HSCT to share their experiences and engage in collaborative studies. The official journal of EBMT is *Bone Marrow Transplantation*.

More than 500 organizations report outcomes data to EBMT. Through continuing harmonization efforts with CIBMTR, the EBMT minimal clinical dataset (MED A) is identical to the CIBMTR TED. Like CIBMTR, EBMT also collects a comprehensive research dataset (MED B). EBMT holds its annual meeting in the spring of each year.

## Eurocord

Eurocord, like NetCord, emerged to fill a niche created by the appearance of cord blood as a new and promising HSCT cellular therapy. It was established in 1995 on behalf of EBMT in order to promote and evaluate umbilical cord blood transplantation. Eurocord collects transplant outcome data from EBMT and non-EBMT transplant centers and merges these data with UCB unit data provided by cord blood banks. More than 3300 UCB HSCT cases have been reported to Eurocord. Eurocord shares UCB data with EBMT and collaborates closely with NetCord and CIBMTR in sharing data and conducting cord blood transplantation research.

## Asia-Pacific Blood and Marrow Transplantation Group

The APBMT is an association of 12 Asian countries organized for the purpose of encouraging and enhancing HSCT activity throughout Asia. In 2006, at the 11th Annual Congress of APBMT in Nagoya, Japan, participants agreed to establish the Asian BMT Registry for the collection of HSCT outcomes data. APBMT subsequently adopted the TED/Med A dataset of CIBMTR/EBMT. In 2007, APBMT conducted a survey of HSCT activity in which seven of its member nations participated.<sup>42</sup> The survey documented 4500 total transplants in 2005, of which two-thirds were allogeneic transplants. Japan accounted for most (75%) of the transplant activity, but China exhibited the most rapidly increasing transplant numbers.

## International Society for Cellular Therapy

The International Society for Cellular Therapy (ISCT) is a professional organization established in 1992 for individuals involved in cell-based research, processing, manipulation, and clinical therapy. The society pursues scientific and educational activities in cellular therapy and seeks to influence regulatory authorities in the North America, Europe, and elsewhere. ISCT holds its annual meeting in the spring of each year. The Society's journal is *Cytotherapy*. FACT was cofounded by ISCT and ASBMT.

ISCT Europe is a regional branch of the organization with its own leadership. ISCT Europe partnered with EBMT in the founding of the Joint Accreditation Committee—ISCT and EBMT (JACIE).

## Worldwide Group for Blood and Marrow Transplantation

The Worldwide Group for Blood and Marrow Transplantation (WBMT) is a recently established collaboration created with the goal of encouraging, harmonizing, and compiling international HSCT outcomes data. Founding partners in WBMT include CIBMTR, EBMT, APBMT, and WMDA. Just as WMDA exists as a collaboration of international HSCT graft suppliers, WBMT seeks to stimulate and enhance international collection of standardized HSCT outcomes data. WBMT is early in its organizational history, but activities on its preliminary docket include: 1) maintaining consensus on a standard outcomes dataset for HSCT recipients and donors, 2) encouraging the development and participation of regional outcomes registries, 3) establishing a nomenclature system for unambiguous identification of centers engaged in HSCT activities, 4) establishing systems for unambiguous identification of recipients and donors that also preserve confidentiality and privacy, and 5) investigating the practicality and utility of periodic global surveys of HSCT activity.

---

## Accrediting Organizations

Official governmental agencies (also called the competent authorities) regulate cellular therapies. The transplant community's achievement of regulatory compliance, however, is in large part buttressed by voluntary accrediting organizations, established by professional associations in order to provide self-assessment and self-regulation. As previously discussed, WMDA has established a voluntary accreditation program for international unrelated donor registries. This program is being phased-in over several years. Currently 12 WMDA members have received accreditation certification.

## AABB

AABB has a long history of standard-setting and accreditation for blood services. In the last 10 years, AABB accreditation has been extended to facilities engaged in the collection, processing, and release of cellular therapy products. The *AABB Standards for Cellular Therapy Product Services* covers marrow, PBPC, and UCB collections.<sup>41</sup> AABB-accredited laboratory and cell processing-based facilities include 43 cord blood banks, 106 cell therapy programs, and two somatic cell services in 16 countries.

### Foundation for the Accreditation of Cellular Therapy

FACT was co-founded by ASBMT and ISCT in 1996.<sup>43,44</sup> FACT accredits both laboratory-based programs and clinical programs engaged in cellular therapies. In contrast to AABB, FACT has established a separate set of standards for cord blood banks in collaboration with NetCord. The *NetCord-FACT International Standards for Cord Blood Collection, Processing, Testing, Banking, Selection and Release* address the stated components of cord blood banking.<sup>45</sup> The standards for clinical HSCT programs, as well as collection, processing, and distribution of cells isolated from marrow and blood, are addressed in the *FACT-JACIE International Standards for Cellular Product Collection, Processing and Administration*.<sup>46</sup> As implied by the title, these standards have been developed in collaboration with JACIE.

FACT has accredited 15 cord blood banks in nine countries. Accreditation under FACT-JACIE standards is complex because a center may be accredited for any combination of seven categories, which include cell processing, marrow collection, PBPC collection, adult allogeneic HSCT, adult autologous HSCT, pediatric allogeneic HSCT, or pediatric autologous HSCT. FACT has accredited cell processing in 156 programs in the United States and Canada. FACT accredits 150 programs for hematopoietic cell collections and processing and 140 for HSCT.

### Joint Accreditation Committee—ISCT and EBMT

JACIE was established in 1998.<sup>47,48</sup> As noted above, it accredits according to the harmonized *FACT-JACIE International Standards for Cellular Product Collection, Processing and Administration*.<sup>46</sup> JACIE has accredited 52 programs in 10 European Union nations. Thirty-nine programs are accredited for cell processing, 46 for hematopoietic cell collections, and 41 for HSCT.

### Alliance for Harmonisation of Cellular Therapy Accreditation

The Alliance for Harmonisation of Cellular Therapy Accreditation (AHCTA) was established in 2006 with the intent to provide international harmonization of the cellular therapy standards and to represent the standard-setting organizations to the various regulatory authorities worldwide. Current members of AHCTA include AABB, ASBMT, EBMT, the European Foundation for Immunogenetics, FACT, ISCT, ISCT-Europe, JACIE, the NetCord Foundation, and WMDA. AHCTA has created a position paper on global standards in cellular therapies and is working toward a detailed crosswalk of various regulations and professional standards in existence today.

## Governmental Agencies in Cellular Therapy

### Health Resources and Services Administration

Governmental agencies are involved in diverse aspects of cellular therapies. Governmental agencies also provide funding for the conduct of laboratory and clinical research in support of cellular therapies. In the United States, the National Institutes of Health is the primary health research funding agency. However,

governmental funding also provides programmatic support for enhancing cellular therapies. In 2005, Congress passed the Stem Cell Therapeutic and Research Act.<sup>40</sup> The Act established two components for the advancement of cellular therapies. The first, the C. W. Bill Young Cell Transplantation Program (the Program) was created to extend the work of the previous congressionally authorized National Bone Marrow Donor Registry. The Program recognizes Congressman C. W. Bill Young (R) from Florida, who has been a long-time supporter of federal funding for the development of unrelated donor registries and the expansion of HSCT therapies. The second component of the Act established the National Cord Blood Inventory (NCBI) with a goal to collect and store 150,000 high-quality UCB units in public banks. The Act contained other noteworthy features. It required that one or more organizations would be selected for accrediting the cord blood banks participating in the NCBI program. Further, it established an Advisory Council on Blood Stem Cell Transplantation, that reports to the Secretary of Health and Human Services (HHS) with advice on the matters related to the Program and the NCBI. Responsibility for implementing the requirements of the Act fell to the Health Resources and Services Administration (HRSA) within HHS. HRSA established four contracts for operation of the Program and through a competitive bidding process these were awarded to NMDP and CIBMTR. In addition HRSA has awarded NCBI contracts to eight cord blood banks.

Program and NCBI information for potential transplant recipients, their families, potential donors, and the public is provided online (<http://bloodcell.transplant.hrsa.gov>). Twenty years of federal funding for the establishment of adult donor registries and more recently umbilical cord blood registries in the United States have had a major impact. Much of the progress in unrelated donor HSCT has accrued because of congressional leadership, and thoughtful implementation by federal agencies.

### World Health Organization

Another type of governmental programmatic support is provided by the World Health Organization (WHO). The transplantation program of WHO has held two global consultations on the subject of human cells and tissues for transplantation. These consultations addressed the global needs for systems of vigilance and surveillance to ensure the safety of cell and tissue transplantation. The consultations led to the development of two Aide-Memoire documents, which establish basic requirements in the field of cell and tissue transplantation.<sup>49,50</sup> In addition, the WHO transplantation program has established the Global Knowledge Base on Transplantation (GKT), which is envisioned as a database of information on transplantation of organs, cells, and tissues from around the world. The GKT is intended to address four topics: 1) Activities and practices in allogeneic transplantation, 2) legal frameworks and organizational structures in existence, 3) threats and responses identified through vigilance and surveillance programs, and 4) issues in xenotransplantation. Success of the GKT depends upon collaborations with many of the cellular therapy organizations and networks described in this chapter.

## Summary

Many organizations are engaged in managing cellular therapies (Table 65-3). Most of them are currently supporting HSCT therapies, which use products from adult donors and umbilical cord blood donors. Examination of these organizations and their diverse and interactive roles gives a clear picture of the impressive level of activities needed to support a relatively mature but expanding field. As new cellular therapies such as the burgeoning field of regenerative medicine emerge, the complex functions needed to support them will be met in some cases by expanding the reach of the existing organizations and in others through the establishment of new ones.

# Hospital Transfusion Committee and Quality Assurance

**Pamela Clark<sup>1</sup> & Paul D. Mintz<sup>2</sup>**

<sup>1</sup>Associate Professor of Pathology, Division of Clinical Pathology, and Associate Director, Blood Bank and Transfusion Medicine Services, University of Virginia Health System, Charlottesville, Virginia, USA

<sup>2</sup>Professor of Pathology and Internal Medicine, Chief, Division of Clinical Pathology, and Director, Clinical Laboratories and Transfusion Medicine Services, University of Virginia Health System, Charlottesville, Virginia, USA

*Blood bank*, coined by Fantus,<sup>1</sup> was the term originally applied to that area of a hospital in which blood was stored in containers for transfusion to patients. The dynamic roles of the medical director and staff of this area in contemporary clinical practice make the term *transfusion service* more appropriate. This term better captures the responsibilities of ensuring safe transfusion practice and appropriate blood use. The transfusion service, in many instances, functions more as a trust fund than a bank. The US Food and Drug Administration (FDA) and the AABB have their own nomenclature for the terms *blood bank* and *transfusion service* as described later. The generic term *transfusion service* is used throughout this chapter to describe all hospital facilities that engage in storing blood components and providing them for transfusion.

The role of the transfusion service laboratory in performing pretransfusion compatibility testing has evolved dramatically from a matrix of elaborate protocols, including major and minor crossmatches and antibody detection tests performed at both room temperature and 37°C, to the present practice in many laboratories of performing a computer crossmatch when certain conditions are met for patients in whom no red cell alloantibody has been detected in current or previous testing.<sup>2,3</sup> At the same time, development of preoperative crossmatch guidelines and the introduction of testing only for ABO group, Rh type, and unexpected antibodies for patients unlikely to need transfusion have been implemented to conserve transfusion service inventories.<sup>4-7</sup>

The Clinical Laboratory Improvement Act and Amendments (CLIA) stipulate requirements for the qualifications of staff who perform or supervise the highly complex testing conducted within a transfusion service. AABB standards<sup>8(p3)</sup> and FDA current good manufacturing practice (cGMP) regulations also require that the transfusion service have a process for personnel training and competency evaluation.

Written standard operating procedures are required by the FDA in the *Code of Federal Regulations* (Title 21 CFR 606.160). A system must be in place to ensure process control for validation of processes and procedures, introduction and change of processes and procedures, proficiency testing, quality control, and the use of materials and other aspects of performance of procedures. This is also required by AABB standards and FDA cGMP regulations. A defined system of documentation and record retention is also required by both (21 CFR 606.100, 606.140, and 606.160). Further aspects of FDA regulations and accreditation requirements of the AABB, The Joint Commission, College of American Pathologists (CAP), and other accrediting organizations are as described later.

---

## Role of the Medical Director

The role of the transfusion medicine specialist is to maintain a “central position in the flow of blood components and products” within the institution.<sup>9</sup> Consequently, the medical director of a transfusion service has three essential roles: administrative, clinical, and educational.

### Administrative

Of the three roles mentioned above, the administrative role is the most problematic, because most statutory and regulatory bodies do not mandate that the medical director be the administrative head of the blood bank and transfusion service. The FDA no longer requires that a “blood establishment” be under the direction of a designated, qualified person in all matters relating to compliance. Similarly, the AABB *Standards for Blood Banks and Transfusion Services*<sup>8</sup> requires that the transfusion service have a medical director with responsibility and authority for all medical and technical policies, processes, and procedures (including those pertaining to personnel and test performance) as well as for consultative services related to the care and safety of transfusion recipients. However, it does not require that overall executive management be under the control of the medical

director.<sup>8(p1)</sup> The Joint Commission also does not require that the overall direction of the laboratory be performed by a physician but does state that “a pathologist or physician qualified in immunohematology, hemotherapy, and blood banking directs blood transfusion services” (HR 1.15).<sup>10</sup>

Consequently, different organizational structures are possible, and the medical director, while retaining authority for all medical and consultative aspects of the transfusion service, may or may not be its overall administrative head. Depending upon the management structure of the laboratory, administrative authority that may lie outside the medical director's control includes responsibility for the operations, quality system, compliance with standards and regulations, and review of the quality system. Many transfusion services have a chief supervisor, who reports to a laboratory manager, who in turn reports to the executive management of the hospital. In this arrangement, the medical director is not in a direct reporting relationship to those responsible for laboratory administration. This often excludes the medical director from authority in personnel (other than policies and procedures), purchasing, budgeting, and other administrative matters. However, CLIA (1988) mandates that the director of a laboratory have responsibility for its functions. The regulation states that the laboratory director must be a doctor of medicine or doctor of osteopathy (42 CFR 493.1443).<sup>11</sup> This creates a situation in which the medical director has statutory responsibility without administrative authority. This dilemma must be solved with pragmatic cooperation between the administrators and the medical director.

## Clinical

The medical director of the transfusion service should work with the clinical staff and hospital administration regarding all aspects of blood transfusion. The director should be recognized as the specialist in transfusion medicine within the institution and serve as the primary resource in related matters. There are many ways to establish this role, but they typically require that the director develop and implement initiatives in a variety of areas. Within the blood bank, the director can bring his or her clinical knowledge to bear on decisions regarding the extent of pretransfusion compatibility testing, the investigation of alloantibodies, the length of time specimens are held for subsequent testing, and the selection of components for inventory (eg, type of fibrin sealant, timing of leukocyte reduction, type of platelet component, inventory of pathogen-inactivated components). Even if the medical director is not responsible for the overall quality assurance program, he or she must participate actively in any quality assurance program related to blood transfusion. As described later, the director represents the transfusion service on the hospital transfusion committee in the institution.

Outside of the laboratory, the medical director should provide expertise and develop policies and procedures that address all aspects of blood supply, blood administration, and adverse reactions. The director should participate in the formulation of institutional policies to ensure an adequate supply of blood to

meet patient needs, review of procedures for blood administration, development and implementation of procedures for perioperative blood conservation and reinfusion, and consideration of alternatives to blood component transfusion (eg, hematopoietic growth factors, blood substitutes when licensed). This provides leadership in shaping and standardizing transfusion practice, and may be done in conjunction with the hospital transfusion committee.

The director must ensure that appropriate processes for blood administration minimize the possibility of human error contributing to an adverse outcome. The AABB standards include accountability of the director for the care and safety of transfusion recipients.<sup>8(p1)</sup> A system for correct identification of patients is critical. Because most transfusions are performed by nurses, the transfusion service should work with the nursing services to ensure that their procedures are appropriate and clear and that appropriate education of the nursing staff occurs. Most hospitals require that two persons verify all of the appropriate information at the bedside before transfusion. The transfusion service director should plan an active role in reviewing and ensuring appropriate use of devices associated with transfusion, including filters and blood warmers. Policies regarding the addition of other fluids to blood components also should be reviewed by the director. In addition, CAP requires that the medical director be involved in resolving a system failure in blood administration (TRM.41770).<sup>12</sup>

The director is also responsible for evaluating all reported adverse events resulting from blood transfusions and making recommendations regarding future hemotherapy. The institution must have a procedure for ensuring that adverse events are reported promptly to a physician caring for the patient and to the transfusion service. The FDA, AABB, and CAP all have requirements regarding the evaluation and reporting of adverse effects of blood transfusion. The FDA requires that records be maintained of any reports of adverse reactions to blood transfusion and that a thorough investigation of each reported reaction be conducted. All transfusion services must report deaths confirmed as being caused by a transfusion to the Office of Compliance, Center for Biologics Evaluation and Research, by telephone (301-827-6220); fax (301-827-6748) or email (fatalities2@fda.hhs.gov) as soon as possible and by writing within 7 days, in accord with 21 CFR 606.170.<sup>13</sup> The AABB requires that a transfusion service have a process for the detection, reporting, and evaluation of suspected complications of transfusion and that all suspected transfusion complications are evaluated and reviewed by the director.<sup>8(p94)</sup> The CAP requires that all transfusion reactions or incidents be reported immediately to the laboratory (TRM.41750) and that documented procedures exist for actions to be taken in the event of a transfusion reaction (TRM.41700).<sup>12</sup> An interpretation by the director of all hemolytic transfusion reaction investigations must be recorded in the patient's chart (TRM.42050).<sup>12</sup>

The director should also create a variety of opportunities for interaction with the clinical staff and should market his or her

availability for consultation. Requested consultations typically concern massive transfusion, therapeutic apheresis, refractoriness to platelet transfusion, unexpected perioperative bleeding, and invasive procedures possibly necessitating preprocedure platelet or plasma transfusion. More informal consultation opportunities arise in response to transfusion orders that appear excessive, inappropriate, or unusual. Here, interaction with ordering physicians serves the dual purpose of shaping improved patient care while informing them of the expertise available from the transfusion service. Each facility should develop its own list of situations in which contact is initiated according to the scope of services of the facility. These can include requests for more than one platelet transfusion, more than 6 units of Fresh Frozen Plasma (FFP) per day for the same patient, a granulocyte concentrate, fresh blood, or a customized blood component (eg, a cytomegalovirus-reduced-risk or irradiated product). If inventory issues dictate exceptions to practices (eg, an Rh-negative patient will receive Rh-positive red cells), the medical director should call the patient's physician to explain the situation and suggest appropriate patient follow-up care. Directors of transfusion services also should speak to a patient's physician when transfusion will be delayed because of the presence of red cell alloantibodies or for any other reason.

The director should review the laboratory and clinical data to assist in ordering of diagnostic tests and in blood transfusion management, particularly for patients who have received a large number of Red Blood Cell (RBC) units without other components. Such review of laboratory information for patients receiving blood components also provides the director with other opportunities for informal consultation. For example, the director may note refractoriness to platelet transfusions and offer prompt advice for diagnosis and management. Drug-induced platelet antibodies are not always detected by clinicians. A review by the transfusion service director of patients who do not respond to platelet transfusions is likely to uncover such occurrences.

Advice also can be provided as the result of established testing algorithms within an institution. Approved by the medical staff, such reflexive systems can meet compliance requirements and lead to interpretive, billable reports that provide for efficient clinical care. Bleeding and thrombotic disorders are complex clinical situations that can be clarified more efficiently through directed laboratory testing algorithms. Red cell alloantibody identifications also lend themselves to interpretations by the transfusion service director regarding the likelihood of delays in blood availability and the potential clinical significance.

Each engagement between a transfusion service director and a clinician provides opportunities not only for improving an individual patient's care but also for forging relationships that will lead to future consultation. Cooperative efforts among physicians from different disciplines are important to improve the use and ongoing evaluation of blood components.<sup>14,15</sup> For example, to ensure the appropriate use of FFP, the cooperative effort of hematologists knowledgeable in coagulation, treating physicians,

and the transfusion service director often is useful. Similarly, the director may consult with hematologists to establish a threshold for prophylactic platelet transfusions that may be lower than current practice. Patients would be exposed to fewer blood components, resulting in improved patient care, institutional cost savings, and conservation of the blood supply.

## Education

The heightened awareness of patients and physicians regarding the risks of blood transfusion therapy has made the role of the transfusion service director a more public one. This prominence has influenced attending physicians to be receptive to advice and education from the director.

The transfusion service director serves as the principal educator of clinicians and house staff in blood transfusion practice. The director must be aware of the contemporary literature on the use of blood components, including consensus conference statements, practice guidelines, and emerging standards of practice. The director can educate the clinical staff on the availability of newly introduced blood components and pharmaceuticals (eg, pathogen-inactivated blood components, fibrin sealant), and serve as an aggressive patient advocate for the introduction of these products for improved patient care.<sup>16</sup> Interactions between the transfusion service director and the attending physician should be designed as educational and nonconfrontational and should be conducted in the spirit of mutual patient advocacy. The available forums for such educational opportunities are numerous and include informal consultations as noted above as well as more formal teaching opportunities such as grand rounds or continuing education lectures given to hospital staff actively involved in blood transfusion practices.

The foregoing activities provide for improved care, reduced costs, and shorter hospital stays. The quiet accomplishment of a laboratory director in obtaining an adequate blood supply and making this available for transfusion may not always be recognized as evidence of the director's contribution to patient care. Although the director may be held responsible for the failure to achieve these objectives, there may be a presumption that little effort or training was required to accomplish them. The transfusion service director, therefore, must strive not only to add value to medical care but also to educate others about this important effort.<sup>14</sup>

---

## Quality Assurance

### Historical Overview

As long ago as 1667, Denis' historic transfusion was subjected to extensive review.<sup>17</sup> Concern about abuse of blood was published in 1936.<sup>18</sup> In 1951, the Ministry of Health in England called for the review of blood use at medical staff meetings. In the same year, an editorial in the *New England Journal of Medicine* noted the inappropriateness of some transfusions.<sup>19</sup> A 1953 audit study concluded that only 241 of 290 transfusions were indicated.<sup>20</sup>

Additional publications between 1956 and 1960<sup>21-26</sup> echoed this message, emphasized the physician's potential liability if an unnecessary transfusion were administered, and suggested the usefulness of audits. In 1961, The Joint Commission on the Accreditation of Hospitals and other experts emphasized the need to review transfusion practices.<sup>27,28</sup>

By 1962, indications for blood transfusion were being included in the bylaws of hospitals.<sup>29</sup> In the same year, the Joint Blood Council called for a review of transfusion practices by a medical staff committee.<sup>30</sup> Several authorities recommended the establishment of a hospital transfusion board to review transfusion practices and called attention to the educational function such a committee would serve.<sup>31-34</sup> A 1965 study showed that a large number of transfusions were inappropriate and could not be justified by the ordering physicians.<sup>35</sup> In 1974, 14 of 46 Minnesota hospitals responding to a survey had procedures for reviewing indications for blood transfusion; among them, 25 had some form of transfusion committee.<sup>36</sup>

With the advent of the AIDS epidemic in the 1980s these existing institutions for review of blood utilization acquired new importance as the infectious hazards of blood transfusion became increasingly evident. New transfusion guidelines provided more stringent criteria for transfusion based on available evidence of transfusion efficacy.<sup>37-39</sup> Over the next several years, the entire blood community focused on reducing the risks of viral transmission, not only for human immunodeficiency virus (HIV), but for several other important pathogens with remarkable results.<sup>40</sup>

## Process Control

The disappearance of viruses as a major transfusion hazard did not end the increased emphasis on improving safety. The concept of a "zero-risk" blood supply and the application of the precautionary principle to transfusion medicine as a result of the AIDS epidemic encouraged the extension of industrial management theory into clinical laboratories; and quality assurance programs derived from industrial practices have been increasingly applied to clinical medicine.<sup>41,42</sup> This is not to say that numerous safeguards were not already in place. AABB standards were first enacted in 1958 to prevent untoward events associated with blood transfusions, long before the application of industrial quality systems to blood banking. However, industrial methods of continuous quality improvement are an important addition to blood safety because fatal errors can occur at any point in the blood supply chain from donor to recipient. At the blood collecting agency, errors in collection, testing, component processing, labeling, storage, and transport all can result in a misidentified or substandard product. The transfusion service must have policies and procedures in place for proper patient identification, sample testing, blood administration, and overall transfusion practice. In order to have a total quality system, institutions must have systems that, on the front end, reduce opportunities for error; and on the back end, appropriately evaluate and manage those errors that inevitably occur.

On the front end, the quality system<sup>43,44</sup> is a program implemented to ensure that all parts of the processes of an enterprise work together to produce the expected output. Quality management is the totality of activities planned and performed to provide confidence that all procedures are functioning as expected. A quality management program must be designed and implemented to ensure that procedures are consistently performed. Elements of a quality program include quality control procedures and standards for personnel, facilities, procedures, equipment, and record-keeping. Audits are an integral component of a quality program. As a matter of good practice, those responsible for quality assurance should report to senior management and not to operations personnel.

Total quality systems have been required for blood banks and transfusion services since 1975 when the FDA incorporated cGMP into the *Code of Federal Regulations*. Although the regulations were aimed primarily at blood centers, many of the provisions apply to transfusion services as well. AABB *Standards for Blood Banks and Transfusion Services* apply equally to member blood centers and transfusion services. These standards provide a blueprint for a total quality system, breaking operations down into 10 Quality System Essentials (QSEs) listed in Table 66-1. These 10 QSEs require that there be policies, processes, and procedures in place governing each of the 10 areas outlined in the essentials; exactly how the AABB standards are implemented is determined by the individual institution. The AABB quality system is discussed in detail below.

The development of a quality system in transfusion services allows certification by the International Organization for Standardization (ISO) quality management system that has been used by many businesses since 1986.<sup>45</sup> A few blood and tissue centers have received ISO 9002 accreditation. The ISO 9002 standards provide guidance in the development and implementation of an effective quality management system. It is not specific to any particular product or service but can be used generically by all enterprises. Complying with ISO 9002 standards does not mean that every product or service meets specific requirements. It means only that the quality system in use is capable of meeting them. The ISO standards basically require that an enterprise document its processes and then follow them as stated.

In general, all quality systems strive to identify process errors and defects and then eliminate them with sustainable changes through redesign of processes. In these programs, the staff of an institution strives to create cycles of continuous improvement in the course of designing, measuring, assessing, and refining work processes. Existing processes are carefully described and the outcomes are measured. The measurable outcome of the process monitored must be defined at the outset. Data are then analyzed and opportunities for improvement are identified. Changes that should improve the process and eliminate outcome variability are implemented and the outcome is again measured. The goal is process control: the collective set of actions taken to minimize variability in a process, thereby minimizing

**Table 66-1.** AABB Quality System Essentials

|                                                                     |                                                                                                                                                                                                                                                                                                                                        |
|---------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Organization</b>                                                 | A structure that clearly defines and documents those responsible for the provision of blood components and services and the relationship of individuals responsible for key quality functions.                                                                                                                                         |
| <b>Resources</b>                                                    | Policies, processes, and procedures to ensure the provision of adequate resources to perform, verify, and manage each of the activities of the transfusion service.                                                                                                                                                                    |
| <b>Equipment</b>                                                    | Policies, processes, and procedures to ensure that calibration, maintenance, and monitoring of equipment conform to standards and applicable requirements.                                                                                                                                                                             |
| <b>Supplier and customer issues</b>                                 | Policies, processes, and procedures to evaluate the ability of providers to meet requirements consistently.                                                                                                                                                                                                                            |
| <b>Process control</b>                                              | Policies and validated processes and procedures to ensure the quality of the blood components, tissue, and services provided and that procedures are conducted under controlled conditions.                                                                                                                                            |
| <b>Documents and records</b>                                        | Policies, processes, and procedures to ensure that documents are identified, reviewed, approved, and retained and that records are created, stored, and archived in accord with retention policies.                                                                                                                                    |
| <b>Deviations, nonconformances, and adverse events</b>              | Policies, processes, and procedures to ensure the capture, assessment, investigation, and monitoring of deviations from, or of failures to meet, specified requirements. Definition of responsibility for review and authority for the disposition of nonconforming products and for appropriate reporting of deviations and failures. |
| <b>Assessments: internal and external</b>                           | Policies, processes, and procedures to ensure that external assessments are obtained at defined intervals and that internal assessments are conducted.                                                                                                                                                                                 |
| <b>Process improvement through corrective and preventive action</b> | Policies, processes, and procedures for data collection, analysis, and follow-up of issues that require corrective or preventive action.                                                                                                                                                                                               |
| <b>Facilities and safety</b>                                        | Policies, processes, and procedures for the provision of a safe and adequate workplace.                                                                                                                                                                                                                                                |

variability of outcome. Such a data-driven approach, in which multiple cycles of outcome assessment are measured, results in overall improvement of the process being measured and uniformity of outcome.<sup>46</sup>

As an example of improved process control, the instances of unacceptable turnaround time for release of a blood product can be reduced simply by reducing the variability in the time required to process a request for blood, even if the mean time is not changed. When variance is reduced and consistency improved, control of a process is demonstrated, and benefits for interrelated systems are generated. For example, if there is minimal variability in turnaround times for release of blood products, transportation services and clinical services can coordinate their activities with this expectation.

However, a reasonable approach to documentation should be maintained. No purpose is served by collection of data without analysis and interpretation and without using the interpretation to improve a process. Once a process has been shown to result in minimal variation in outcome and to meet expectations, it is reasonable to consider whether requirements can then be raised. In this way, an effective quality assurance program can directly lead to increased operational efficiency. Again using the example of unacceptable turnaround times, once process control improves variability in turnaround time, it is reasonable to reexamine the process to see whether an absolute reduction in turnaround time could now be attained.

Any quality program must include a commitment from management to build quality into the system rather than just rely on inspection of a final product or service. There should be a spirit of cooperation between quality assurance and operations

personnel. The goal is continuing improvement that will translate into improved patient care, regulatory and accreditation compliance, and good business practices. Quality assurance plans must be manageable and clearly understood by the all hospital staff as well as by individual workers charged with compliance. Finally, for any hospital quality assessment program to work successfully, physicians must give priority to the process, and hospital administration must make the necessary resources available to ensure its development, implementation, refinement, and continuation.

### Error Management

Although the safety of the blood supply has increased dramatically, the overall safety of blood administration has not. Transfusion error continues to be a great risk, and most errors result from preventable human mistakes. Fully 70% of these untoward events occur outside of the blood bank laboratory, and the most common error is failure to properly identify a patient during the transfusion process—either at the time of sample collection or at the time of transfusion.<sup>47,48</sup> Several studies have documented miscollection of samples, the so-called “wrong blood in tube” error, at a rate of approximately 1 in 2000.<sup>49–51</sup> In one study, samples with detectable labeling errors were 40 times more likely to have been miscollected than samples that were properly labeled.<sup>51</sup> Comparison with prior records prevents many ABO-incompatible transfusions; however, safety checks in the blood bank cannot detect miscollected samples where there is either no prior blood type on record or where the blood in the tube matches the recipient blood type by chance. (For this reason, some hospitals require that two samples be drawn at different times to confirm blood type on patients

without historical records.) One study noted that approximately 1 in 3400 samples could be identified as miscollected on the basis of ABO discrepancy, suggesting that the rate of miscollection is much higher.<sup>52</sup>

The most common error in the transfusion chain, however, is failure to properly identify a patient at the time of blood transfusion. A recent review from the United Kingdom hemovigilance program (the Serious Hazards of Transfusion, or SHOT, program), cited failure to perform a proper bedside check as the proximate cause for 27% of reported mistransfusions.<sup>48</sup> Another study found that in 25% of audited transfusions, there was no comparison of the patient's wristband with the blood tag, an omission of a vital safety step.<sup>53</sup> Further, errors in identification may actually be increasing. Reports document a significant increase in problems with identification of patients, samples, and units.<sup>53,54</sup> Patient identification has been at the heart of errors in other areas of hospital practice, most notably delivery of medications, and because of these problems, The Joint Commission has made proper patient identification its primary safety goal.

At present, the risk that a patient will receive the wrong unit of blood in the United States is in the order of 1 in 12,000 to 1 in 19,000, approximately 100 times the risk of acquiring hepatitis C virus or HIV by means of blood transfusion.<sup>55,56</sup> Reports on mistransfusion from other countries have quoted remarkably similar rates.<sup>57–59</sup> The actual transfusion-related death rate due to ABO hemolytic transfusion reactions lies somewhere between 1 in 1,000,000 and 1 in 2,000,000.<sup>55,56,60</sup> Similarly, the SHOT program reported that the likelihood of receiving an ABO-incompatible unit at 1 in 100,000.<sup>47</sup> Again, assuming a fatality rate of between 5% and 10% for an ABO-incompatible transfusion, this translates to a death rate of between 1 in 500,000 and 1 in 1,000,000.

Although 70% of transfusion errors occur in clinical areas of the hospital, the remaining 30% of mistransfusions result from laboratory error.<sup>47,55</sup> Not surprisingly, as with transfusion errors elsewhere, clerical mistakes such as selection of the wrong sample for testing explain most of these errors. A disproportionate percentage of laboratory errors occur outside of peak hours of operation. The SHOT program reported that 40% of laboratory errors occurred during periods where only 20% of the workload was processed. Commentators have suggested that this discrepancy between workload and error rate can be accounted for by several factors, including decreased staffing during off-hours, relatively inexperienced staff, and the pressure of medical emergencies occurring at times when staffing is less than optimal.<sup>47</sup>

Several countries have instituted measures to address these noninfectious serious hazards of transfusion. Hemovigilance refers to comprehensive surveillance systems that monitor the entire transfusion process from beginning to end by collecting data on adverse events associated with transfusion. The aim is to collect and assess information obtained from adverse events so that recurrence can be prevented. In effect, hemovigilance is the introduction of process control measures to the entire transfusion process. All member states of the European Union are required to have hemovigilance systems (EU directive 2002/98/EC),

although the form of these systems can differ. Some countries (for example, France) have mandatory programs where all serious adverse hazards must be reported.<sup>61</sup> Others, such as England, have centralized, nationalized programs where reporting is voluntary.<sup>47,48</sup> Clearly, the introduction of hemovigilance systems results in increased reporting of noninfectious transfusion complications. For example, introduction of a notification system in Quebec resulted in a dramatic increase in the reporting of such incidents.<sup>62</sup> Similarly, the reports of incorrect transfusion of blood components increased yearly with the implementation of the SHOT program in England, but were coupled with a noticeable downward trend in the number of ABO-incompatible transfusions several years after the introduction of the hemovigilance system.<sup>47</sup>

The United States began implementing a hemovigilance program in 2008. The voluntary, nonpunitive, Internet-based system was created through a public-private partnership involving the Centers for Disease Control and Prevention, the AABB, and other stakeholders. The FDA requires that errors or accidents affecting the safety, quality, integrity, purity, or potency of a blood product be reported, and this requirement extends to both licensed blood establishments and transfusion services (CFR 606.171).<sup>13</sup> However, this statutory authority extends only to the blood product itself, and does not permit FDA oversight of the actual transfusion episode. Although the FDA Medwatch program provides a voluntary venue for reporting adverse events, most hospitals do not voluntarily report errors to this particular program. Hence, the FDA's purview extends only as far as the laboratory door, and there is no requirement to report a patient misidentification error unless it results in a death. (A transfusion-related death, however, must be reported to the CBER division of FDA within 24 hours.) To give an example of this regulatory lacuna, the following example suffices: failure to irradiate a unit of RBCs that was so ordered results in an FDA reportable error. Transfusion of the same unit to the wrong patient does not result in a reportable error unless the patient dies.

Clearly, the continuing noninfectious risks of blood transfusion coupled with the lack of a national hemovigilance program constitutes a strong argument for hospital-wide efforts at improving the process of transfusion safety. There has been inadequate commitment of financial resources directed toward improving safety in this area, although The Joint Commission's safety goal of proper patient identification may change this. The introduction of process control to the transfusion service itself has not eliminated the major risks of a blood transfusion because most of the steps involved in the transfusion of a unit of blood lie outside the direct control of the transfusion service. Given the number of steps required to correctly identify a patient at the time of phlebotomy, properly label a blood sample, and properly coordinate identification of a specific patient with a specific unit of blood at the time of transfusion, it is not surprising that errors occur. Staff may not understand the importance of proper patient identification in the transfusion setting, because similar identification is not required for other equally common hospital

procedures. Consequently, there is a strong inclination to either ignore the identification procedures or to circumvent them, because they take time and are difficult to perform correctly. Further, workload on busy hospital services is more difficult to manage than laboratory workload, and therefore is less amenable to process control. A patient's condition can change dramatically in a matter of minutes. Hospital staff must respond to medical emergencies and unanticipated events. Therefore, in an emergency, there is a tendency to truncate necessary safety procedures in order to provide rapid care, and as a result, errors occur. Studies show that fatal transfusion errors are most likely to occur in areas of the hospital where emergencies occur frequently such as the operating room and intensive care units.<sup>47,63</sup>

Error management must be a comprehensive system for identifying all errors, analyzing those errors, and determining the best system-wide approach to ensure that similar errors do not recur. An effective error management system should identify all "near-miss" errors as well as errors that cause actual harm to a patient. The concept of near miss is taken from industries where errors can cause catastrophic results. Near-miss errors are errors that do not cause actual harm, but could have had the circumstances been slightly different.<sup>64</sup> One study suggested that near miss errors occur three to 300 times more commonly than errors that cause harm.<sup>65</sup> As such, they provide a window into systems problems, and also provide the opportunity to analyze and restructure so as to prevent an actual medical catastrophe. An example of a near miss is as follows. Nursing personnel fail to properly identify a patient, resulting in mistransfusion, but the unit transfused is group O blood. The patient suffers no harm, but the error provides an opportunity to examine the overall transfusion process and make changes before a similar event results in a serious ABO-incompatible transfusion.

One other important concept fundamental to a well-functioning error management system is that human errors are inevitable, and most are unintentional. Therefore, error management should be conducted by means of detecting and solving system problems rather than placing blame and punishing individual workers for making a mistake. Such punitive management of error discourages reporting and decreases the potential for improvement. It is vital that staff be encouraged to report errors, because only with comprehensive detection of all errors can effective change be initiated. Once errors are detected, careful root cause analysis provides insight into system-wide dysfunctions and permits the development of system-wide changes.<sup>66</sup> One such system specific for blood transfusion is the Medical Event Reporting System developed under the auspices of the National Heart, Lung, and Blood Institute in 1995 and in use at several hospitals throughout the country. The system aims for exhaustive detection of errors including examination of quality assurance records, chart audits, and direct reports of errors by staff. Each event is assigned a numeric value based on the potential severity of harm and the likelihood of recurrence. Only those errors that reach the appropriate numeric threshold are subjected to a complete root cause analysis. Additionally, each error is

classified using a predetermined set of event codes and entered into a computer database so that patterns and trends can be identified. The results of the root cause analysis are then used to institute changes if necessary to prevent a recurrence.<sup>67</sup>

Technology can also be used to address transfusion error. As noted above, the majority of errors involve failure to follow proper patient identification procedures. Two of the weak points in the transfusion process—namely, patient sample collection and blood administration—can be subjected to technology that prevents identification errors. Both barcode and radio frequency identification (RFID) technologies can automatically read encoded information on the patient's wristband and on an accompanying blood bag tag. In the case of sample collection, a phlebotomist merely scans a patient's wristband, and produces a label at the bedside from a hand-held printer. As long as the tube is also labeled at the bedside, the problem of "wrong blood in tube" disappears. In the case of blood administration both the wristband and the bag tag are scanned, and again, a handheld device determines whether the two sets of information match. Although this technology is in its infancy, systems have been developed and are now being used in several hospitals around the world.<sup>68–70</sup>

### Improving Transfusion Practice

An important component of overall quality assurance in transfusion is ensuring that each transfusion that occurs is a necessary and appropriate medical therapy. Most clinicians have no formal training in transfusion medicine. Consequently, their practice is based on what they learned during training. Therefore, much of what they know is either outdated, or based on the transfusion "mythology" extant in their training hospital. One study documented that well over half of physicians given various clinical scenarios would have prescribed transfusion therapy that was inappropriate.<sup>71</sup> A number of approaches have been used successfully to improve clinical transfusion practices. Toy<sup>72</sup> has summarized five processes for which there is published evidence of success.

One approach is to give lectures, because written materials alone have been shown to be ineffective in changing medical practice.<sup>73</sup> Although many physicians may be reached simultaneously, it may be difficult to have a durable impact on transfusion practice. Publications on this approach have documented a decrease in inappropriate use of FFP from 53% to 22% through an educational conference program,<sup>74</sup> a 75% decrease in the total number of red cells transfused in an obstetrics and gynecology service,<sup>75</sup> and a 46% decrease in use of FFP over a 2-year period.<sup>76</sup> The proportion of patients donating autologous blood decreased from 53% to 26%, the overall transfusion rate decreased from 10% to 7%, and the allogeneic transfusion rate did not change in a program that decreased unnecessary autologous collections without increasing the number of allogeneic transfusions.<sup>77</sup>

A second approach is for a specialist in transfusion medicine to meet one-on-one with physicians. Although this is

time-consuming, it can be particularly effective. Brief face-to-face conferences with surgeons reduced the proportion of transfusions not in compliance with criteria from 40% to 24%. Surgeons who participated in the study decreased their transfusion trigger significantly whereas control physicians did not.<sup>78</sup> The use of autologous blood donation increased with visits to surgeons. No changes occurred in control hospitals where no visits were made. There was no increase in inappropriate use of autologous blood donations in study hospitals for procedures that required no preoperative blood order.<sup>79</sup> Review of transfusions 1 day after administration with discussions with the ordering physician led to a reduction from 3.2% to 0.5% in the number of transfusions that failed to meet auditing criteria.<sup>80</sup> In this study, the rate of unjustified transfusions decreased from 1.4% to 0% during a 1-year audit.

A third approach is to make patient rounds on a regular basis. This approach is time-consuming but directs physician attention to a particular patient who needs treatment and therefore may be particularly effective. A 77% reduction in the use of FFP over a 2-year period after implementation of a next-day review accompanied by an educational program has been demonstrated.<sup>81</sup> The number of units transfused to patients with a hematocrit greater than 30% decreased from 30% to 10% when daily rounds were made.<sup>82</sup>

A fourth approach is to review each transfusion order before the blood component is issued. This prospective review can be highly effective in improving transfusion practices. One mechanism for implementing this process is to have physicians select the indication for transfusion from a computerized order menu or by checking manually a transfusion order request form. Requests can also be reviewed by blood bank physicians and staff in conjunction with available laboratory data. Such a prospective review of blood utilization resulted in a significant reduction of allogeneic donor exposure in one study.<sup>83</sup> One paper<sup>84</sup> described how prospective audit of platelet transfusions, in which a substantial number of orders were initially denied or modified, resulted in significant improvement in platelet-ordering practices and a 56% reduction in platelet use over a 3-year period. An audit of platelet use followed by modified practice guidelines applied prospectively to requests for platelets led to a 14% decrease in the number of platelet units transfused during the following year.<sup>85</sup> A mandatory pretransfusion approval program resulted in a 33% decrease in FFP transfusions.<sup>86</sup> A decrease from 28.6% to 27.7% in the hematocrits of persons receiving transfused occurred, as did a reduction in the number of transfusion orders requiring review, after computerized screening of blood transfusion requests was implemented.<sup>87</sup> A significant reduction in inappropriate platelet and FFP transfusions occurred after introduction of a new component request form that included transfusion guidelines.<sup>88</sup> A significant decrease in inappropriate red blood cell, platelet, and FFP transfusions after the request form was modified to include indications for transfusion and relevant clinical and laboratory data was shown in another study.<sup>89</sup>

A fifth approach to improving transfusion practices is to develop and implement algorithms. Success of an intraoperative algorithm for transfusion in cardiac surgery has been reported.<sup>90</sup>

Retrospective review of charts, while satisfying some accreditation requirements, has not been shown conclusively to influence transfusion practices when used as a single tool. Retrospective analyses can, however, augment utilization review when combined with other approaches. This activity, along with other approaches to reviewing the process of transfusion, and the development of review criteria are addressed later, in the section on the transfusion committee.

The combination of approaches has been successful in improvement of transfusion practice. Reviewing clinical and laboratory data for all transfusions with follow-up consultations substantially reduced the number of transfusions of red cells, platelets, FFP, and cryoprecipitate over a 4-year period.<sup>91</sup> A 52% decrease in use of FFP occurred after implementation of a retrospective utilization audit, an educational program, a new FFP request form that required the ordering physician to indicate the reason for the request, and pathologist approval in cases lacking documentation of abnormal results of coagulation studies.<sup>92</sup> The establishment of transfusion guidelines based on national standards accompanied by the implementation of a monitoring system that required physicians to record medical indications for all nonemergency transfusions and followed by selective retrospective auditing resulted in a 35.9% decrease in allogeneic donor exposures over a 3-year period.<sup>93</sup> In a novel approach, a quality assessment program that permitted oversight of transfusionists' practices resulted in a decline from 50% to nearly zero in the percentage of transfusions at variance from institutional blood administration policy.<sup>71</sup>

Educational strategies should be aimed at the attending physician who has the final responsibility for transfusion orders.<sup>94</sup> One study showed that attending physicians had lower knowledge scores than did residents but exhibited more confidence in what they knew. Resident ordering practices were heavily influenced by the wishes of attending physicians. Most residents who answered the survey stated they had ordered transfusions they had judged unnecessary because a more senior physician had suggested that they do so. Multi-institutional audits also serve as useful benchmarking tools.<sup>95</sup>

---

## Regulatory and Accreditation Requirements

A number of regulatory agencies and accrediting organizations in the United States have developed standards regarding the quality assessment and improvement of blood transfusion practices.

### Food and Drug Administration

#### FDA and Transfusion Services

The FDA considers establishments that perform certain activities that it defines as manufacturing steps to be hospital blood banks, which are required to register annually using form FDA2830.

A hospital blood bank is an entity that routinely collects or processes whole blood or blood components. These components may be collected by means of apheresis or prepared from whole blood. Processing includes freezing, deglycerolizing, washing, irradiating, rejuvenating, or removing leukocytes from components. Hospital laboratories that solely prepare RBCs or Recovered Plasma, pool Platelets or Cryoprecipitated AHE, or issue bedside leukocyte reduction filters are considered hospital transfusion services and are not required to register [21 CFR 607.65(f)].<sup>13</sup>

Because blood and blood components are drugs under the Federal Food, Drug, and Cosmetic Act, the FDA cGMP regulations (21 CFR 210 and 211) apply to the manufacture of these products.<sup>96</sup> In addition, cGMP regulations for blood and blood components exist in 21 CFR 606.<sup>13</sup> All of these regulations apply to FDA-defined hospital blood banks. FDA registration allows the agency to plan and perform routine cGMP inspections.

The *Code of Federal Regulations* requires a quality program. In 42 CFR 493.1701, it is mandated that “each laboratory establish and follow written policies and procedures for a comprehensive quality assurance program . . . The laboratory’s quality assurance program must evaluate the effectiveness of its policies and procedures; identify and correct problems . . . All quality assurance activities must be documented.”<sup>11</sup> In 1995, the Center for Biologics Evaluation and Research produced a guideline to assist establishments in developing quality programs in accord with applicable regulations.<sup>97</sup>

Although the FDA does not routinely inspect hospital transfusion services, these services also engage in manufacturing in the view of the FDA, because compatibility testing, blood storage, labeling, and record-keeping are considered steps in the manufacturing process. Thus, transfusion services are also subject to cGMP regulations. Inspection of hospital transfusion services is overseen by the Centers for Medicare and Medicaid Services (CMS) through a 1980 memorandum of understanding with the FDA that addresses inspection of these establishments. In an effort to reduce duplication of inspections, it was agreed that inspection of hospital transfusion services that are approved for Medicare reimbursement and that engage in compatibility testing but that neither routinely collect nor process blood components would be subject to inspection by the CMS. This agreement pertains to responsibility for inspection only. No statutory authority transferred between the agencies. As part of the agreement, the CMS adopted FDA regulations in 21 CFR 606 titled “Current Good Manufacturing Practice for Blood and Blood Components” and 21 CFR 640 titled “Additional Standards for Human Blood and Blood Components.”<sup>13</sup> These are the FDA requirements that have been incorporated into the CLIA regulations. Observations made by the CMS may be communicated to the FDA, which can then directly inspect a hospital transfusion service.

All transfusion services, registered or unregistered and regardless of FDA nomenclature, must also comply with the regulations in 42 CFR 493 in accord with CLIA 1988.<sup>11</sup> For the purposes of CLIA certification, CMS retains responsibility for inspection of all transfusion services.

Many transfusion services may not be surveyed directly by the CMS. Some are in an exempt state or have been accredited by an organization that has been granted deemed status.

### FDA and Transfusion Service Error Reporting

Both registered and unregistered blood establishments, including transfusion services, must report errors and accidents in manufacturing to the FDA. Manufacturing is defined as including “testing, processing, packing, labeling, storage, holding, or distribution” of both licensed and unlicensed blood components. Errors and accidents (termed *biologic product deviations*) and unexpected events in manufacturing that can affect the safety, purity, and potency of a product are deemed reportable (21 CFR 606.171 and 21 CFR 600.14).<sup>13</sup> The FDA has devised a form, FDA3486, for reporting these deviations. The requirement to report applies only to manufacturing errors and not to transfusion errors occurring in clinical areas outside of the transfusion service.

Deviations must be reported only if the product was distributed. This is defined as having left the control of the establishment. If the product was not distributed, the incident still must be recorded in internal records [21 CFR 606.160(b)(7)(iii)].<sup>13</sup> If the product was distributed, a report must be submitted to the Center for Biologics Evaluation and Research within 45 calendar days from the date information is acquired that reasonably suggests a reportable event occurred. The incident must also be recorded [21 CFR 606.160(b)(7)(iii)] and investigated [21 CFR 606.100(c), 211.192 and 211.198].<sup>13,96</sup> The FDA has stated that the purpose of this reporting system is to provide early warning of faulty processes as an indicator for potentially immediate problems that may be related to recalls and as surveillance for improving training and establishing guidance.

The deviation or unexpected event must occur in the facility or another facility under contract with the controlling facility. If a facility under contract to the hospital blood bank or transfusion service is responsible for a deviation, the hospital blood bank or transfusion service is responsible for reporting the problem if the product is distributed. The contract facility must perform an investigation but is not required to report. For example, if a test laboratory under contract to a hospital blood bank fails to provide viral marker testing and the unit is subsequently distributed, the blood bank must report this. If a transfusion service discovers that a unit is mislabeled with an extended outdate, the transfusion service must notify the blood center responsible for reporting to the FDA. The transfusion service would report this incident only if it further distributed the unit without correcting the label.

Deviations and unexpected events occurring within the facility or a facility under contract must be reported if they may affect the safety, purity, or potency of both licensed and unlicensed products that have been distributed. However, as noted above, an error occurring after a product has left the facility need not be reported. Examples of events that would not require a report include a unit not being held at the appropriate temperature

before transfusion after release from the blood bank, transfusion of a unit to the wrong patient, or failure by hospital staff to use a filter issued by the transfusion service. Reportable, unexpected events may occur even if all established procedures are followed within the transfusion service itself. An example of this would be a patient sample used for compatibility testing that was collected from the wrong patient.

Not reporting an event to the FDA within 45 days in and of itself constitutes a nonreportable deviation. A record-keeping deviation, such as failure to include the signature of the person preparing the unit in component preparation, would not be reportable because it would not affect the safety, purity, or potency of the product. A unit labeled with a shortened expiration date would also not be reportable, nor would a unit drawn too soon after the last donation. It would not be a reportable event if an allogeneic unit were issued when autologous blood was available. However, a unit labeled with an extended expiration date would be a reportable deviation. In summary, a deviation or unexpected event is reportable if all of the following criteria are met:

- It was associated with manufacturing.
- It occurred in the facility or at a contract facility.
- It may have affected the safety, purity, or potency of the product.
- The facility had control over the product.
- The product was distributed.

### AABB

The AABB QSEs are consistent with FDA quality assurance guidelines and ISO 9002 standards. The intent of the QSEs is to provide assurance that quality principles are applied consistently throughout the entire enterprise, not just within specific operational areas. Use of the QSEs affords any transfusion service a guideline for organizing its activities and documentation. The use of audits for systems and processes provides an opportunity for considering each aspect of an activity and for influencing the quality of activities outside the immediate control of the transfusion service. Implementation of a quality management system provides for the routine capture of errors and accidents, some of which are required to be reported to the FDA. The activities of a quality system involve data collection and analysis to select processes for internal audits. These internal audits provide information necessary to make process improvements to prevent errors.

Although not required by the AABB or others, a quality manual provides a convenient means of ensuring that a transfusion service is meeting all the requirements of the QSEs. One such manual has been described and made available.<sup>98</sup> This manual includes a matrix that links AABB QSEs to source documents within the institution that demonstrate compliance. Existing procedure manuals can still be used.

The AABB assessment incorporates evaluation of the quality system at an institution and of each operational system. The quality system assessment is based on the same criteria for every facility. The operational systems, however, are identified by the

activities performed within an individual facility. The AABB standards use the quality management system as a framework.

The AABB accreditation program has deemed status under the regulations of CLIA to perform on-site assessments to meet CMS requirements. This status means that the CMS has determined that the AABB accreditation process provides assurance that facilities meet or exceed conditions required by federal law and regulations. A laboratory accredited by the AABB that designated AABB as its CLIA provider does not need to be inspected routinely by the CMS. However, these facilities are subject to validation surveys and surveys performed in response to complaints to the CMS or state agencies on behalf of the CMS.

### The Joint Commission

Since 1961, review of blood use has been an element of the accreditation process of The Joint Commission.<sup>27</sup> By 1970, The Joint Commission required review not only of blood utilization, but of transfusion reactions as well. The 1986 standards were more comprehensive, mandating review of transfusion policies and procedures, ordering practices, and adequacy of the transfusion service generally. The standards also required evaluation of all transfusions.<sup>99</sup> After repeated blood utilization review consistently documented appropriate blood use, sampling became acceptable. Although only a minority of hospitals complied with this requirement for 100% evaluation, this standard was nevertheless the driving force behind blood utilization review in the United States.

Since 1991, The Joint Commission has made a series of modifications to this standard, and 100% review is no longer required. The actual number of transfusions to be reviewed is not mandated, although recommendations are provided. Additionally, as part of an effort to reduce medical errors, The Joint Commission has developed National Patient Safety Goals; the number one goal is to “improve the accuracy of patient identification.” Although this safety goal was implemented because of the recognition that patient misidentification affects all aspects of medical care, its relevance to transfusion therapy was clearly recognized by The Joint Commission. One of the implementation expectations for the goal clearly states that “Two patient identifiers are used when administering medications or blood products” and “when collecting blood samples ...for clinical testing.” There are also explicit statements that specimens collected from a patient must be labeled at the bedside and that the patient’s location may not be used as an identifier. The patient safety goal is reiterated in the body of the standards themselves. An element of performance of standard PC 5.10 also requires two identifiers for patient samples.

The Joint Commission views transfusion services from a dual perspective. Standards are devoted both to the entire process of blood transfusion from blood ordering through infusion and to the laboratory procedures and practices. Two accreditation manuals have standards regarding blood transfusion. The *Comprehensive Accreditation Manual for Hospitals*<sup>100</sup> provides specific standards for hospitals that transfuse and monitor

blood components. The *Comprehensive Accreditation Manual for Pathology and Clinical Laboratory Services*<sup>101</sup> contains technical standards that are patterned after the CLIA 1988 requirements and AABB standards. This dual approach provides The Joint Commission with the opportunity to assess the entire spectrum of clinical and laboratory blood transfusion practices. The Joint Commission Laboratory Accreditation Program has deemed status with the CMS.

Standards related to blood transfusion are included in the *Comprehensive Accreditation Manual for Hospitals* in those sections addressing the medical staff, provision of care, treatment and services, management of information, improvement of organization performance, environment of care, and sentinel event review. Among the salient standards, MS 3.10 states that the medical staff must have “a leadership role in hospital performance improvement activities to improve quality of care.” One of the specific elements of performance for MS 3.10 requires that the medical staff be “actively involved in measurement, assessment and improvement in the use of blood and blood components.” A similar provision, PI 1.10 in the section on performance improvement, states that the hospital must “collect data to monitor its performance,” and this requirement includes collecting data on blood and blood product use. PI 2.20 requires that “undesirable patterns and trends in performance are analyzed,” including all confirmed transfusion reactions. In addition, hemolytic transfusion reactions involving the administration of blood having major blood group incompatibilities are identified as reviewable sentinel events subject to specific review by The Joint Commission.

The *Comprehensive Manual for Laboratory and Point of Care Testing*<sup>10</sup> contains more specific provisions governing transfusion services. HR 1.15 requires that the director of the blood bank must be a physician, either a pathologist or other physician qualified in immunohematology and hemotherapy. Sections QC 5.10 through QC 5.260 provide guidance on what The Joint Commission regards as critical elements comprising an acceptable transfusion service. Section QC 5.10 requires that the transfusion service have written policies and procedures that “are acceptable in format, content, review process and availability.” These policies and procedures must be consistent with AABB standards, and must be reviewed annually. There must also be policies and procedures governing transfusion reactions and adverse events. Every adverse event must be evaluated by the medical director and documented in the patient’s medical record.

### College of American Pathologists

The CAP laboratory accreditation program expects a participant laboratory to demonstrate that it is in compliance with the CAP standards for laboratory accreditation. These standards relate to requirements for laboratory direction, physical facilities and safety, quality control and performance improvement, and inspection. Assessment of whether a laboratory meets the standards is accomplished through a series of checklists.

Any applicable question that cannot be answered “yes” is considered a deficiency and must be corrected within 30 days with the submission of supporting documentation for accreditation to be achieved. The inspector does not grant or deny accreditation, but makes a recommendation. The accreditation decision is made by the CAP Commission on Laboratory Accreditation. In addition to the on-site inspection program, the CAP laboratory accreditation program monitors proficiency testing performance of its participant laboratories. The CAP has deemed status with The Joint Commission and the CMS.

---

## Transfusion Medicine Committee

A clinical staff committee concerned exclusively with practices and policies related to transfusion and the transfusion service is not mandated by The Joint Commission or other accreditation entities. However, it has become routine in most hospitals because a standing transfusion committee is an efficient way of meeting quality assurance and peer review requirements.<sup>102</sup> It reports to the health-care evaluation office or committee, or directly to the medical policy committee of the institution.

### Membership

The membership of the transfusion committee should represent the departments that are the principal users of blood and blood components, such as hematology or oncology, surgery, and anesthesiology. Obstetrics/gynecology and pediatrics departments also should be represented if these departments are part of the hospital. In addition, staff from some of the surgical subspecialties (eg, cardiovascular surgery) and from services with specialized needs (eg, neonatal, emergency, intensive care) are appropriate members. The transfusion service supervisor is a valuable resource concerning laboratory operations and the feasibility of proposed policies. Clinical staff members with special interests or expertise in transfusion medicine should be encouraged to accept appointment on the committee. Committee activities are educational for the participating physicians.<sup>103-105</sup> Transfusion committee appointments should last several years so that expertise can be acquired and should be staggered to ensure continuity.

The medical director of the transfusion service must be a committee member; however, it is preferable for the director not to serve as chair of the transfusion committee. Changes in policy are more readily accepted if the transfusion committee is perceived as a distinct entity, independent of the transfusion service. As the expert, the director always has the opportunity to present views and shape policy. However, having a consumer of blood products serve as chair is likely to enhance the credibility, visibility, and effectiveness of the transfusion committee.

Other services in the hospital that often send representatives to the transfusion committee meetings include the hospital

compliance office; the divisions of quality, risk, and utilization management of the health-care evaluation office; the medical records department; medical and surgical nursing services; and the intravenous therapy team. If the hospital has a residency training program, it is helpful to have a resident physician present for committee meetings. The director of the blood center that supplies the hospital may be a valuable resource to provide comparisons of transfusion activities at different hospitals in the community, advice on meeting regulatory requirements, and education on transfusion-related issues.<sup>106</sup> For example, if one hospital follows markedly different policies and does not encounter differences in outcome, this information can be the basis for adopting an alternative approach. When policies with medicolegal implications are under discussion (eg, a policy for recipient consent for blood transfusion, implementation of look-back procedures), it is useful to have the hospital attorney attend committee meetings.

A multidisciplinary transfusion committee can serve as an active and effective guiding force in the development of policies and procedures related to the transfusion of blood components. Physicians must give sufficient priority to this process, and the hospital administration must make the necessary resources available to ensure effective committee work. A prompt and thoughtful response to committee recommendations by hospital and clinical governing bodies is essential to creating the correct environment. In academic centers, department chairs should support the participation of faculty on clinical staff committees and appreciate that this is an important element of the faculty member's educational and service efforts. Data derived from the committee's work can serve as a source of clinical scholarship.

### Functions of a Transfusion Committee

The transfusion committee should be involved in evaluation of all aspects of transfusion and transfusion practice in the hospital. Although utilization review is perhaps the most well known and obvious function of the transfusion committee, the committee should also be the leader in establishing hospital-wide policies and procedures governing transfusion practice as well as sponsoring educational activities to improve transfusion practice in the hospital.<sup>107</sup> Each transfusion committee should determine the topics it wants to consider. It should select areas that will help the institution achieve compliance with accreditation standards and regulatory requirements and focus on those most in need of systematic oversight or improvement. High-volume and high-risk procedures have been suggested as important focal points for review of transfusion practices.<sup>108</sup>

### Utilization Review

Although effective utilization review need not involve the transfusion committee, the participation of the committee supplements other efforts. The functions can also be performed by transfusion service physicians prospectively or soon after transfusion. The transfusion committee and others performing utilization review should be familiar with state laws and regulations

governing the discoverability for legal proceedings of the committee's minutes, records, correspondence, and reports. The committee and others need to shape their practices accordingly. State statutes often prevent the routine release of these documents as a result of legal discovery proceedings, but sometimes permit courts to order the disclosure of such records if it is found that extraordinary circumstances make such an action desirable. Considerable caution must be taken regarding the content of all written records with respect to their discoverability.

### Undertransfusion

A patient who needs a blood transfusion but does not receive one is more likely to be harmed than is a patient who receives a transfusion that is unnecessary. Most attention has been devoted to identifying unnecessary transfusions. However, hospital transfusion committees may want to determine whether patients who need transfusions are receiving them.<sup>109</sup> For example, the members of the transfusion committee may want to review the medical records of patients with hemoglobin levels less than 5.5 or 5.0 g/dL who did not receive transfusions.

There is great variability in transfusion practices among institutions. This variability illustrates that good clinical data are often lacking and indications for transfusion are not universally accepted. This prompts concern that undertransfusion could be a problem. Some data suggest higher hematocrit levels are needed to prevent myocardial ischemia after surgery in selected patients.<sup>110</sup>

Undertransfusion can also occur if units of blood are not being released from the blood bank in a sufficiently timely manner.<sup>111</sup> The publicity regarding the risks of transfusion and inappropriate transfusions and the strict policies, procedures, accreditation standards, and regulations governing blood banks may have combined to create undue concern about the release of blood components for transfusion. Members of transfusion committees may want to ensure that blood bank technical staffs are not delaying the release of urgently required components because of excessive concern about exceptions to routine practice.

### Unnecessary Transfusion

Review of transfusion practices has the potential to improve the quality of clinical care, educate clinical staff, reduce costs, ensure regulatory and accreditation compliance, reduce the risk of litigation, provide information about the practices of individual physicians and specific clinical services, and establish consistent practices. It is onerous and unnecessary to review intensively each transfusion in an institution. Rather, the transfusion service director and medical staff representatives of each hospital should determine the timing, scope, and intensity of the review. One approach used by many hospitals is to review only orders for transfusions for which certain predetermined screening criteria are not met. Intensive assessment of an individual case also may be initiated in response to concerns of a patient, provider, or third-party payer.

### Timing of Utilization Review

Utilization review can be conducted prospectively or retrospectively.<sup>112</sup> Prospective review requires verification by a reviewer that criteria have been met before a blood component is made available for transfusion. Although this on-site validation is desirable and presumably the most beneficial, it is labor intensive and not always feasible in an emergency. Furthermore, in the care of an acutely ill patient, a discussion regarding transfusion practice is not conducive to effective education and is sometimes inappropriate. Although prospective auditing may prove useful for customized blood products, such as irradiated components or unusually large orders, it is not likely to be feasible for all blood transfusions within an institution. Retrospective audits are most effective if performed soon after the transfusion—for example, within 24 hours. Although common sense suggests that this prompt feedback would be useful to physicians, it requires a continuing effort and is not always practical. Retrospective audits later are the least difficult to perform but also should be completed in as timely a manner as possible to be maximally effective. There are no data to substantiate the effectiveness of retrospective review alone in improving transfusion practices, although there are many reports of success with other approaches, some of which have been combined with retrospective review.

One method that has been used frequently requires prospective justification with either a computer-generated ordering menu or simply a requisition slip. In both cases, screening criteria are used as part of the ordering process. The ordering physician selects from a menu the transfusion criterion met by a particular patient or presents another clinical justification for transfusion. Table 66-2 contains examples of screening criteria that are used. Screening criteria for adult<sup>114,115</sup> and pediatric<sup>116,117</sup> blood transfusion practices have been published. All or some of the orders in which another reason was provided as the indication for transfusion are reviewed more intensively, either before or after the transfusion. Transfusions thought to pose the greatest risk or be the most likely to be inappropriate can be reviewed. For hospitals that do not use screening criteria, these unusual transfusion episodes are a logical place to begin blood utilization review. Each type of component transfused in the institution should be reviewed, and each clinical service that uses blood should be evaluated.

If a retrospective review is conducted long after the transfusion, the reviewer must consider the information available to the clinician and the patient's clinical condition at the time the decision to perform transfusion was made.

### Screening Criteria

Criteria used for evaluating clinical care should ideally be established from a scientific database. However, this information is not always available, and it may be necessary to use a consensus opinion.<sup>118</sup> Implicit criteria are used when a designated expert reviews a particular case and judges the quality of care. Explicit criteria are specified in advance, before the assessment of individual cases is undertaken. Reviews based on implicit criteria can be individualized but are costly and inherently imprecise.<sup>119,120</sup>

Explicit criteria can be used to make reproducible assessments at a relatively low cost. They are, however, not responsive to the subtle variations in individual patients that can prompt different standards of therapeutic intervention. Implicit and explicit criteria frequently are combined in a particular quality assessment program of clinical practices. Explicit criteria often are used to separate cases that should not require further review (because they most likely have already met accepted standards of practice) from those that need to be reviewed individually (according to implicit criteria or a combination of implicit and explicit criteria). As institutions measure and assess various processes, criteria have to be modified as new clinical information becomes available and a different level of performance is required.

Although explicit screening criteria are useful to select transfusion episodes for intensive review, the criteria do not constitute a standard of practice. Not every patient who meets a screening criterion necessarily needs a blood transfusion, and there are patients who do not meet the screening criteria who need a transfusion. It is necessary to differentiate between criteria used simply to select a medical record for further intensive review and what is appropriate clinical practice. Nevertheless, those who control the screening criteria exert great influence on clinical practice. Therefore, the committee might want to review selectively some cases in which a transfusion has fallen within the criteria. Initially the criteria can be designed liberally to capture transfusion episodes in which inappropriate practices were most likely to have occurred. However, once these have been addressed, the criteria can be modified to become more restrictive. Differences in patient populations, professional judgment, and prevailing practices result in different screening criteria among hospitals. The clinical staff has overall responsibility for approving the screening criteria. The intriguing suggestion has been made that hospitals' clinical staffs should review each other to avoid the collegiality that arises within institutions.<sup>121</sup>

The input and approval of practicing physicians are helpful to lessen the debate about the validity of screening criteria. The criteria should be limited to one or a few easily identified elements, and exceptions should be minimized. Policies regarding the administrative response to deficient transfusion practice should be publicized, so that there will be no surprises when blood utilization review is implemented. The screening criteria should be publicized regularly. If the criteria are not on an order menu, house staff and new members of the clinical staff should receive copies of the criteria, which should be disseminated throughout the institution.

Screening criteria should be evaluated on a regular basis. New clinical practices require reassessment of the criteria. Intensive assessment of a medical record or subsequent discussion about a specific clinical practice with a treating physician may prompt a revision of the criteria.

An alternative approach is a system in which the admission and discharge hematocrits of patients are used to determine the appropriateness of blood transfusions.<sup>122,123</sup> The advantages of this system include possible elimination of extensive chart audits, individualization of reviews according to patient or procedure,

## Section VI

**Table 66-2.** Threshold Criteria for Blood Utilization Review\*

---

### Red Blood Cells

- Hematocrit less than 25%
- Acute blood loss greater than 20% of blood volume
- Coronary or cerebral vascular disease and hematocrit less than 30%
- More than 10% surface burns and hematocrit less than 30%
- For neonates: hematocrit less than 40% with respiratory distress; otherwise, hematocrit less than 30% or blood loss more than 10% of blood volume

### Platelets

- Bleeding or a planned invasive or surgical procedure and any of the following:
  - Platelet count  $<80,000/\mu\text{L}$
  - Bleeding time longer than 7.5 minutes
  - Documented platelet function disorder
  - Administration of more than one blood volume of red cells and other volume-expanding fluids in previous 24 hours
- Platelet count  $<100,000/\mu\text{L}$  in a patient who is either of the following:
  - Experiencing retinal or cerebral hemorrhage
  - Recovering from a cardiopulmonary bypass procedure
- Prophylactically for platelet count  $<20,000/\mu\text{L}$  ( $<40,000/\mu\text{L}$  in neonate)
- Neonate with bleeding or a planned invasive or surgical procedure and platelet count  $<100,000/\mu\text{L}$

### Fresh Frozen Plasma

- Hemorrhage or a planned invasive or surgical procedure and either of the following:
  - International normalized ratio 1.5 or higher (other than for central nervous system)
  - International normalized ratio type 1.3 or higher (for central nervous system)
- Documented deficiency of Factor II, V, VII, X, or XI
- Administration of more than one blood volume of red cells and other volume-expanding fluids in previous 24 hours
- Thrombotic thrombocytopenic purpura
- Hemolytic uremic syndrome

### Cryoprecipitate

- Bleeding or a planned invasive or surgical procedure and any of the following:
  - Documented deficiency of fibrinogen ( $<80\text{ mg/dL}$ )
  - Documented von Willebrand disease
  - Documented deficiency of Factor XIII
  - Uremic platelet dysfunction (bleeding time longer than 7.5 minutes)

### Plasma Cryoprecipitate Reduced

- Bleeding or a planned invasive or surgical procedure and documented deficiency of Factor II, V, VII, X, or XI
- Thrombotic thrombocytopenic purpura
- Hemolytic uremic syndrome

### Granulocytes

- Neutropenia ( $<1000/\mu\text{L}$ ) with documented infection unresponsive to antibiotics

### Rh Immune Globulin

- Postpartum Rh-negative mother with Rh-positive infant
  - Antepartum Rh-negative woman at 28 weeks of gestation or with risk of recent fetomaternal hemorrhage or who received antepartum Rh Immune Globulin 12 weeks previously
  - Rh-negative woman after abortion, ectopic pregnancy, miscarriage, or amniocentesis
  - Transfusion of Rh-positive cellular blood components to Rh-negative patient
  - These are not indications for transfusion. They are criteria that may be used to preclude more intensive review of blood transfusion. They may be incorporated into blood ordering forms or computer programs. Adapted with permission from Mintz.<sup>113</sup>
- 

and lack of dependence on a single hematocrit level at either admission or discharge, which can be misleading.

### *Consequences of Utilization Review*

A retrospective utilization review must consider carefully the clinical situation at the time the transfusion was given. If, however, it

is determined that a transfusion deviated from acceptable practice, the involved physician should be informed in writing and invited to provide an explanation for the transfusion in question. After the physician's response is received, the committee makes a final determination regarding the transfusion and informs the physician. Audit findings should be summarized for departments

and divisions and be made available to their chairs and directors. If blood transfusion practices are audited selectively, the review should be rotated so that at some point all of the divisions within the hospital are subject to review. Collected information should be sent regularly to the committee or individual to whom the transfusion committee reports. When particular problems with transfusion practices are identified, they should be subjected to repeated intense evaluation. The overall effect of the review program on clinical practices may be assessed as well.

It is important to communicate conclusions regarding appropriate transfusion practices to the clinical staff. These communications can reinforce good practices and increase the openness of practitioners to future, perhaps less supportive comments. Because an important element of any quality assessment program is the continuing education of the clinical staff, the auditing process should be designed more as a tutorial activity than as a punitive one. Improperly performed audits can antagonize those whom they are designed to instruct, thereby hindering acceptance of other well-designed programs. If the institutional leadership provides the necessary resources for the auditing process and physicians provide sufficient time and effort, utilization review can be an important element in documenting sustained excellence or continuing improvement in clinical practices.

### **Oversight of Transfusion Policies, Procedures, and Guidelines**

The transfusion committee should provide oversight of hospital-wide policies and procedures. It should also oversee the entire transfusion process, carefully examining each step in the transfusion chain to ensure compliance with safety concerns, regulatory requirements, and clinical appropriateness.<sup>124</sup> It is very important that transfusion policies be consistent throughout the hospital. Consistency encourages compliance with transfusion procedures and facilitates staff training. The transfusion committee plays an important role in ensuring this consistency. Table 66-3 and the list below identify selected items regarding the overall transfusion process that either the transfusion service or the committee may wish to monitor.

1. Review the institution's policies and procedures for proper patient, specimen, and blood component identification and other policies and procedures related to blood administration.
2. Review that transfusions are appropriately documented in the medical record. This activity should include a review of the documentation required by the institution's policies. The blood transfusion record can be audited to ensure that it includes the information the institution requires regarding the intended recipient's name, identification number, and ABO group and Rh type; the component's unique identification number; the donor's ABO group and Rh type; interpretation of compatibility tests; the volume administered; the expiration date or time of the component; time of transfusion; identification of the transfusionist; and information about patient monitoring during the transfusion. A systematic education program for transfusion nurses can improve documentation and monitoring procedures.<sup>126</sup> The review can include verification that

the medical record contains the documentation of the indications for transfusion, the prescription for the transfusion, and the outcome of the transfusion.

3. Review compliance with recipient consent process for blood transfusion. This includes determination that consent has been obtained, that the required signatures (patient, witness, and physician) are included, and that the consent is appropriately dated and placed in the record.
4. Review that there is appropriate documentation in the medical record of prescription for transfusion, indications for transfusion, and outcome of transfusion.
5. Ensure that adequate policies and procedures exist for detecting, reporting, and evaluating transfusion reactions, and review the timeliness and adequacy of the investigations of these adverse events. Assess whether reasonable effort is made to ensure the reporting and evaluation of suspected instances of transfusion-transmitted infectious disease.<sup>127</sup>
6. Review the hospital's look-back activities to ensure that they comply with federal regulations and accreditation standards and are being completed on a timely basis.
7. Evaluate the utilization of devices used in blood transfusion. The committee can ascertain that appropriate quality control has been performed on blood warmers and infusion pumps, the devices used are appropriate for the purpose, and personnel have been trained adequately in use of devices.
8. Review autologous blood collection and transfusion activities. A quality improvement team significantly improved the availability of autologous donor blood and had a far-reaching effect on quality improvement methods throughout one medical center.<sup>128</sup> The committee can review how such services are being used, whether allogeneic blood was ever transfused when autologous blood was available, and whether autologous blood has been transfused more liberally than the committee deems appropriate. In view of the risks of bacterial contamination, clerical error, and hypervolemia that exist with autologous blood transfusion, the committee can reasonably require that the same standards used for allogeneic blood transfusion be used for autologous blood transfusion. An alternative, because autologous blood is safer, is for the transfusion committee to accept more liberal indications for transfusion of autologous blood. In either case, the same screening criteria can be used to determine which cases require more intensive review. This practice allows individual consideration of the use of autologous blood in situations in which allogeneic transfusion would be considered inappropriate. The collection, manipulation, and utilization of autologous blood collected intraoperatively, postoperatively, and after trauma also can be reviewed.
9. Review blood bank performance in such areas as timeliness of response to requests, productivity, and outdating of products.
10. Review the utilization of certain customized products such as irradiated blood.
11. Review the use and underuse of single-unit transfusions. Single-unit transfusion sometimes represents good practice. If one RBC transfusion increases oxygen delivery adequately, there is no need for additional transfusions.

**Table 66-3.** Factors to Consider in Monitoring the Ordering, Dispensing, and Administration of Blood Components

---

|     |                                                                                                                                     |
|-----|-------------------------------------------------------------------------------------------------------------------------------------|
| 1.  | What time was request for blood component received?                                                                                 |
| 2.  | Was there a prescription for the transfusion?                                                                                       |
| 3.  | Was the request submitted correctly?                                                                                                |
| 4.  | Was the correct component selected for issue?                                                                                       |
| 5.  | Was the component inspected?                                                                                                        |
| 6.  | Was the component verified to be in date?                                                                                           |
| 7.  | Was documentation before issue completed correctly?                                                                                 |
| 8.  | What time was the transportation department notified that the component was available?                                              |
| 9.  | What time was the component issued?                                                                                                 |
| 10. | Was the correct filter issued?                                                                                                      |
| 11. | Was documentation regarding transportation completed correctly?                                                                     |
| 12. | What time was the component delivered by transportation?                                                                            |
| 13. | Was the blood component unattended after release from the blood bank? Where was it?                                                 |
| 14. | Was informed consent obtained in accord with written procedure?                                                                     |
| 15. | Were patient and blood component identification properly performed in accord with written procedure before transfusion was started? |
| 16. | Was documentation on the transfusion slip accurate and complete?                                                                    |
| 17. | Were pretransfusion vital signs obtained and recorded?                                                                              |
| 18. | Was the filter attached properly?                                                                                                   |
| 19. | Was arm/port preparation properly performed?                                                                                        |
| 20. | When was the transfusion started? Was this documented?                                                                              |
| 21. | Were only approved solutions in contact with the component?                                                                         |
| 22. | Were only approved solutions mixed with the component?                                                                              |
| 23. | If utilized, was a blood warmer or infusion pump used in accord with written procedure?                                             |
| 24. | Were vital signs obtained and recorded during the transfusion in accord with written procedure?                                     |
| 25. | Was any transfusion reaction reported to a physician and the blood bank in accord with written procedure?                           |
| 26. | What time was the transfusion completed? Was this documented?                                                                       |
| 27. | Were vital signs taken and recorded, and was the patient observed after transfusion in accord with written procedures?              |

12. Ensure that the last unit or units of several transfusions given sequentially are appropriate. A single low hemoglobin concentration or episode of bleeding can lead to the transfusion of several units of blood, of which the last or last few units may have been the least needed transfusions provided. These transfusions may not come routinely to the attention of the committee because the patient may have met a particular criterion initially. The committee may want to assure itself that when more than one unit of blood is transfused for a specific criterion, each of the units is truly indicated. In one study, 2-unit transfusions were commonly given to patients undergoing total hip replacement when 1 unit would have sufficed.<sup>129</sup> In another study, intertransfusion assessment was frequently not completed for

postoperative patients.<sup>130</sup> Results of another study suggested that determining the hematocrit immediately before administration of each unit of blood would have reduced by 25% the amount of blood transfused to patients undergoing colonic resection.<sup>131</sup>

13. Review whether the institution's guidelines for preoperative ordering of blood crossmatching<sup>5</sup> are followed. The effective use of preoperative crossmatching guidelines for elective surgery has been shown not to compromise patient care.<sup>132</sup>

14. Review the veracity of the ordering physicians in choosing the criteria met to justify blood transfusion, if the institution has a system in which physicians indicate in advance the reason for the transfusion.

15. Review blood wastage caused by failure to return unused units to the blood bank on a timely basis.<sup>133</sup>

16. Audit the blood bank staff to ensure that they are following written policies and procedures for handling and release of blood from the blood bank. Audit the procedures to determine whether appropriate review has occurred within the past 12 months.

17. Audit the transfusion practices on various clinical services to ensure that staff appropriately identify patients before transfusion, appropriately identify blood components before administration, appropriately monitor the patient during transfusion, and appropriately document the transfusion episode in the patient's hospital record. Boone et al<sup>134</sup> found that careful monitoring can effectively identify correctable errors in blood administration.

18. Review the timeliness and adequacy of delivery of blood components from the blood supplier. It may be helpful to invite blood center management to attend discussions regarding this issue.

19. Review blood bank proficiency testing, accreditation reports, and quality control results.

20. Determine, on occasion, the crossmatched to transfused ratio from selected services or within the entire institution. Although this calculation was emphasized in the past, its utility has frequently been overstated. There is no accreditation requirement to determine this statistic. However, institutions or selected departments or divisions that show a significantly elevated ratio, might be ordering more blood than is reasonable. An appropriate ratio is less than 2.

21. Assist in the development of hospital policies related to transfusion practices. In one study, significant decreases in red cell usage during four common surgical procedures were seen after the hospital transfusion committee introduced a requirement that hemoglobin be less than 8g/dL in asymptomatic patients.<sup>135</sup> Members of the transfusion committee could also help to shape policies regarding recipient consent for blood transfusion, the availability of directed donations from friends or relatives of patients, and the development of look-back procedures for patients who may have received blood from donors subsequently known to have infection with an agent transmissible through blood transfusion.

22. Serve as an advocate for the blood bank to the hospital's clinical staff and administration for personnel, equipment, or space needs.

23. Review staff training and continuing education in blood administration to ensure competence of personnel who transfuse blood components.

## Education

The transfusion committee stands in a unique position to advocate optimal transfusion practice. Although the utilization review process itself provides an opportunity for education of individual clinicians about their ordering practices and use of blood products, other modalities are available to the committee. A hospital

intranet affords the committee a venue for posting important transfusion-related information. Such important items as appropriate transfusion criteria, surgical crossmatch ordering guidelines, signs and symptoms of adverse reactions to transfusion and transfusion-related policies can be posted for easy referral by hospital staff. A web site is also easily updated as new medical knowledge or new guidelines in transfusion medicine become available. Each individual committee member is also an important educational resource. Transfusion committee members can take important information back to their respective departments. They can also provide one-on-one informal teaching to residents and hospital staff when transfusion-related issues come up during daily practice.

## Summary

Although blood components typically represent only approximately 1% of an average hospital's budget, transfusion is at once a life-saving and potentially life-threatening procedure. Remarkable progress has been made in reducing the transmission of viruses through blood transfusion, but this advance has not been matched in improved safety with respect to other important transfusion hazards. Although knowledge is still incomplete regarding indications for blood component transfusions, quality assessment programs for blood transfusion are needed to improve transfusion practice.

A successful quality program creates "an environment of watchful concern"<sup>26</sup> and is conducted in a professional, nonadversarial, and educational manner. Assessment of transfusion practices has the potential to enhance the knowledge and judgment of health-care professionals, provide significant information about patient care, reduce the risk of litigation, decrease costs, ensure compliance with regulatory and accreditation requirements, conserve the blood supply, provide an opportunity to demonstrate quality and value to the public, and above all help create, sustain, and document excellence in patient care.

    - in pregnancy 409
  - type 1 436, 437–8
  - type 2 436–7, 438
  - type 2B 201
  - type 3 437, 438
- von Willebrand factor **249**, 250
  - acquired deficiency 383
  - deficiency 436
  - Factor VIII
    - binding to 436
    - cryoprecipitation 277
  - gene mutations 436–7
  - glycoprotein 98
  - platelet adhesion to vessel wall 158
  - platelet plug 159
  - synthesis 436
- von Willebrand factor-cleaving protease *see* ADAMTS13
- Waldenström macroglobulinemia
  - cryoglobulins 641
  - hematopoietic stem cell transplantation 534
  - therapeutic plasma exchange 638
  - treatment 635
- walking donor program 596
- warfarin 386–7
  - bleeding risk 386
  - reversal of effect 291, 386–7
  - surgery 387
  - venous limb gangrene 358
  - venous thromboembolism in children 440, 441
- warm agglutinins, autoimmune hemolytic anemia 640
- warm-type autoimmune hemolytic anemia (WAIHA) 116
- Washington University v. Catalona 1001
- weak secretors, classical 97
- weak-D expression 111, 112, 114
- Wegener's granulomatosis 643
- West Nile virus 755, 801
  - blood screening 984
  - negligence claim 994
  - organ transplantation transmission 604
  - tissue-transmissible 902
  - transfusion-transmitted 490
- Western blot testing
  - CMV 753
  - HIV infection 749
  - p24 core antigen antibodies 752
- white cells *see* leukocyte(s)
- whole blood
  - citrate-phosphate-dextrose-anticoagulated 247
  - collection 982
    - in emergencies 61, 63
  - diversion 778–9
  - donation
    - complications 689, **690**
    - long-term effects 689
  - preservation 8
  - separation 61
  - testing 10
  - use 596
- Wiskott-Aldrich syndrome
  - gene therapy 945
  - graft-vs-host disease 849
- World Health Organization (WHO)
  - blood services 978
  - guideline on adverse event reporting 683
  - transplantation program 1038, **1039**
- World Marrow Donor Association 1035, **1039**
- Worldwide Group for Blood and Marrow Transplantation 1037, **1039**
- wound(s)
  - bleeding into cavities 585
  - fibrinolysis 585
  - infections 903
  - wound healing, gene therapy 953
- Wr<sub>a</sub> antigen 126
- Wr<sub>b</sub> antigen 126
- wrong blood in tube (WBIT) 87
  - hemolytic transfusion reactions 814–15
- Xg blood group system 127
- XK protein 121, 123
- X-linked immunodeficiency, gene therapy 937–8
- Yersinia enterocolitica* 774, 780
  - leukocyte reduction 785
- yolk sac, macrophages 393
- zidovudine, HIV-associated thrombocytopenia 356
- zinc finger nucleases 945
