# Contents

Contributors, viii

Preface, xiii

- 1 Transfusion in the New Millennium, 1  
*Ennio C. Rossi & Toby L. Simon*

## Section I. Blood Components and Derivatives, 15

### Part I. Red Blood Cells, 17

- 2 Red Cell Production and Kinetics, 17  
*Mark J. Koury*
- 3 Regulation of Oxygen Delivery by Red Cells and Red Cell Substitutes, 29  
*Christopher P. Stowell*
- 4 Red Cell Metabolism and Preservation, 54  
*Bjarte G. Solheim & John R. Hess*
- 5 Red Cell Immunology and Compatibility Testing, 69  
*W. John Judd*
- 6 Carbohydrate Blood Groups, 89  
*Eldad A. Hod, Patrice F. Spitalnik, & Steven L. Spitalnik*
- 7 Rh and LW Blood Group Antigens, 109  
*Connie M. Westhoff & Don L. Siegel*
- 8 Other Protein Blood Groups, 121  
*Petr Jarolim*
- 9 Anemia and Red Blood Cell Transfusion, 131  
*Jeffrey L. Carson & Paul Hébert*

### Part II. Platelets, 149

- 10 Platelet Production, Kinetics, and Hemostasis, 149  
*Henry M. Rinder & Aaron Tomer*
- 11 Platelet Immunology and Alloimmunization, 168  
*Brian R. Curtis & Janice G. McFarland*
- 12 Preparation, Preservation, and Storage of Platelet Concentrates, 187  
*Ralph R. Vassallo, Jr.*
- 13 Thrombocytopenia and Platelet Transfusion, 199  
*Peter W. Marks*

### Part III. White Blood Cells, 211

- 14 Neutrophil Production and Kinetics: Neutropenia and Neutrophilia, 211  
*Thomas H. Price*
- 15 Neutrophil Collection and Transfusion, 219  
*Ronald G. Strauss*
- 16 Leukocyte-Reduced Blood Components: Laboratory and Clinical Aspects, 228  
*Darrell J. Triulzi & Walter H. Dzik*

### Part IV. Plasma, 247

- 17 Composition and Mechanisms of Blood Coagulation and Fibrinolysis, 247  
*Peter Hellstern*
- 18 Immunoglobulins, 260  
*Urs E. Nydegger*
- 19 Preparation of Plasma Derivatives, 273  
*Toby L. Simon, Kirsten Seidel, & Albrecht Gröner*

- 20 Plasma Transfusion and Use of Albumin, 287  
*Simon J. Stanworth & Alan T. Tinnmouth*

## **Part V. Cell Kinetics, 298**

- 21 Applications of Cellular Radiolabeling in Transfusion Medicine, 298  
*Larry J. Dumont, James P. AuBuchon, & Richard J. Davey*

## **Section II. Clinical Practice, 319**

### **Part I. Medical Patients, 321**

- 22 Autoimmune Hemolytic Anemia and Paroxysmal Nocturnal Hemoglobinuria, 321  
*Thomas P. Duffy*
- 23 Management of Immune Thrombocytopenia, 344  
*Donald M. Arnold, James W. Smith, & Theodore E. Warkentin*
- 24 Bleeding from Acquired Coagulation Defects and Antithrombotic Therapy, 376  
*Thomas J. Raife, Jeffrey S. Rose, & Steven R. Lentz*

### **Part II. Obstetric and Pediatric Patients, 391**

- 25 Fetal and Neonatal Hematopoiesis, 391  
*Robert D. Christensen & Martha C. Sola-Visner*
- 26 Obstetric Transfusion Practice, 406  
*Humphrey H.H. Kanhai, Jos J.M. van Roosmalen, & Anneke Brand*
- 27 Hemolytic Disease of the Fetus and Newborn, 418  
*Bjarte G. Solheim & Morten Grønn*
- 28 Congenital Disorders of Clotting Proteins and Hypercoagulable States in Pediatrics, 426  
*Linda J. Butros & Prasad Mathew*
- 29 Management of Congenital Hemolytic Anemias, 448  
*Bruce I. Sharon*
- 30 Blood Component Transfusions for Infants, 470  
*Ronald G. Strauss*

### **Part III. Oncology Patients, 482**

- 31 Transfusion Support for the Oncology Patient, 482  
*Christopher A. Tormey & Edward L. Snyder*
- 32 Hematopoietic Growth Factors (Cytokines), 498  
*W. Conrad Liles & David C. Dale*

- 33 Hematopoietic Progenitor Cells: Biology and Processing, 508  
*Thomas Leemhuis & Ronald A. Sacher*

- 34 Hematopoietic Progenitor Cells: Autologous Transplantation, 521  
*Hooman H. Rashidi & Scott D. Rowley*

- 35 Hematopoietic Progenitor Cells: Allogeneic Transplantation, 542  
*Amin M. Alousi & Sergio A. Giralt*

- 36 Umbilical Cord Blood: A Reliable Source of Stem and Progenitor Cells for Human Transplantation, 559  
*Suhag H. Parikh & Joanne Kurtzberg*

### **Part IV. Surgery Patients, 566**

- 37 Alternatives to Transfusion: Perioperative Blood Management, 566  
*Lynne Uhl*
- 38 Blood Components to Achieve Hemostasis for Surgery and Invasive Procedures, 575  
*Walter H. Dzik*
- 39 Transfusion Therapy in the Care of Trauma and Burn Patients, 589  
*Ellen C. Omi & Richard L. Gamelli*
- 40 Transfusion Therapy in Solid-Organ Transplantation, 604  
*Glenn Ramsey*

## **Section III. Apheresis, 615**

- 41 Apheresis: Principles and Technology of Hemapheresis, 617  
*Ronald O. Gilcher & James W. Smith*
- 42 Therapeutic Plasma Exchange, 629  
*Bruce C. McLeod*
- 43 Specialized Therapeutic Hemapheresis and Phlebotomy, 652  
*Robert Weinstein*

## **Section IV. Hazards of Transfusion, 681**

### **Part I. Hemovigilance, 683**

- 44 Overview of Hemovigilance, 683  
*Dorothy Stainsby, Jean-Claude Faber, & Jan Jørgensen*
- 45 Immunomodulatory and Proinflammatory Effects of Allogeneic Blood Transfusion, 699  
*Eleftherios C. Vamvakas, José O. Bordin, & Morris A. Blajchman*

**Part II. Infectious Hazards of Transfusion, 718**

- 46 Transfusion-Transmitted Hepatitis, 718  
*Harvey J. Alter & Juan I. Esteban-Mur*
- 47 Retroviruses and Other Viruses, 746  
*John A. J. Barbara, & Brian C. Dow*
- 48 Transfusion Transmission of Parasites, 760  
*Bryan R. Spencer*
- 49 Bacterial Contamination of Blood Products, 773  
*Yara A. Park & Mark E. Brecher*
- 50 Prion Diseases, 791  
*Marc L. Turner*
- 51 Pathogen Inactivation, 801  
*Bjarte G. Solheim & Jerard Seghatchian*

**Part III. Noninfectious Hazards, 811**

- 52 Hemolytic Transfusion Reactions, 811  
*Robertson D. Davenport*
- 53 Febrile, Allergic, and Nonimmune Transfusion Reactions, 826  
*Gregory J. Pomper*
- 54 Transfusion-Associated Graft-vs-Host Disease, 847  
*John E. Levine & James L. M. Ferrara*
- 55 Transfusional Iron Overload, 858  
*Sujit Sheth*
- 56 Transfusion-Related Acute Lung Injury, 870  
*Jonathan P. Wallis & Ulrich J. H. Sachs*

**Section V. Cell and Tissue Therapy, 885**

- 57 HLA Antigens and Alleles, 887  
*Thomas M. Williams*
- 58 Tissue Banking, 898  
*Jeanne V. Linden, William F. Zaloga, & A. Bradley Eisenbrey*
- 59 Adoptive Immunotherapy, 920  
*Catherine M. Bollard & Helen E. Heslop*
- 60 Gene Therapy in Transfusion Medicine, 936  
*Emanuela M. Bruscia & Diane S. Krause*
- 61 Tissue Engineering and Regenerative Medicine, 950  
*Clay Quint & Laura Niklason*

**Section VI. Delivery of Transfusion and Transplantation Services, 973**

- 62 Recruitment and Screening of Donors and the Collection, Processing, and Testing of Blood, 975  
*Kendall P. Crookston, Susan L. Wilkinson, & Toby L. Simon*
- 63 Current Legal Issues in Transfusion Medicine, 993  
*Edward M. Mansfield, Thomas K. Berg, Kurt A. Leifheit, John Parker Sweeney & P. Robert Rigney*
- 64 Current Good Manufacturing Practice, 1010  
*P. Ann Hoppe & Sheryl A. Kochman*
- 65 Transplant Organizations and Networks in the Regulation of Cellular Therapy Programs, 1032  
*Dennis L. Confer*
- 66 Hospital Transfusion Committee and Quality Assurance, 1041  
*Pamela Clark & Paul D. Mintz*

**Index, 1061**

| Companion PC - and, MAC - Compatible CD-ROMs                                 |                                                                                         |
|------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------|
| CD-ROM 1: All chapters of the book with a full text search function.         | 5 Platelet Refractoriness<br><i>Marian Petrides</i>                                     |
| CD-ROM 2: Interactive case studies for self-testing.                         | 6 An Unexpected Panagglutinin<br><i>Marian Petrides</i>                                 |
| <b>CD-ROM 2: Cases</b>                                                       | 7 Postsurgical Bleeding<br><i>Marian Petrides</i>                                       |
| 1 Posttransfusion Hemolysis<br><i>Marian Petrides &amp; Nicole A. Pele</i>   | 8 Jehovah's Witness Surgery<br><i>Christopher P. Stowell &amp; Marian Petrides</i>      |
| 2 Child with Low Fibrinogen<br><i>Marian Petrides &amp; Donna Castellone</i> | 9 Delayed Fever and Dark Urine<br><i>Marian Petrides</i>                                |
| 3 Head Injury, Sudden Dyspnea<br><i>Marian Petrides</i>                      | 10 Fever in Neutropenic Child<br><i>Marian Petrides &amp; Dava S. Cleveland-Noriega</i> |
| 4 A Transfusion Fatality<br><i>Marian Petrides</i>                           |                                                                                         |

# Contributors

## Chapter Contributors

### **Amin M. Alousi, MD**

Assistant Professor  
Stem Cell Transplantation  
The University of Texas  
M.D. Anderson Cancer Center  
Houston, Texas, USA

### **Harvey J. Alter, MD**

Chief, Clinical Studies  
Associate Director for Research  
Department of Transfusion Medicine  
Warren Grant Magnuson Clinical Center  
National Institutes of Health  
Bethesda, Maryland, USA

### **Donald M. Arnold, MD**

Assistant Professor  
Department of Medicine  
Michael G. DeGroote School of Medicine  
McMaster University  
Hamilton, Ontario, Canada

### **James P. AuBuchon, MD**

President and Chief Executive Officer  
Puget Sound Blood Center  
Seattle, Washington, USA

### **John A.J. Barbara, MA, MSc, PhD, FIBiol, FRCPath**

Emeritus Microbiology Consultant to  
National Blood Service  
London, UK;  
Visiting Professor  
University of West of England  
Bristol, UK

### **Thomas K. Berg, JD**

Partner  
Hinshaw & Culbertson LLP  
Minneapolis, Minnesota, USA

### **Morris A. Blajchman, MD, FRCP(C)**

Professor Emeritus  
Departments of Pathology and Medicine  
McMaster University;  
Medical Director  
Canadian Blood Services  
Hamilton, Ontario, Canada

### **Catherine M. Bollard, MD**

Associate Professor of Pediatrics,  
Immunology and Medicine  
Center for Cell and Gene Therapy  
Baylor College of Medicine, Texas Children's  
Hospital and The Methodist Hospital  
Houston, Texas, USA

### **José O. Bordin, MD**

Associate Professor  
Division of Hematology and Transfusion Medicine  
Universidade Federal de Sao Paulo  
Sao Paulo, Brazil

### **Anneke Brand, MD, PhD**

Professor of Transfusion Medicine  
Sanquin Division Southwest  
Department of Immunohematology and Blood  
Transfusion  
Leiden University Medical Center  
Leiden, The Netherlands

### **Mark E. Brecher, MD**

Director, McLendon Clinical Laboratories,  
University of North Carolina Hospitals;  
Professor and Vice Chair for Clinical Services  
Department of Pathology and Laboratory Medicine  
University of North Carolina at Chapel Hill,  
Chapel Hill, North Carolina, USA

### **Emanuela M. Bruscia, PhD**

Associate Research Scientist  
Department of Pediatrics, Yale University  
New Haven, Connecticut, USA

### **Linda J. Butros, MD**

Assistant Professor of Pediatrics  
Pediatric Hematology/Oncology  
University of New Mexico  
Albuquerque, New Mexico, USA

### **Jeffrey L. Carson, MD**

Richard C. Reynolds Professor of Medicine  
Chief, Division of General Internal Medicine  
Robert Wood Johnson Medical School  
University of Medicine and Dentistry  
of New Jersey  
New Brunswick, New Jersey, USA

### **Robert D. Christensen, MD**

Director of Research  
Department of Neonatology  
Intermountain Health Care  
Ogden, Utah, USA

### **Pamela Clark, MD, JD**

Associate Professor of Pathology  
Division of Clinical Pathology;  
Associate Director  
Blood Bank and Transfusion Medicine Services  
University of Virginia Health System  
Charlottesville, Virginia, USA

### **Dennis L. Confer, MD**

Clinical Professor of Medicine  
University of Minnesota;  
Chief Medical Officer  
National Marrow Donor Program  
Minneapolis, Minnesota, USA

### **Kendall P. Crookston, MD, PhD**

Associate Professor  
University of New Mexico Department  
of Pathology;  
Associate Medical Director  
Tricore Reference Laboratories;  
Medical Director  
United Blood Services of New Mexico  
Albuquerque, New Mexico, USA

### **Brian R. Curtis, MSTM, MT(ASCP)SBB**

Technical Director  
Platelet and Neutrophil Immunology Laboratory  
BloodCenter of Wisconsin  
Milwaukee, Wisconsin, USA

### **David C. Dale, MD**

Professor of Medicine  
Department of Medicine  
University of Washington  
Seattle, Washington, USA

### **Robertson D. Davenport, MD**

Associate Professor  
Department of Pathology  
The University of Michigan Medical School  
Ann Arbor, Michigan, USA

**Richard J. Davey, MD**

Professor of Pathology and Laboratory Medicine  
Weill Cornell Medical College;  
Director of Transfusion Medicine  
The Methodist Hospital  
Houston, Texas, USA

**Brian C. Dow, BSc, PhD, CSci, FIBMS**

Consultant Clinical Microbiologist;  
Head of National Microbiology Reference Unit  
Scottish National Blood Transfusion Service  
Glasgow, Scotland, UK

**Thomas P. Duffy, MD**

Professor of Medicine  
Department of Internal Medicine and Hematology  
Yale University School of Medicine  
New Haven, Connecticut, USA

**Larry J. Dumont, MBA, PhD**

Director, Cell Labeling Laboratory  
Assistant Professor  
Dartmouth Medical School  
Dartmouth-Hitchcock Medical Center  
Lebanon, New Hampshire, USA

**Walter H. Dzik, MD**

Co-Director, Blood Transfusion Service  
Massachusetts General Hospital;  
Associate Professor of Pathology  
Harvard Medical School  
Boston, Massachusetts, USA

**A. Bradley Eisenbrey, MD, PhD**

Laboratory Director  
Gift of Life Michigan  
Ann Arbor, Michigan;  
Assistant Professor of Pathology  
Wayne State University School of Medicine  
Detroit, Michigan, USA

**Juan I. Esteban-Mur, MD**

Section Head  
Liver Unit, Department of Medicine  
Hospital Universitari Vall d'Hebron  
Universitat Autònoma de Barcelona  
Centro de Investigaciones Biomédicas en Red  
(Ciberehd)  
Instituto de Salud Carlos III  
Barcelona, Spain

**Jean-Claude Faber, MD**

Director (Retired)  
Blood Transfusion Service  
Luxembourg Red Cross  
Luxembourg, Luxembourg

**James L.M. Ferrara, MD**

Professor of Pediatrics and Internal Medicine  
Director, Combined Blood and Marrow  
Transplantation Program  
University of Michigan  
Ann Arbor, Michigan, USA

**Richard L. Gamelli, MD, FACS**

The Robert J. Freeark Professor and Chair  
Department of Surgery

Director, Burn and Shock Trauma Institute  
Chief, Burn Center  
Loyola University Medical Center  
Strich School of Medicine  
Maywood, Illinois, USA

**Ronald O. Gilcher, MD**

Medical Director Emeritus  
Oklahoma Blood Institute  
Oklahoma City, Oklahoma, USA

**Sergio A. Giral, MD, MPH**

Professor, Stem Cell Transplantation and  
Lymphoma/Myeloma  
The University of Texas  
M.D. Anderson Cancer Center  
Houston, Texas, USA

**Albrecht Gröner, PhD**

Head of Virology  
CSL Behring GmbH  
Marburg, Germany

**Morten Grønn, MD**

Head Physician  
Division of Paediatrics  
Rikshospitalet University Hospital  
Oslo, Norway

**Paul Hébert, MD**

Professor of Medicine, Surgery,  
Anesthesiology, and Epidemiology,  
University of Ottawa; Critical Care  
Physician;  
The Ottawa Hospital; Senior Scientist,  
Ottawa Health Research Institute  
Ottawa, Ontario Canada

**Peter Hellstern, MD**

Director and Professor  
Institute of Hemostaseology and  
Transfusion Medicine  
Academic City Hospital  
Ludwigshafen, Germany

**Helen E. Heslop, MD**

Professor of Medicine and Pediatrics and Dan L.  
Duncan Chair  
Center for Cell and Gene Therapy  
Baylor College of Medicine, Texas Children's  
Hospital and The Methodist Hospital  
Houston, Texas, USA

**John R. Hess, MD, MPH**

Professor  
Blood Bank  
University of Maryland Medical Center  
Baltimore, Maryland, USA

**Eldad A. Hod, MD**

Transfusion Medicine Fellow  
Department of Pathology and Cell Biology  
Columbia University Medical Center  
New York, New York, USA

**P. Ann Hoppe, MT(ASCP)SBB**

President  
Hoppe Regulatory Consultants, LLC  
Decatur, Georgia, USA

**Petr Jarolim, MD, PhD**

Director, Clinical Chemistry  
Brigham and Women's Hospital and the Dana  
Farber Cancer Institute;  
Associate Professor of Pathology  
Harvard Medical School  
Boston, Massachusetts, USA

**Jan Jørgensen, MD**

Director (Retired)  
Blood Transfusion Centre  
Aarhus University Hospital  
Aarhus, Denmark

**W. John Judd, FIBMS, MIBiol**

Emeritus Professor of Immunohematology  
Department of Pathology  
University Hospitals  
University of Michigan  
Ann Arbor, Michigan, USA

**Humphrey H.H. Kanhai, MD, PhD**

Professor of Obstetrics and Fetal Medicine  
Department of Obstetrics  
Leiden University Medical Center  
Leiden, The Netherlands

**Sheryl A. Kochman, MT(ASCP)**

Chief, Devices Review Branch  
Division of Blood Applications  
Office of Blood Research and Review  
Center for Biologics Evaluation and Research  
Food and Drug Administration  
Rockville, Maryland, USA

**Mark J. Koury, MD**

Professor of Medicine  
Division of Hematology/Oncology  
Vanderbilt University and VA Tennessee Valley  
Healthcare System  
Nashville, Tennessee, USA

**Diane S. Krause, MD, PhD**

Professor, Laboratory Medicine and Pathology  
Yale University School of Medicine  
New Haven, Connecticut, USA

**Joanne Kurtzberg, MD**

Susan Dees Distinguished Professor of Pediatrics  
Professor of Pathology  
Chief, Pediatric Blood and Marrow  
Transplant Program  
Director, Carolinas Cord Blood Bank  
Co-Director, Stem Cell Laboratory  
Duke University Medical Center  
Durham, North Carolina, USA

## Contributors

### **Thomas Leemhuis, PhD**

Director  
Cellular Therapies Division  
Hoxworth Blood Center  
University of Cincinnati Academic  
Health Center  
Cincinnati, Ohio, USA

### **Kurt A. Leifheit, JD**

Associate  
Hinshaw & Culbertson LLP  
Chicago, Illinois, USA

### **Steven R. Lentz, MD, PhD**

Hamilton Professor of Hematology;  
Director  
Division of Hematology, Oncology, and Blood and  
Marrow Transplantation;  
Professor of Medicine  
Department of Internal Medicine  
Carver College of Medicine  
University of Iowa  
Iowa City, Iowa, USA

### **John E. Levine, MD, MS**

Professor of Pediatrics and Internal Medicine  
Clinical Director, Pediatric Blood and  
Marrow Stem Cell Transplantation Program  
University of Michigan  
Ann Arbor, Michigan, USA

### **W. Conrad Liles, MD, PhD**

Professor and Vice-Chair of Medicine  
Director, Division of Infectious Diseases  
University of Toronto  
Toronto, Ontario, Canada

### **Jeanne V. Linden, MD, MPH**

Director, Blood and Tissue Resources  
Wadsworth Center  
New York State Department of Health;  
Clinical Associate Professor  
Albany Medical College;  
Adjunct Associate Professor  
School of Public Health  
State University of New York at Albany  
Albany, New York, USA

### **Edward M. Mansfield, JD**

Equity Member  
Belin Lamson McCormick Zumbach Flynn PC  
Des Moines, Iowa, USA

### **Peter W. Marks, MD, PhD**

Associate Professor of Medicine  
Section of Hematology  
Yale University School of Medicine  
New Haven, Connecticut, USA

### **Prasad Mathew, MD**

Professor of Pediatrics  
Pediatric Hematology/Oncology

University of New Mexico  
Albuquerque, New Mexico, USA

### **Janice G. McFarland, MD**

Director  
Platelet and Neutrophil Immunology Laboratory  
BloodCenter of Wisconsin  
Milwaukee, Wisconsin, USA

### **Bruce C. McLeod, MD**

Professor of Medicine and Pathology  
Rush Medical College;  
Director, Blood Center  
Rush University Medical Center  
Chicago, Illinois, USA

### **Paul D. Mintz, MD**

Professor of Pathology and Internal Medicine;  
Chief, Division of Clinical Pathology;  
Director, Clinical Laboratories and  
Transfusion Medicine Services;  
University of Virginia Health System  
Charlottesville, Virginia, USA

### **Laura Niklason, MD, PhD**

Associate Professor  
Anesthesiology and Biomedical Engineering  
Yale University School of Medicine  
New Haven, Connecticut, USA

### **Urs E. Nydegger, MD**

Professor Emeritus  
University of Bern;  
Consultant  
Transfusion Therapy Consultancy  
Bern, Switzerland

### **Ellen C. Omi, MD**

Assistant Professor of Surgery  
Division of Critical Care, Trauma and Burn  
Loyola University Medical Center  
Stritch School of Medicine  
Maywood, Illinois, USA

### **Suhag H. Parikh, MD**

Assistant Professor  
Pediatric Stem Cell Transplant Program  
Duke University Medical Center  
Durham, North Carolina, USA

### **Yara A. Park, MD**

Assistant Professor  
Department of Pathology and Laboratory  
Medicine  
University of North Carolina at Chapel Hill  
Chapel Hill, North Carolina, USA

### **Gregory J. Pomper, MD**

Assistant Professor of Pathology

# Preface

More than 6 years have elapsed since the third edition of *Rossi's Principles of Transfusion Medicine* was published. During that time, the field has continued to be dynamic and many advances have been made. Molecular techniques are increasingly utilized; measurements of cell kinetics have been further refined; new treatments for bleeding disorders have been developed; progenitor cell transplantation protocols have matured; hemovigilance efforts have become more organized globally; pathogen inactivation and apheresis techniques have advanced; new treatments have emerged for iron overload; gene therapy and regenerative medicine are having an impact on the field; and regulation has become more complex in a global environment.

As expected, some controversies remain unresolved. For example, the effect of red cell age on clinical outcome and whether transfusion itself affects patient recovery are at the center of recent articles that commanded attention from both professionals and the public. At the same time, pharmacologic agents intended to reduce the need for transfusion have also become subjects of controversy. Whether recombinant human erythropoietin has deleterious effects on patients, the potential for cell-free hemoglobin solutions to cause more harm than good, and the balance between efficacy and toxicity of recombinant Factor VIIa are being discussed at the national level of health-care decision-making.

This edition provides updated comprehensive assessments of the subjects that remain important to the daily work of those who practice transfusion medicine today. The contents include information on controversies that are still percolating, as well as those new developments that have been widely adopted in practice. This volume also features those scientific areas that represent the frontiers of transfusion medicine such as cellular and gene therapy and regenerative medicine.

Section I reviews the preparation and use of components and derivatives of blood used in clinical practice. Section II provides information and approaches to the major clinical issues related to transfusion in medical, obstetric, pediatric, oncology, and surgery patients, including transplant recipients. Section III focuses

attention on both donor and patient apheresis. Section IV introduces the major concerns related to hazards of transfusion and covers the infectious and noninfectious risks in separate chapters. Section V covers the broad issues related to cells and tissue therapy in our field. Section VI contains an overview of the logistic and regulatory aspects of the profession.

The fourth edition is an example of both continuity and change. We have retained the general organizational plan of the prior edition. The comprehensive scope has been retained with emphasis on the scientific and clinical over the technical. Our objective is to create the best single reference for the professional who is managing transfusion issues both at the bedside and at the interface of the laboratory and the clinic. Yet at the same time, the volume is intended to provide a helpful resource for trainees.

New chapters that have either combined material from several chapters in prior editions or ventured into new areas include cell kinetics, obstetric practice, cord blood, transfusion alternatives, regenerative medicine, hemovigilance, iron overload, and transplant organization and regulation. Once again, case studies have been included to enhance the educational aspects, but with this edition they are in an electronic format. In addition to the CD-ROM containing the case studies a second CD-ROM contains the 66 book chapters as searchable pdf files.

Four of the editors from the last edition have returned along with many of the expert chapter authors. This edition also welcomes new chapter contributors with fresh approaches and two new editors—Bjarte G. Solheim, who has led the effort to include more international perspectives, and Marian Petrides, who developed the software for, and managed the transition to, the interactive case study format. Joining the team effort for this edition are publishing staff at AABB Press and Wiley-Blackwell.

In a work of this magnitude, there are many to whom we owe words of appreciation. Clearly, thanks are due to the authors for their superb chapters, AABB Press staff for their expertise and assistance, and personnel at Wiley-Blackwell for their professional and collegial efforts on behalf of the book. Just as

important, the editors thank our families, colleagues, employers, teachers, and students for the support that sustained us throughout the development process.

All of us have chosen to work in this field because of our commitment to improving and saving the lives of those in our communities who can benefit from transfusion therapies. Some have used the analogy of those who work backstage in a theatrical production; the actors take the bows but the play can go on only with the contributions of the unseen workers behind the curtains. When the surgeons, oncologists, pediatricians, obstetricians, intensive care specialists, other physicians, and nurses are successful in treating the patients, those of us in transfusion

medicine and related therapies can take satisfaction in the work we do. Our hope is that this book will help support those who can make a difference in transfusion medicine and serve as an example of the teamwork so urgently needed to move all of health care forward for the benefit of the global community.

## Transfusion in the New Millennium

**Ennio C. Rossi<sup>1</sup> & Toby L. Simon<sup>2</sup>**

<sup>1</sup> Professor Emeritus of Medicine, Northwestern University School of Medicine, Chicago, Illinois, USA

<sup>2</sup> Corporate Medical Director, ZLB Plasma, a CSL Behring Company, Boca Raton, Florida, and Clinical Professor, University of New Mexico School of Medicine, Albuquerque, New Mexico, USA

Prehistoric man left drawings of himself pierced by arrows.<sup>1</sup> This means he was as aware of blood as he was of his own limbs. The flint implements he used as tools and weapons distinguished him from other creatures and contributed to the violence of his era. As he hunted food and fought enemies, he observed bleeding and the properties of blood. A cut, received or inflicted, yielded a vivid red color. If the cut was shallow, there was little blood. But if the cut was deep, a red torrent flowing from the stricken victim quickly led to death, with shed blood congealed and darkening in the sun. Fatal hemorrhage was commonplace. Nonetheless, the sight must have been fearful and possibly existential as life flowed red out of the body of an enemy or a wounded animal.<sup>2</sup> It is no wonder, then, that at the dawn of recorded history, blood was already celebrated in religious rites and rituals as a life-giving force.

The cultural expressions of primitive and ancient societies, though separated by time or space, can be strikingly similar. Whether these expressions emerged independently or were diffused about the world by unknown voyagers will probably always remain clouded in mystery.<sup>2</sup> Nonetheless, there is a common thread in the ancient rituals that celebrate blood as a mystical vital principle. In Leviticus 17:11, “the life of the flesh is in the blood,” and the Chinese Neiching (circa 1000 BC) claims the blood contains the soul.<sup>2</sup> Pre-Columbian North American Indians bled their bodies “of its greatest power” as self-punishment,<sup>3</sup> Egyptians took blood baths as a recuperative measure, and Romans drank the blood of fallen gladiators in an effort to cure epilepsy.<sup>4</sup> The Romans also practiced a ceremony called taurobolium—a blood bath for spiritual restoration. A citizen seeking spiritual rebirth descended into a pit or fossa sanguinis. Above him on a platform, a priest sacrificed a bull, and the animal’s blood cascaded down in a shower upon the beneficiary. Then, in a powerful visual image, the subject emerged up from the other end of the pit, covered with blood and reborn.<sup>1</sup>

The legend of Medea and Aeson taken from Ovid’s *Metamorphoses* and quoted in Bulfinch’s *Mythology*<sup>5</sup> also ascribed rejuvenating powers to blood. Jason asked Medea to “take some years off his life and add them to those of his father Aeson.” Medea, however, pursued an alternative course. She prepared a cauldron with the blood of a sacrificed black sheep. To this, she added magic herbs, hoarfrost gathered by moonlight, the entrails of a wolf, and many other things “without a name.” The boiling cauldron was stirred with a withered olive branch, which became green and full of leaves and young olives when it was withdrawn. Seeing that all was ready,

Medea cut the throat of the old man and let out all his blood, and poured into his mouth and into his wound the juices of her cauldron. As soon as he had imbibed them, his hair and beard laid by their whiteness and assumed the blackness of youth; his paleness and emaciation were gone; his veins were full of blood, his limbs of vigour and robustness. Aeson is amazed at himself and remembers that such as he now is, he was in his youthful days, 40 years before. This legend seems to echo in the apocryphal story of Pope Innocent VIII, who is said to have received the blood of three young boys in 1492 while on his deathbed. As the story goes, a physician attempted to save the pope’s life by using blood drawn from three boys 10 years of age, all of whom died soon thereafter. Some 19th-century versions of this tale suggest the blood was transfused. However, earlier renditions more plausibly suggest that the blood was intended for a potion to be taken by mouth. In any event, there is no evidence the pope actually received any blood in any form.<sup>6,7</sup>

The folklore that flowed with blood was not accompanied by a great deal of accurate information. The ancient Greeks believed that blood formed in the heart and passed through the veins to the rest of the body, where it was consumed. Arteries were part of an independent system transporting air from the lungs. Although Erasistratos (circa 270 BC) had imagined the heart as a pump, his idea was ahead of its time. As long as veins and arteries were dead-end channels transporting blood and air, there was little need for a pump in the system. Although Galen (131-201 AD) finally proved that arteries contain blood, communication with

the venous system was not suspected. Blood, formed in the liver, merely passed through the blood vessels and heart on its way to the periphery.<sup>1</sup> These teachings remained in place for 1400 years until they were swept away in 1628 by Harvey's discovery of the circulation.

The realization that blood moved in a circulating stream opened the way to experiments on vascular infusion. In 1642 George von Wahrendorff injected wine<sup>8</sup>—and in 1656 Christopher Wren and Robert Boyle injected opium and other drugs<sup>9</sup>—intravenously into dogs. The latter studies, performed at Oxford, were the inspiration for Richard Lower's experiments in animal transfusion.

---

## The First Animal Transfusion

Richard Lower (1631-1691) was a student at Oxford when Christopher Wren and Robert Boyle began their experiments on infusion. In due course, Lower joined their scientific group and studied the intravenous injection of opiates, emetics, and other substances into living animals.<sup>10</sup> In time, the transfusion of blood itself became the objective. The announcement of the first successful transfusion, performed by Richard Lower at Oxford in February 1665, was published on November 19, 1666, in the *Philosophical Transactions of the Royal Society Transactions (Transactions)* in a short notation titled, "The Success of the Experiment of Transfusing the Blood of One Animal into Another."<sup>11</sup> The entire notation is as follows<sup>11</sup>:

This experiment, hitherto look'd upon to be of an almost insurmountable difficulty, hath been of late very successfully perform'd not only at Oxford, by the directions of that expert anatomist Dr. Lower, but also in London, by order of the R. Society, at their publick meeting in Gresham Colledge: the Description of the particulars whereof, and the Method of Operation is referred to the next opportunity.

The December 17, 1666 issue of the *Transactions* contained the full description as promised.<sup>12</sup> It was taken from a letter<sup>13</sup> written by Lower to Robert Boyle on July 6, 1666, in which Lower described direct transfusion from the carotid artery of one dog to the jugular vein of another. After describing the insertion of quills into the blood vessels of the donor and recipient dogs, Lower wrote<sup>13</sup>:

When you have done this you may lay the dogs on their side and fasten them densely together as best you may to insure the connection of the two quills. Quickly tighten the noose around the neck of the receiving animal as in venasection, or at all events compress the vein on the opposite side of the neck with your finger, then take out the stopper and open the upper jugular quill so that while the foreign blood is flowing into the lower quill, the animal's own blood flows out from the upper into suitable receptacles—until at last the second animal, amid howls, faintings, and spasms, finally loses its life together with its vital fluid.

When the tragedy is over, take both quills out of the jugular vein of the surviving animal, tie tightly with the former slipknots,

and divide the vein. After the vessel has been divided, sew up the skin, slacken the cords binding the dog, and let it jump down from the table. It shakes itself a little, as though aroused from sleep, and runs away lively and strong, more active and vigorous perhaps, with the blood of its fellow than its own.

These studies inevitably led to the transfusion of animal blood to humans. In England, this occurred on November 23, 1667, when Lower and Edmund King transfused sheep blood into a man named Arthur Coga.<sup>14</sup> Described by Samuel Pepys as "a little frantic," Coga was paid 20 shillings to accept this transfusion, with the expectation that it might have a beneficial "cooling" effect. One week later, Coga appeared before the society and claimed to be a new man, although Pepys concluded he was "cracked a little in the head."<sup>15</sup> However, this was not the first transfusion performed in a human. The credit for that accomplishment belongs to Jean-Baptiste Denis (1635-1704), who had performed the first human transfusion several months earlier in Paris.

---

## The First Animal-to-Human Transfusion

The founding of the Royal Society in London in 1662 was followed in 1666 by the establishment of the Academie des Sciences in Paris under the patronage of King Louis XIV. The new Academie reviewed the English reports on transfusion with great interest. Denis probably read of Lower's experiments in the *Journal des Savants* on January 31, 1667, and he began his own studies approximately 1 month later.<sup>15,16</sup> The first human transfusion was then performed on June 15, 1667, when Denis administered the blood of a lamb to a 15-year-old boy (Fig 1-1).

Although discovery of the circulation had suggested the idea of transfusion, indications for the procedure remained unformed. Transfusion was still thought to alter behavior and possibly achieve rejuvenation. The blood of young dogs made old dogs seem frisky; the blood of lions was proposed as a cure for cowardice; and 5 months later, Arthur Coga would receive a transfusion of sheep blood because of its presumed "cooling" effect. Denis used animal blood for transfusion because he thought it was "less full of impurities"<sup>17</sup>:

Sadness, Envy, Anger, Melancholy, Disquiet and generally all the Passions, are as so many causes which trouble the life of man, and corrupt the whole substance of the blood: Whereas the life of Brutes is much more regular, and less subject to all these miseries.

It is thus ironic that the symptoms of the first transfusion recipient may have been explained in part by profound anemia; the single transfusion of lamb blood may have produced temporary amelioration owing to increased oxygen transport. Denis described the case as follows<sup>17</sup>:

On the 15 of this Moneth, we hapned upon a Youth aged between 15 and 16 years, who had for above two moneths bin tormented with a contumacious and violent fever, which obliged his Physitians to bleed him 20 times, in order to assuage the excessive heat.

Before this disease, he was not observed to be of a lumpish dull spirit, his memory was happy enough, and he seem'd chearful and nimble enough in body; but since the violence of this fever, his wit seem'd wholly sunk, his memory perfectly lost, and his body so heavy and drowsie that he was not fit for anything. I beheld him fall asleep as he sat at dinner, as he was eating his Breakfast, and in all occurrences where men seem most unlikely to sleep. If he went to bed at nine of the clock in the Evening, he needed to be wakened several times before he could be got to rise by nine the next morning, and he pass'd the rest of the day in an incredible stupidity.

I attributed all these changes to the great evacuations of blood, the Physitians had been oblig'd to make for saving his life.

Three ounces of the boy's blood were exchanged for 9 ounces of lamb arterial blood. Several hours later the boy arose, and "for the rest of the day, he spent it with much more liveliness than ordinary." Thus the first human transfusion, which was heterologous, was accomplished without any evident unfavorable effect.

This report stimulated a firestorm of controversy over priority of discovery.<sup>18,19</sup> The letter by Denis was published in the *Transactions* on July 22, 1667, while the editor, Henry Oldenburg, was imprisoned in the Tower of London. Oldenburg, following some critical comments concerning the Anglo-Dutch War then in progress (1665-1667), had been arrested under a warrant issued June 20, 1667. After his release 2 months later, Oldenburg returned to his editorial post and found the letter published in his absence. He took offense at Denis's opening statement, which claimed that the French had conceived of transfusion "about ten years agoe, in the illustrious Society of Virtuosi . . ." (Fig 1-1). This seemed to deny the English contributions to the field. Oldenburg cited these omissions in an issue of the *Transactions* published September 23, 1667, "for the Months of July, August, and September." By numbering this issue 27 and beginning pagination with 489, Oldenburg attempted to suppress the letter by Denis.<sup>18</sup> However, as is evident, this did not ultimately succeed. Nonetheless, subsequent events created even greater difficulties for Denis.

Although the first two subjects who underwent transfusion by Denis were not adversely affected, the third and fourth recipients died. The death of the third subject was easily attributable to other causes. However, the fourth case initiated a sequence of events that put an end to transfusion for 150 years.

Anthony du Mauroy was a 34-year-old man who suffered from intermittent bouts of maniacal behavior. On December 19, 1667, Denis and his assistant Paul Emmerez removed 10 ounces of the man's blood and replaced it with 5 or 6 ounces of blood from the femoral artery of a calf. Failing to note any apparent improvement, they repeated the transfusion 2 days later. After the second transfusion, du Mauroy experienced a classic transfusion reaction<sup>20</sup>:

His pulse rose presently, and soon after we observ'd a plentiful sweat over all his face. His pulse varied extremely at this instant, and he complain'd of great pains in his kidneys and that he was not well in his stomach.

(489) *Numb. 27.*

# A LETTER

*Concerning a new way of curing sundry diseases by Transfusion of Blood, Written to Monsieur de MONTMOR, Counsellor to the French King, and Master of Requests.*

By J: DENIS *Professor of Philosophy, and the Mathematicks.*

Munday July 22. 1667.

SIR,

THE project of causing the Blood of a healthy animal to passe into the veins of one diseased, having been conceived about ten years agoe, in the illustrious Society of Virtuosi which assembles at your house, and your goodness having received M. Emmerez, & my self, very favorably at such times as we have presum'd to entertain you either with discourse concerning it, or the sight of some not inconsiderable effects of it: You will not think it strange that I now take the liberty of troubling you with this Letter, and design to inform you fully of what pursuances and successes we have made in this Operation; wherein you are justly intitled to a greater share than any other, considering that it was first spoken of in your *Academy*, & that the Publick is beholding to you for this as well as for many other discoveries, for the benefits & advantages it shall reap from the same.

But that I may give you the reasons of our procedure & convince

Ccc

Figure 1-1. The first human transfusion.<sup>17</sup>

Du Mauroy fell asleep at about 10 o'clock in the evening. He awoke the following morning and "made a great glass full of urine, of a colour as black, as if it had been mixed with the soot of chimneys."<sup>20</sup> Two months later, the patient again became maniacal, and his wife again sought transfusion therapy. Denis was reluctant but finally gave in to her urgings. However, the transfusion could not be accomplished, and du Mauroy died the next evening.

The physicians of Paris strongly disapproved of the experiments in transfusion. Three of them approached du Mauroy's widow and encouraged her to lodge a malpractice complaint against Denis. She instead went to Denis and attempted to extort money from him in return for her silence. Denis refused and filed a complaint before the Lieutenant in Criminal Causes. During the subsequent hearing, evidence was introduced to indicate that Madame du Mauroy had poisoned her husband with arsenic. In a judgment handed down at the Chatelet in Paris on April 17, 1668, Denis was exonerated, and the woman was held for trial. The court also stipulated "that for the future no Transfusion should

be made upon any Human Body but by the approbation of the Physicians of the Parisian Faculty.”<sup>21</sup> At this point, transfusion research went into decline, and within 10 years it was prohibited in both France and England.

## The Beginnings of Modern Transfusion

After the edict that ended transfusion in the 17th century, the technique lay dormant for 150 years. Stimulated by earlier experiments by Leacock, transfusion was “resuscitated” and placed on a rational basis by James Blundell (1790-1877), a London obstetrician who had received his medical degree from the University of Edinburgh.<sup>22</sup> Soon after graduation, Blundell accepted a post in physiology and midwifery at Guy’s Hospital. It was there that he began the experiments on transfusion that led to its rebirth. The frequency of postpartum hemorrhage and death troubled Blundell. In 1818 he wrote<sup>23</sup>:

A few months ago I was requested to visit a woman who was sinking under uterine hemorrhage . . . Her fate was decided, and notwithstanding every exertion of the medical attendants, she died in the course of two hours.

Reflecting afterwards on this melancholy scene . . . , I could not forbear considering, that the patient might very probably have been saved by transfusion; and that . . . the vessels might have been replenished by means of the syringe with facility and promptitude. This opening statement introduced Blundell’s epoch-making study titled “Experiments on the Transfusion of Blood by the Syringe.”<sup>23</sup> (See Fig 1-2.) Blundell described in detail a series of animal experiments. He demonstrated that a syringe could be

used effectively to perform transfusion, that the lethal effects of arterial exsanguination could be reversed by the transfusion of either venous or arterial blood, and that the injection of 5 drams (20 cc) of air into the veins of a small dog was not fatal but transfusion across species ultimately was lethal to the recipient.<sup>23</sup> Thus Blundell was the first to state clearly that only human blood should be used for human transfusion. The latter conclusion was confirmed in France by Dumas and Prevost, who demonstrated that the infusion of heterologous blood into an exsanguinated animal produced only temporary improvement and was followed by death within 6 days.<sup>24</sup> These scientific studies provided the basis for Blundell’s subsequent efforts in clinical transfusion.

The first well-documented transfusion with human blood took place on September 26, 1818.<sup>25</sup> The patient was an extremely emaciated man in his mid-thirties who had pyloric obstruction caused by carcinoma. He received 12 to 14 ounces of blood in the course of 30 or 40 minutes. Despite initial apparent improvement, the patient died 2 days later. Transfusion in the treatment of women with postpartum hemorrhage was more successful. In all, Blundell performed 10 transfusions, of which five were successful. Three of the unsuccessful transfusions were performed on moribund patients; the fourth was performed on a patient with puerperal sepsis; and the fifth was performed on the aforementioned patient with terminal carcinoma. Four of the successful transfusions were given for postpartum hemorrhage, and the fifth was administered to a boy who bled after amputation.<sup>22</sup> Blundell also devised various instruments for the performance of transfusion. They included an “impellor,” which collected blood in a warmed cup and “impelled” the blood into the recipient via an attached syringe, and a “gravitator”<sup>26</sup> (Fig 1-3), which received blood and delivered it by gravity through a long vertical cannula.

The writings of Blundell provided evidence against the use of animal blood in humans and established rational indications for transfusion. However, the gravitator (Fig 1-3) graphically demonstrated the technical problems that remained to be solved. Blood from the donor, typically the patient’s husband, flowed into a funnel-like device and down a flexible cannula into the patient’s vein “with as little exposure as possible to air, cold and inanimate surface.”<sup>25</sup> The amount of blood transfused was estimated from the amount spilled into the apparatus by the donor. In this clinical atmosphere, charged with apprehension and anxiety, the amount of blood issuing from a donor easily could be overstated. Clotting within the apparatus then ensured that only a portion of that blood actually reached the patient. Thus the amount of blood actually transfused may have been seriously overestimated. This may explain the apparent absence of transfusion reactions. Alternatively, reactions may have been unrecognized. Patients who underwent transfusion frequently were agonal. As Blundell<sup>26</sup> stated, “It seems right, as the operation now stands, to confine transfusion to the first class of cases only, namely, those in which there seems to be no hope for the patient, unless blood can be thrown into the veins.” Under these circumstances, “symptoms” associated with an “unsuccessful” transfusion might be ascribed to the agonal state rather than the

Figure 1-2. The beginnings of modern transfusion.<sup>23</sup>

transfusion itself. For a time, the problem of coagulation during transfusion was circumvented by the use of defibrinated blood. This undoubtedly increased the amount of blood actually transfused. However, there were numerous deaths. Interestingly, these deaths were attributed to intravascular coagulation when in actuality they were probably fatal hemolytic reactions caused by the infusion of incompatible blood.<sup>27</sup>

Transfusion at the end of the 19th century, therefore, was neither safe nor efficient. The following description, written in 1884, illustrates this point<sup>28</sup>:

Students, with smiling faces, are rapidly leaving the theatre of one of our metropolitan hospitals. The most brilliant operator of the day has just performed immediate transfusion with the greatest success. By means of a very beautiful instrument, the most complex and ingenious that modern science has yet produced, a skilful surgeon has transfused half a pint, or perhaps a pint, of blood from a healthy individual to a fellow creature profoundly collapsed from the effects of severe hemorrhage. Some little difficulty was experienced prior to the operation, as one of the many stop-cocks of the

transfusion apparatus was found to work stiffly; but this error was quickly rectified by a mechanic in attendance. Towards the close of the operation the blood-donor, a powerful and heavy young man, swooned. Two porters carried him on a stretcher into an adjoining room.

In the latter half of the 19th century, there were many attempts to render transfusion a more predictable and less arduous procedure. In 1869, Braxton-Hicks,<sup>29</sup> using blood anticoagulated with phosphate solutions, performed a number of transfusions on women with obstetric bleeding. Many of the patients were in extremis, and ultimately all died. Unfortunately, a detailed description of terminal symptoms was not provided.<sup>29</sup> Some investigators attempted to rejuvenate animal-to-human transfusion, and Oscar Hasse persisted in this approach despite disastrous results. Studies by Emil Ponfick and by Leonard Landois finally put an end to this practice. Ponfick, in carefully controlled studies, confirmed the lethality of heterologous transfusion and identified the resulting hemoglobinuria along with its donor erythrocyte source. Landois documented the poor results of animal-to-human transfusion and demonstrated the lysis of sheep erythrocytes by human serum in vitro.<sup>8</sup>

Frustration with blood as a transfusion product led to even more bizarre innovations. From 1873 to 1880, cow, goat, and even human milk was transfused as a blood substitute.<sup>30</sup> The rationale derived from an earlier suggestion that the fat particles of milk could be converted into blood cells. Milk transfusion was particularly popular in the United States,<sup>30</sup> where the practice of animal-to-human transfusion was recorded as late as 1890.<sup>31</sup> Fortunately, these astonishing practices were discontinued when saline solutions were introduced as "a life-saving measure" and "a substitute for the transfusion of blood."<sup>32</sup> A passage from an article written by Bull in 1884<sup>32</sup> is particularly instructive:

The danger from loss of blood, even to two-thirds of its whole volume, lies in the disturbed relationship between the calibre of the vessels and the quantity of the blood contained therein, and not in the diminished number of red blood-corpuscles; and ... This danger concerns the volume of the injected fluids also, it being a matter of indifference whether they be albuminous or containing blood corpuscles or not ...

Mercifully, volume replacement with saline solutions deflected attention from the unpredictable and still dangerous practice of blood transfusion. Accordingly, transfusions were abandoned until interest was rekindled by the scientific and technical advances of the early 20th century.

## The 20th Century

The 20th century was ushered in by a truly monumental discovery. In 1900, Karl Landsteiner (1868-1943) observed that the sera of some persons agglutinated the red blood cells of others. This study, published in 1901 in the *Wiener Klinische Wochenschrift*<sup>33</sup> (Fig 1-4), showed for the first time the cellular differences in

Vol. II.] LONDON, SATURDAY, JUNE 13. [1828-9.

### OBSERVATIONS ON TRANSFUSION OF BLOOD.

By DR. BLUNDELL.

*With a Description of his Gravitator.\**

STATES of the body really requiring the infusion of blood into the veins are probably rare; yet we sometimes meet with cases in which the patient must die unless such operation can be performed; and still more frequently with cases which seem to require a supply of blood, in order to prevent the ill health which usually arises from large losses of the vital fluid, even when they do not prove fatal.

\* The instrument is manufactured by Messrs. Maw, 35, Aldermanbury.

In the present state of our knowledge respecting the operation, although it has not been clearly shown to have proved fatal in any one instance, yet not to mention possible, though unknown risks, inflammation of the arm has certainly been produced by it on one or two occasions; and therefore it seems right, as the operation now stands, to confine transfusion to the first class of cases only, namely, those in which there seems to be no hope for the patient, unless blood can be thrown into the veins.

The object of the Gravitator is, to give help in this last extremity, by transmitting the blood in a regulated stream from one individual to another, with as little exposure as may be to air, cold, and inanimate surface; ordinary venesection being the only operation performed on the person who emits the blood; and the insertion of a small tube into the vein usually laid open in bleeding, being all the operation which it is necessary to execute on the person who receives it.

The following plate represents the whole apparatus connected for use and in action:—

Tab. 1.

Von Dr. Karl Landsteiner, Assistenten am pathologisch-anatomischen  
Institute.

**Figure 1-4.** Landsteiner's description of blood groups.<sup>33</sup>

individuals from the same species. In his article, Landsteiner wrote<sup>34</sup>:

In a number of cases (Group A) the serum reacts on the corpuscles of another group (B), but not, however, on those of group A, while, again, the corpuscles of A will be influenced likewise by serum B. The serum of the third group (C) agglutinates the corpuscles of A and B, while the corpuscles of C will not be influenced by the sera of A and B. The corpuscles are naturally apparently insensitive to the agglutinins which exist in the same serum.

With the identification of blood groups A, B, and C (subsequently renamed group O) by Landsteiner and of group AB by Decastello and Sturli,<sup>35</sup> the stage was set for the performance of safe transfusion. For this work, Landsteiner somewhat belatedly received the Nobel Prize in 1930. But even that high recognition does not adequately express the true magnitude of Landsteiner's discovery. His work was like a burst of light in a darkened room. He gave us our first glimpse of immunohematology and transplantation biology and provided the tools for important discoveries in genetics, anthropology, and forensic medicine. Viewed from this perspective, the identification of human blood groups is one of only a few scientific discoveries of the 20th century that changed all of our lives.<sup>34</sup> Yet the translation of Landsteiner's discovery into transfusion practice took many years.

At the turn of the century, the effective transfer of blood from one person to another remained a formidable task. Clotting, still uncontrolled, quickly occluded transfusion devices and frustrated most efforts. In 1901 the methods used in transfusion were too primitive to demonstrate the importance of Landsteiner's discovery. Indeed, the study of in-vitro red cell agglutination may have seemed rather remote from the technical problems that demanded attention. An intermediate step was needed before the importance of Landsteiner's breakthrough could be perceived and the appropriate changes could be incorporated into practice. This process was initiated by Alexis Carrel (1873-1944), another Nobel laureate, who developed a surgical procedure that allowed direct transfusion through an arteriovenous anastomosis.

Carrel<sup>36</sup> introduced the technique of end-to-end vascular anastomosis with triple-threaded suture material. This procedure brought the ends of vessels in close apposition and preserved luminal continuity, thus avoiding leakage or thrombosis. This technique paved the way for successful organ transplantation and brought Carrel the Nobel Prize in 1912. It was also adapted by Carrel<sup>37</sup> and others<sup>38,39</sup> to the performance of transfusion. Crile<sup>38</sup> introduced the use of a metal tube to facilitate placement of sutures, and Bernheim<sup>39</sup> used a two-piece cannula to unite the artery to the vein (Fig 1-5). Because all of these procedures usually culminated in the

sacrifice of the two vessels, they were not performed frequently. Direct transfusion was also fraught with danger. In a passage written two decades later, the procedure was recalled in the following manner<sup>40</sup>:

The direct artery to vein anastomosis was the best method available but was often very difficult or even unsuccessful. And, what was almost as bad, one never knew how much blood one had transfused at any moment or when to stop (unless the donor collapsed). (I remember one such collapse in which the donor almost died—and the surgeon needed to be revived.)

Despite these many difficulties, direct transfusion through an arteriovenous anastomosis for the first time efficiently transferred blood from one person to another. The process also disclosed fatal hemolytic reactions that were undeniably caused by transfusion<sup>41</sup> (Fig 1-6). However, the relation of these fatal reactions to Landsteiner's discovery was not recognized until Reuben Ottenberg (1882-1959) demonstrated the importance of compatibility testing.

Ottenberg's interest in transfusion began in 1906 while he was an intern at German (now Lenox Hill) Hospital in New York. There Ottenberg learned of Landsteiner's discovery and in 1907 began pretransfusion compatibility testing.<sup>42</sup> Ottenberg accepted an appointment at Mount Sinai Hospital the next year and continued

Accidents following transfusion have been sufficiently frequent to make many medical men hesitate to advise transfusion, except in desperate cases. It has been our opinion since we began making observations on this question in 1908 that such accidents could be prevented by careful preliminary tests, leading to the exclusion of agglutinative or hemolytic donors. Our observations on over 125 cases have confirmed this view and we believe that untoward symptoms can be prevented with absolute certainty.

**Figure 1-7.** Report of the importance of testing before transfusion.<sup>43</sup>

his studies on transfusion. In 1913, Ottenberg published the report that conclusively demonstrated the importance of preliminary blood testing for the prevention of transfusion “accidents”<sup>43</sup> (Fig 1-7). This was not Ottenberg’s only contribution. He observed the mendelian inheritance of blood groups,<sup>44</sup> and he was the first to recognize the relative unimportance of donor antibodies and consequently the “universal” utility of type O blood donors.<sup>45</sup>

Further advances in immunohematology were to occur in succeeding decades. The M, N, and P systems were described in the period between 1927 and 1947.<sup>46</sup> The Rh system was discovered in connection with an unusual transfusion reaction. In 1939, Levine and Stetson<sup>47</sup> described an immediate reaction in a group O woman who had received her husband’s group O blood soon after delivery of a stillborn fetus with erythroblastosis. This sequence of events suggested that the infant had inherited a red cell agglutinin from the father that was foreign to the mother. At about the same time, Landsteiner and Wiener<sup>48</sup> harvested a rhesus monkey red cell antibody from immunized guinea pigs and rabbits. This antibody agglutinated 85% of human red cell samples (Rh-positive) and left 15% (Rh-negative) unaffected. When the experimentally induced antibody was tested in parallel with the serum from Levine’s patient, a similar positive and negative distribution was observed, and the Rh system had been discovered. Other red cell antigen systems were subsequently described, but when Rh Immune Globulin was introduced as a preventive measure for hemolytic disease of the newborn, it became one of the major public health advances of the century.

Despite the introduction of compatibility testing by Ottenberg, transfusion could not be performed frequently as long as arteriovenous anastomosis remained the procedure of choice. Using this method, Ottenberg needed 5 years (Fig 1-7) to accumulate the 128 transfusions he reported in his study on pretransfusion testing.<sup>43</sup> New techniques, such as Unger’s two-syringe method introduced in 1915<sup>49</sup> (Fig 1-8), eventually put an end to transfusion by means of arteriovenous anastomosis. However, transfusions did not become commonplace until anticoagulants were developed and direct methods of transfusion were rendered obsolete.

**Figure 1-8.** Apparatus for Unger’s two-syringe, four-way stopcock method of indirect transfusion.<sup>49</sup>

## Anticoagulants, the Blood Bank, and Component Therapy

The anticoagulant action of sodium citrate completely transformed the practice of transfusion. Early reports from Belgium<sup>50</sup> and Argentina<sup>51</sup> were followed by the work of Lewisohn<sup>52</sup> that established the optimal citrate concentration for anticoagulation. The work of Weil<sup>53</sup> then demonstrated the feasibility of refrigerated storage. Subsequently, Rous and Turner<sup>54</sup> developed the anticoagulant solution that was used during World War I.<sup>55</sup> Despite its very large volume, this solution remained the anticoagulant of choice until World War II, when Loutit and Mollison<sup>56</sup> developed an acid-citrate-dextrose (ACD) solution. Used in a ratio of 70 mL ACD to 450 mL blood, ACD provided 3 to 4 weeks of preservation of a more concentrated red cell infusion. Thus, the two world wars were the stimuli for the development of citrate anticoagulants and the introduction of indirect transfusion.<sup>46</sup> For the first time, the donation process could be separated, in time and place, from the actual transfusion. Blood drawn and set aside now awaited the emergence of systems of storage and distribution. Again, it was the provision of medical support during armed conflict that stimulated these developments.

A blood transfusion service, organized by the Republican Army during the Spanish Civil War (1936-1939), collected 9000 L of blood in citrate-dextrose anticoagulant for the treatment of battle casualties.<sup>57</sup> At about that same time, Fantus<sup>58</sup> began operation of the first hospital blood bank at Cook County Hospital in Chicago. His interest had been stimulated by Yudin’s report<sup>59</sup> on the use of cadaveric blood in Russia. Apart from certain scruples attached to the use of cadaveric blood, Fantus reasoned that a transfusion service based on such a limited source of supply would be impractical. Accordingly, he established the principle of a “blood bank” from which blood could be withdrawn, provided it had previously been deposited. As Fantus<sup>58</sup> himself stated, “just as one cannot draw money from a bank unless one has deposited some, so the blood preservation department cannot supply blood unless as much comes in as goes out. The term ‘blood bank’ is not a mere metaphor.” The development of anticoagulants and the concept of blood banks provided an infrastructure upon which a more elaborate blood services organization could be built. World War II was the catalyst for these further developments.

At the beginning of World War II, blood procurement programs were greatly expanded.<sup>46</sup> In Great Britain an efficient system had been developed through the organization of regional centers. When the war started, these centers, already in place, were able to increase their level of operation. In the United States the use of plasma in the management of shock had led to the development of plasma collection facilities.<sup>60</sup> The efficient long-term storage of plasma had been further facilitated by the process of lyophilization developed by Flosdorf and Mudd and the introduction of ABO-independent “universal” plasma produced by pooling of several thousand units of plasma.<sup>61</sup> In 1940, the United States organized a program for the collection of blood and the shipment of plasma to Europe. The American Red Cross, through its local chapters, participated in the project, which collected 13 million units by the end of the war.<sup>46</sup>

The national program of the American Red Cross ceased at the end of the war. However, many of the local chapters continued to help recruit donors for local blood banks, and in 1948, the first regional Red Cross blood center was begun in Rochester, New York. By 1949-1950 in the United States, the blood procurement system included 1500 hospital blood banks, 1100 of which performed all blood bank functions. There were 46 nonhospital blood banks and 31 Red Cross regional blood centers. By 1962, these numbers had grown to 4400 hospital blood banks, 123 nonhospital blood banks, and 55 American Red Cross regional blood centers, and the number of units collected had grown to between 5 and 6 million per year.<sup>62</sup>

During this time, blood was collected through steel needles and rubber tubing into rubber-stoppered bottles. After washing and resterilization, the materials were reused. On occasion, “vacuum bottles” were used to speed up the collection. However, the high incidence of pyrogenic reactions soon led to the development of disposable plastic blood collection equipment.

In a classic article written in 1952, Walter and Murphy<sup>63</sup> described a closed, gravity technique for whole blood preservation. They used a laminar flow phlebotomy needle, an interval donor tube, and a collapsible bag of polyvinyl resin designed so that the unit could be assembled and ready for use after sterilization with steam. The polyvinyl resin was chemically inert to biologic fluids and nonirritating to tissue. Soon thereafter, Gibson et al<sup>64</sup> demonstrated that plastic systems were more flexible and allowed removal of plasma after sedimentation or centrifugation. In time, glass was replaced with plastic, and component therapy began to emerge. This development was enhanced by the US military’s need to reduce the weight and breakage of blood bottles during shipment in the Korean War.

Component and derivative therapy began during World War II when Edwin J. Cohn and his collaborators developed the cold ethanol method of plasma fractionation.<sup>65</sup> As a result of their work, albumin, globulin, and fibrinogen became available for clinical use. As plastic equipment replaced glass, component separation became a more widespread practice, and the introduction of automated cell separators provided even greater capabilities in this area.

Clotting factor concentrates for the treatment of patients with hemophilia and other hemorrhagic disorders also were developed during the postwar era. Although antihemophilic globulin had been described in 1937,<sup>66</sup> unconcentrated plasma was the only therapeutic material until Pool discovered that Factor VIII could be harvested in the cryoprecipitable fraction of blood.<sup>67</sup> This resulted in the development of cryoprecipitate, which was introduced in 1965 for the management of hemophilia. Pool showed that cryoprecipitate could be made in a closed-bag system and urged its harvest from as many donations as possible. The development of cryoprecipitate and other concentrates was the dawn of a golden age in the care of patients with hemophilia. Self-infusion programs, made possible by technologic advances in plasma fractionation, allowed early therapy and greatly reduced disability and unemployment. This golden age came abruptly to an end with the appearance of the AIDS virus.

---

## Transfusion in the Age of Technology

In contrast to the long ledger of lives lost in previous centuries because of the lack of blood, transfusion in the 20th century saved countless lives. In 1937, during those early halcyon days of transfusion, Ottenberg wrote<sup>40</sup>:

Today transfusion has become so safe and so easy to do that it is seldom omitted in any case in which it may be of benefit. Indeed the chief problem it presents is the finding of the large sums of money needed for the professional donors who now provide most of the blood.

It is ironic that Ottenberg’s statement should refer to paid donors and foreshadow difficulties yet to come. However, experience to that point had not revealed the problem of viral disease transmission. More transfusions would have to be administered before that problem would be perceived.

After the introduction of anticoagulants, blood transfusions were given in progressively increasing numbers. At Mount Sinai Hospital in New York, the number of blood transfusions administered between 1923 and 1953 increased 20-fold<sup>68,69</sup> (Table 1-1). This increase was particularly notable after the establishment of blood banks. It was during this period that Beeson wrote his classic description of transfusion-transmitted hepatitis<sup>70</sup> (Fig 1-9). He had been alerted to the problem by the outbreaks of jaundice that followed inoculation programs with human serum during World War II. Thus blood transfusion entered a new era. Blood components not only saved lives but also transmitted disease. The discovery of the Australian antigen<sup>71</sup> and the subsequent definition of hepatitis A virus and B virus (HBV) still left residual non-A and non-B disease,<sup>72</sup> a gap that has been largely filled by the discovery of the hepatitis C virus (HCV).<sup>73</sup> However, it was the outbreak of AIDS that galvanized public attention to blood transfusion.

The AIDS epidemic was first recognized in the United States, and the first case of AIDS associated with transfusion was observed in a 20-month-old infant.<sup>74</sup> Subsequently the suspicion that AIDS

## JAUNDICE OCCURRING ONE TO FOUR MONTHS AFTER TRANSFUSION OF BLOOD OR PLASMA

### REPORT OF SEVEN CASES

PAUL B. BEESON, M.D.

ATLANTA, GA.

The purpose of this communication is to report 7 cases of jaundice which occurred one to four months after transfusions of whole blood or plasma and to suggest that these illnesses were probably caused by the transfusions.

**Figure 1-9.** The first description of posttransfusion hepatitis. Used with permission from Beeson (JAMA).<sup>70</sup> Copyright 1943, American Medical Association.

could be transmitted by means of transfusion was confirmed.<sup>75</sup> The human immunodeficiency virus (HIV) was identified,<sup>76</sup> and an effective test to detect the HIV antibody was developed.<sup>76</sup>

## Concern for Blood Safety

Since 1943, transfusion therapy has been shadowed by the specter of disease transmission. In that year, Beeson described posttransfusion hepatitis and unveiled a problem that has grown with time. As transfusion increased, so did disease transmission. In 1962, the connection between paid donations and posttransfusion hepatitis was made.<sup>77</sup> A decade later, the National Blood Policy mandated a voluntary donation system in the United States. And yet, blood usage continued to increase.

Concern about posttransfusion hepatitis was not sufficient to decrease the number of transfusions. Although the use of whole blood declined as blood components became more popular, total blood use in the United States doubled between 1971 and 1980 (Table 1-2).<sup>78-84</sup> This pattern changed as the emergence of AIDS exposed all segments of society to a revealing light.

AIDS probably arose in Africa in the 1960s and spread quietly for years before it was detected. By 1980 an estimated 100,000 persons were infected, and by 1981, when the first cases were

reported, a worldwide pandemic lay just beneath the surface.<sup>85</sup> The initial response of the public and officials seemed trifling and insufficient as the outbreak grew to proportions few had foreseen. Criticism was levied against the news media for initially ignoring the story, the government for delay in acknowledging the problem, gay civil rights groups for resistance to epidemiologic measures, research scientists for unseemly competition, blood services for delayed response in a time of crisis, and the US Food and Drug Administration (FDA) for inadequate regulatory activity. Historians with the perspective of time will determine whether there really were more villains than the virus itself.<sup>86</sup>

Improved donor screening and increased donation testing have greatly decreased the risk of disease transmission and rendered the blood supply safer than it has ever been.<sup>86</sup> Nonetheless, the realization that transfusion can transmit an almost invariably fatal disease had a chilling effect on the public. Two major changes in blood services have occurred in the aftermath of the AIDS epidemic. The FDA, using pharmaceutical manufacturing criteria not "tailored to . . . blood banks," has become more aggressive in regulatory actions against blood collection establishments.<sup>87</sup> And, finally, blood use moderated for approximately 10 years. Through the 1980s and early 1990s, red cell and plasma transfusion peaked and began to stabilize (Table 1-2). Only platelet use and human progenitor cell transplantation, driven by the demands of cancer chemotherapy, continued to increase.<sup>79-81</sup> Educational programs to encourage judicious use of blood have been initiated, and they have been favorably received by practicing physicians.

Relentless public pressure for a "zero risk" blood supply resulted in dividends through continued scientific and technologic improvements. Enhanced sensitivity and better use of serologic testing, along with improved scrutiny of donors, resulted in major reductions in risk of transmitted disease by the mid-1990s.<sup>88</sup> Discovery that pools of units subjected to nucleic acid testing almost closed

the window for HIV and HCV virus resulted in application of this testing for both whole blood and plasma donations beginning between 1998 and 2000.<sup>89</sup> This, combined with virus reduction and inactivation of the final product, resulted in plasma derivatives that have not transmitted AIDS or hepatitis since 1994.<sup>90</sup> For whole blood and platelet components, risks have become low. A solvent/detergent-treated fresh frozen plasma component is used in Europe but not in the United States.

With the reduction in the risk of viral transmission, the focus in the developed world has shifted to transfusion-related acute lung injury—possibly from recipient-directed leukocyte antibodies and lipid mediators in transfused plasma—and bacterial infection primarily occurring in room-temperature stored platelets. So that incremental gains can be made against these risks, the use of male plasma only and the culture of platelets before they are released are being discussed and considered in some areas and implemented in others. Geographic exclusions have been aimed at reducing the potential for variant Creutzfeldt-Jakob disease (vCJD) transmission by transfusion, although in the United States such occurrence seems highly unlikely. In many countries, universal leukocyte reduction has been a response to the vCJD risk. Ironically universal application of leukocyte reduction is probably ineffective for vCJD but has stimulated a controversy in the United States over its use for preventing other problems.<sup>91</sup>

Finally, focus on the understanding, management, and prevention of medical errors in general might lead to progress against remaining nemesis hemolytic transfusion reactions caused by mistransfusion. Bar code technology at the bedside, commonly applied to prevent errors in medication administration, has shown efficacy in reducing transfusion errors.<sup>92</sup> Radio-frequency identification shows further promise in error-prone situations such as operating rooms.<sup>93</sup> Transfusion safety officers and hemovigilance systems are other initiatives being considered or instituted.

“Zero risk” has still not been achieved. Emerging global infections such as West Nile virus, Chagas’ disease, and Chikungunya virus remain future potential threats and have encouraged further test development. Nevertheless, increased public and physician confidence in the safety of the blood supply (Table 1-3) combined with both increased aggressiveness of therapies and aging of the population resulted in increased blood use by 1999. For 2001 through 2006, total red cell transfusions in the United States increased by 5.4% and total platelet and plasma transfusions rose by 2% each. A significant decrease was seen in autologous transfusions (47.4%).<sup>84</sup>

Current Megatrends

In the developed world, no cost has been spared in meeting public demands for blood safety. Service fees charged to hospitals by independent blood centers in the United States (Fig 1-10) illustrate the effect each new safety development has had on the cost of Red Blood Cells (RBCs). As the new millennium began, the

Table 1-3. Risk Estimates per Unit of Red Blood Cells Transfused in the United States, Ranked by Frequency

| Type of Risk                       | Estimated Occurrence    |
|------------------------------------|-------------------------|
| Urticaria                          | 1 in 50-100             |
| Red cell allommunization           | 1 in 100                |
| Febrile reaction                   | 1 in 300                |
| TRALI                              | 1 in 5000               |
| Hemolytic reaction                 | 1 in 6000               |
| Transfusion to the wrong recipient | 1 in 14,000-19,000      |
| Anaphylaxis                        | 1 in 20,000-50,000      |
| Hepatitis B virus                  | 1 in 100,000-200,000    |
| HTLV-I/II                          | 1 in 641,000            |
| Hepatitis C virus                  | 1 in 1-2 million        |
| HIV                                | 1 in 2-3 million        |
| Malaria                            | 1 in 4 million          |
| Bacterial contamination            | 1 in 5 million          |
| GVHD                               | Very rare, no estimates |

TRALI = transfusion-related acute lung injury; HTLV-I/II = human T-cell lymphotropic virus, types I and II; HIV = human immunodeficiency virus; GVHD=graft-vs–host disease Adapted from Klein et al.<sup>94</sup>

mean payment for RBC units was \$100, and a leukocyte-reduced unit was \$126. By 2005 those had risen to \$157 and \$188 respectively, with significant annual increases.<sup>95</sup>

One group of researchers (committed to programs to reduce blood use) has published data suggesting that the societal cost of a unit of RBCs is \$1400 per unit taking into account not only the blood center fee but also hospital-related costs, costs of treating adverse reactions, litigation, lost productivity of donors, and hemovigilance.<sup>96</sup> Although the figure might be overinflated, such work does highlight the ever increasing cost of this form of therapy to the patient and society.

In the underdeveloped world, the picture is quite different. The greatest blood need is for women hemorrhaging during childbirth, infants and children with anemia caused by malaria, and victims of trauma. In 80 of 172 countries responding to a World Health Organization (WHO) survey, fewer than 1% of the population donate blood. In sub-Saharan Africa, fewer than 3 million units of blood are collected annually for a population of more than 700 million. Of the 148 countries reporting data to WHO, 41 are unable to screen for minimum safety (HIV, HBV, HVC, and syphilis). WHO estimates that unsafe blood in these countries results in 16 million new infections with HBV, 5 million with HCV, and 160,000 with HIV each year (accounting for 5%-10% of the world’s HIV infections). Fortunately there is progress in some nations in achieving an all-volunteer supply and minimum screening. Thus, there are two drastically different pictures of blood safety and availability worldwide.<sup>97</sup>

Even in the developed world, availability remains a challenge. In the United States, the number in the population eligible to donate blood with all the new restrictions is 111 million, rather than the 177 million previously thought.<sup>98</sup> Finding ways to motivate sufficient numbers of people to donate remains

**Figure 1-10.** Red Blood Cell service fees charged by community blood centers from 1985 to 2007, correlated with safety measures. Courtesy of America's Blood Centers (modified). RBCs = Red Blood Cells; LR = RBCs Leukocytes Reduced; HIV = human immunodeficiency virus (-1/2 = types 1 and 2); Ab = antibody; HBc = hepatitis B core (antigen); ALT = alanine aminotransferase; HTLV-I = human T-cell lymphotropic virus, type I; HCV = hepatitis C virus; FDA cGMP = Food and Drug Administration current good manufacturing practice; NAT = nucleic acid testing; IND = investigational new drug; WNV = West Nile virus.

difficult. One suggestion has been to “personalize” the benefits. An example of this approach is having donors meet face-to-face with groups of recipients. Another response has been the use of cognitive interview evaluation and focus groups to define a more user-friendly questionnaire with computer-assisted techniques in many centers.<sup>99</sup> More aggressive marketing to growing minority populations as well as continued use of various incentives seem to have increased donations in some locations. A clear need is for more group O red cells; populations of non-European ethnicity generally have an increased proportion of group O.<sup>100</sup>

Another approach to maintain adequate availability is to control usage by ensuring that blood is used appropriately. Some US blood centers have been successful in bringing their transfusion medicine expertise into the patient-care setting by providing transfusion services to hospitals. The model in Seattle, WA, has operated for decades.<sup>101,102</sup> In the United Kingdom, liaison systems for blood centers to hospitals employing Web-based technology for supply chain management have been introduced.<sup>103,104</sup> In Denmark, success has been reported using the Thromboelastograph (Haemoscope, Niles, IL) hemostatic system to manage coagulopathy in conjunction with treating physicians—something also done in many US hospitals.<sup>105</sup> Other point-of-care tests to assess the state of the coagulation system and tissue oxygenation could also result in more accurately targeted component transfusion. Transfusion medicine specialists in hospitals—whether from pathology groups, blood center staff, or other areas such as anesthesiology or hematology—are critical to the successful use of blood transfusion in patient care.

Although some advances in transfusion medicine at the end of the last millennium have been difficult to implement, such as use of hemoglobin solutions and some pathogen inactivation technologies, the field has continued to advance into new areas of stem cell biology, regenerative medicine, and cord blood banking. In addition, transfusion medicine specialists increasingly function in collaboration with surgeons, oncologists, and hematologists in treating the acutely ill patient with complex medical problems. With all the added sophistication, the optimal hemoglobin and platelet triggers and endpoints for transfusion remain unsettled. Clinicians are less likely to use oxygenation transport endpoints to determine the need for red cell transfusion but are beginning to look for other means to assess tissue oxygenation. If a patient’s hemoglobin is too high (even when below normal), complications such as thromboembolism can result. Too low an endpoint exposes some patients to the risk of tissue hypoxia. The clearest trend has been away from autologous transfusion, although some medical centers seek bloodless medicine and surgery combining pharmacotherapy (mainly erythropoietin and iron), blood recovery and reinfusion, and conservative triggers and endpoints.<sup>94</sup> More conservative triggers and endpoints for platelet transfusion are becoming accepted, but approaches to alloimmunized patients and bacterial contamination are still in question.<sup>106</sup> Also debatable is whether transfusion, through some poorly quantifiable mechanism such as immunomodulation, confers a poorer prognosis on acutely ill patients.

From ancient times into the new millennium, blood has been a substance that fascinates mankind. Despite unresolved

controversies, blood transfusion remains of critical importance in the care of sick patients throughout the world.

# I Blood Components and Derivatives

## 2

## Red Cell Production and Kinetics

**Mark J. Koury**

Professor of Medicine, Division of Hematology/Oncology, Vanderbilt University; and Associate Chief of Staff for Education, VA Tennessee Valley Healthcare System, Nashville, Tennessee, USA

The main function of erythrocytes (red cells) is to transport oxygen from the lungs to the other tissues of the body. This delivery of oxygen is finely controlled by the number of circulating erythrocytes, which is a function of the rate of old erythrocyte removal from the circulation and the rate of new erythrocyte production. Circulating erythrocytes are maintained in an extremely narrow range because the normal marrow produces almost exactly the same number of new erythrocytes each day as is lost through senescence. This daily turnover of about 1% of circulating erythrocytes represents approximately 250 billion erythrocytes in a healthy adult. When much greater numbers of circulating erythrocytes are lost, such as with bleeding or hemolysis, the production of new erythrocytes increases rapidly to maintain the steady-state number of erythrocytes. This rapid expansion of erythrocyte production in response to bleeding or hemolysis is so well regulated that rebound polycythemia or overproduction of erythrocytes does not occur. This exquisitely controlled production of erythrocytes is mediated through a negative feedback mechanism that involves oxygen delivery to, and utilization by, the kidneys, the hormone erythropoietin (EPO) that is produced by specialized cells in the kidneys, and the erythroid progenitor cells in the marrow that respond to EPO. Normal red cell production also depends upon adequate supplies of specific nutrients, among which folate, vitamin B<sub>12</sub>, and iron are the most important in terms of clinically encountered anemias. Disorders of the hematopoietic system or other disease processes such as chronic inflammation also affect the erythropoietic process.

**Erythropoiesis****Erythropoiesis: A Component of Hematopoiesis**

*Erythropoiesis*, the process of erythrocyte production, is a component of the larger process of hematopoiesis in which a stem

cell proliferates and differentiates to form all the cell types in the blood and immune system.<sup>1</sup> The endproducts of hematopoiesis include platelets, granulocytes, monocytes-macrophages, T lymphocytes, and B lymphocytes as well as erythrocytes. Thus, normally regulated hematopoiesis is required for effective hemostasis, inflammation, immune response, and tissue oxygenation. Among these various functions, tissue oxygenation is the first required during embryonic development and the most tightly regulated in postnatal life. Erythropoiesis has two sequential phases during development—the primitive phase, during weeks 3 to 8 of human gestation, when erythrocytes are produced in “blood islands” of the yolk sac, and the subsequent definitive phase in which erythrocytes are produced in the fetal liver and spleen and later in the marrow.<sup>2-4</sup> In humans, the hemoglobin of the primitive erythrocytes contains embryonic  $\epsilon$ - and  $\zeta$ -globins, whereas the hemoglobin of the definitive erythrocytes contains adult  $\alpha$ -globin and either fetal  $\gamma$ -globin from midgestation through the first few postnatal months or adult  $\beta$ -globin after the first few postnatal months. Embryologic studies demonstrate that the primitive and definitive phases of erythropoiesis arise from different stem cells in the early embryo.<sup>2,3,5,6</sup> The primitive erythroid cells arise in the inner cell mass of the yolk sac blood islands, whereas the definitive erythroid cells arise from the aortogonadomesonephros region of the mesoderm.

Current concepts of hematopoiesis are derived mainly from studies of mice and humans. These studies have included direct morphologic and immunologic analyses of cells in hematopoietic tissues, in-vitro culture of hematopoietic progenitor cells and hematopoietic stromal cells, transplantation studies with hematopoietic cells, and genetic studies of mice with natural mutations, transgene expressions, or targeted gene knockouts. Hematopoietic stem cells (HSCs) appear to be immediate progeny of an even more primitive stem cell, the hemangioblast, which can give rise to both hematopoietic cells and vascular cells during embryonic development.<sup>7</sup> Studies with HSCs have led to a hematopoietic model (Fig 2-1) that applies to postnatal as well as prenatal hematopoiesis because turnover of both blood and immune cells requires new cell production throughout life. In this model, pluripotent HSCs, which have an incidence in

**Figure 2-1.** Hematopoietic stem cell differentiation. Pluripotent hematopoietic stem cells (HSCs) can self-replicate (curved arrow) or give rise to progenitor cells committed to differentiation. Because of uncertainty about events leading to commitment and about self-replication of HSCs around the time of commitment, a hypothetical cell is shown at the border between the HSC and lineage commitment stages. Progeny of HSCs become committed to differentiation along specific cell lineages. After lineage commitment, progenitor cells mature and acquire the characteristics of terminally differentiated cells in blood (eg, erythroid cells produce hemoglobin and enucleate). During this maturation phase, lineage-specific hematopoietic growth factors act on progenitor cells. The stages of HSC differentiation are shown, but the proliferation that accompanies the differentiation is not. Proliferative potential decreases as cells progress through various stages toward mature blood cells. (Used with permission from Koury et al.<sup>8</sup>)

marrow of one per  $10^4$  to  $10^5$  nucleated cells, have two functions—self-replication and production of progenitor cells committed to differentiation into all lymphoid and myeloid cell types. Differentiation of HSCs requires a process called *commitment* in which the stem cell loses self-renewal capacity and is limited to either further differentiation or death. Commitment restricts the hematopoietic progenitor cells to differentiation along either the lymphoid or the myeloid pathway and subsequently to the specific, single-cell lineages (Fig 2-1). Differentiation involves cellular proliferation and additional commitment steps.

Two possible mechanisms of hematopoietic cell commitment are a deterministic one and a stochastic one.<sup>1</sup> In the deterministic mechanism, molecules from the cell's environment react with specific receptors on or in the cell and thereby lead to changes in specific gene structure or expression that, in turn, determine the commitment status of that cell. These environmental molecules can be either soluble growth factors or fixed ligands on other cells or extracellular matrix components in the hematopoietic microenvironment. An example of deterministic commitment is Indian hedgehog upregulating the expression of bone morphogenic protein-4 (BMP-4) in the developing mesodermal cells.<sup>9</sup> BMP-4, in turn, induces hematopoietic and endothelial differentiation, with the ventral portion of the developing dorsal aorta and the subjacent mesoderm inducing definitive hematopoiesis.<sup>9</sup> In the stochastic mechanism, the fate of a hematopoietic cell is determined by the outcome of random intracellular events that

change the structure or expression of specific genes.<sup>10,11</sup> Two examples of such changes in hematopoietic cells are immunoglobulin gene rearrangement in B-lymphocyte progenitors and binding of specific transcription factors such as TAL-1 or GATA-1 to the promoters of erythroid-specific genes.<sup>12,13</sup> With the stochastic mechanism, environmental signals such as the concentration of a specific hematopoietic growth factor, or the interactions with marrow stromal cells, promote survival or proliferation but do not affect commitment. Thus, these environmental factors influence the size of hematopoietic cell populations that have had commitment decisions made by random intracellular events.

### Stages of Erythropoiesis

The stages of erythropoiesis from HSCs and extending through the mature erythrocytes are shown in Fig 2-2. Hematopoietic cell transplantation experiments with mice have demonstrated murine marrow cells that possess the properties of HSCs.<sup>14-16</sup> Through analyses of murine HSCs and comparisons with human hematopoietic cell populations, a subset of hematopoietic cells that is highly enriched in human HSCs can be identified with cellular markers.<sup>1</sup> This human HSC-enriched population displays the CD34 and CD90 (Thy 1) antigens and has low uptake of rhodamine-123 and weak expression of HLA-DR antigens.

After erythroid lineage commitment, the first stage of recognized differentiation is the *burst-forming units–erythroid* (BFU-E)

**(A) Stage of erythroid differentiation****(B) Transcription factors for erythroid differentiation****(C) Receptors for required hematopoietic growth factors****(D) Proteins related to erythrocyte structure and function**

**Figure 2-2.** Cellular events in erythroid differentiation. (A) The relative sizes and the known or presumed morphologic appearances of erythroid cells at various stages of differentiation—pluripotent hematopoietic stem cells (HSCs); burst-forming unit–erythroid (BFU-E); colony-forming unit–erythroid (CFU-E); proerythroblasts (Pro EB); basophilic erythroblasts (Baso EB); polychromatophilic erythroblasts (Poly EB); orthochromatic erythroblasts (Ortho EB), reticulocytes (RET); erythrocytes (RBCs). (B) Erythroid transcription factors—basic helix-loop-helix factor (TAL-1); Lim-domain partner of TAL-1 (LMO-2); zinc finger factors that bind GATA sequences (GATA-1, GATA-2); GATA-1 partner, “friend of GATA” (FOG); retinoblastoma protein (RB); erythroid Krüppel-like factor (EKLF). (C) Receptors for hematopoietic growth factors—stem cell factor receptor (c-KIT); erythropoietin receptor (EPO-R); insulin-like growth factor-1 receptor (IGF-1-R). (D) Proteins related to erythrocyte structure and function. Periods of expression for erythroid-specific forms of proteins are shown. Transferrin receptors are present in all stages, but a period of large up-regulation is shown. Rh-associated glycoprotein (Rh50) is expressed before the proerythroblast stage, while the RhD and RhCE proteins are first expressed in the proerythroblast stage or later. For each transcription factor, growth factor receptor, and erythrocyte-related protein, the degree of expression can vary greatly during the period shown.

that proliferates and differentiates in semisolid tissue culture medium to form large colonies or groups of colonies called *bursts of erythroblasts*.<sup>17</sup> Human BFU-Es need 2 to 3 weeks of culture to form bursts that contain as many as several thousand erythroblasts. The more immature BFU-Es need the longest culture period and form the largest bursts. The next well-defined stage of erythroid development is the *colony-forming unit–erythroid* (CFU-E).<sup>18</sup> Human CFU-Es need 7 days in vitro to proliferate and differentiate into small colonies, usually composed of up to 64 erythroblasts. After the CFU-E stage is the proerythroblast

stage, the last erythroid progenitor with a nonspecific morphologic appearance in the differentiation scheme shown in Fig 2-2. The proerythroblast gives rise to the successive stages of the basophilic, polychromatophilic, and orthochromatic erythroblasts that are recognized by light microscopy of stained marrow samples. Orthochromatic erythroblasts enucleate, forming reticulocytes. Reticulocytes are very irregularly shaped cells containing residual organelles (the “reticulum”) that allow the cells to be distinguished from the more mature erythrocytes. The final stage of differentiation, the erythrocyte, is achieved after the reticulocytes

rid themselves of their residual organelles and remodel their irregular shapes to become uniform biconcave disks. Each progenitor cell loses proliferative potential as it differentiates along this continuum until it reaches the late erythroblast stages in which the cells do not divide. Thus, between the BFU-E and the CFU-E stages are a series of intermediate stages called *mature burst-forming units*, which need more than 1 week but less than 2 weeks in culture to develop into colonies with sizes intermediate between those of typical erythroid bursts and colonies.<sup>19</sup> Similarly, the reticulocyte population has early, intermediate, and late stages of development based on their relative RNA content, which steadily declines with maturation.<sup>20</sup>

### Requirements for Normal Erythroid Differentiation

A series of intracellular and extracellular events are needed for successful completion of the erythroid differentiation scheme as shown in Fig 2-2. The intracellular events include the expression of 1) general hematopoietic and erythroid-specific transcription factors, 2) receptors for hematopoietic growth factors, and 3) proteins such as hemoglobin, membrane, and membrane cytoskeleton proteins found in the mature erythrocyte. Synthesis of hemoglobin begins as the erythroblasts are making the transition from the basophilic to the polychromatophilic stages. Among the erythroid membrane proteins, the Kell and the Rh glycoproteins are expressed before the CFU-E stage, while most of the other membrane proteins found on mature erythrocytes are expressed at the proerythroblast stage or later.<sup>21,22</sup> At the proerythroblast stage,  $\alpha$ - and  $\beta$ -spectrin are synthesized, but they are degraded in the cytoplasm rather than associating with the cytoskeleton.<sup>23</sup> Glycophorin A is present in the plasma membrane of proerythroblasts,<sup>21,22</sup> but the band 3/anion transporter protein is not made until the basophilic erythroblast stage, and band 4.1 does not begin to accumulate until the polychromatophilic stage.<sup>23</sup> Once the band 3/anion transporter protein is present in the membrane,  $\alpha$ - and  $\beta$ -spectrin become membrane associated in the characteristic 1:1 ratio.<sup>23</sup>

Extracellular requirements for erythroid differentiation include 1) the adequate supply of required hematopoietic growth factors, 2) a sufficient supply of nutrients required for progenitor cell proliferation and differentiation, and 3) the presence of stromal cell and matrix support. In Fig 2-2, the transcription factors, growth factor receptors, and hematopoietic growth factors necessary for normal erythropoiesis are shown for the period of differentiation when they are known to be needed. The principal growth factor that regulates erythropoiesis is EPO, which is discussed in detail in the following section. The nutrients that play important roles in erythropoiesis—folate, vitamin B<sub>12</sub>, and iron—are required at all stages of erythroid cell differentiation, but most importantly in the later stages. Deficiency of any of these three nutrients results in decreased erythrocyte production and anemia. The roles of these nutrients in erythropoiesis are described in later sections. HSCs and BFU-Es are found in the hematopoietic organs, but they also can circulate in the blood. Erythroid cells in the CFU-E through orthochromatic stages of

differentiation do not circulate and, in the hematopoietic tissue, they form specific structures with stromal macrophages termed erythroblastic islands.<sup>24</sup> An erythroblastic island consists of a central macrophage surrounded by the adherent erythroid cells that are usually at about the same stage of differentiation within each individual island. Ablation of the stromal macrophages impairs the erythropoietic response to blood loss, indicating that erythroblastic islands have a functional role in red cell production.<sup>25</sup> At least five surface membrane proteins can mediate erythroid-macrophage interactions in erythroblastic islands.

1. Vascular cell adhesion molecule 1 (VCAM-1) on marrow macrophages binds  $\alpha 4 \beta 1$  integrin (also known as very late antigen-4 or VLA-4) on erythroblasts.<sup>26</sup>
2.  $\alpha_V$  component of integrins (eg,  $\alpha_V \beta 1$ ,  $\alpha_V \beta 3$ , and  $\alpha_V \beta 5$ ) on marrow macrophages binds interstitial cell adhesion molecule 4 (ICAM-4, also known as LW glycoprotein) on erythroblasts.<sup>27</sup>
3. Erythroblast-macrophage protein (EMP), a transmembrane protein of both erythroblasts and macrophages, mediates interactions between these two cell types through a homophilic reaction.<sup>28</sup>
4. Sialoadhesin (CD169 or Siglec 1) on macrophages binds sialylated glycoproteins on erythroblasts.<sup>29</sup>
5. Hemoglobin-haptoglobin receptor (CD163) is a marrow macrophage surface glycoprotein that binds an unknown ligand on erythroblasts.<sup>30</sup>

Each of these adhesion protein pairs can be disrupted by antibodies and/or competing peptide ligands such that binding of erythroblasts to macrophages is inhibited. Because disruption of one of these binding protein pairs can inhibit attachment of erythroblasts to macrophages, the proteins may form functional binding complexes on the surfaces of macrophages and erythroblasts.

---

## Erythropoietin

### Regulation of Erythropoietin Production by Tissue Hypoxia

Under normal circumstances, the rate of erythrocyte production is controlled by the interaction of EPO with the EPO receptors on the erythroid progenitor cells. Erythropoietin is a 30.4-kD glycosylated protein, most of which is produced by the kidneys.<sup>31</sup> The kidneys are a major component of the oxygenation-EPO negative feedback mechanism shown in Fig 2-3. The other components are the marrow, the blood erythrocytes, and EPO itself. The negative feedback characteristics account for the fine control of erythrocyte numbers that occur in each individual. The major determinant of oxygen delivery from the lungs to the peripheral tissues is the number of circulating erythrocytes. When erythrocyte numbers decrease, as occurs with bleeding or hemolysis, oxygen delivery decreases and the peripheral tissues become hypoxic. All tissues experience hypoxia, but the major ones that respond with EPO production are the kidneys and the liver.

**Figure 2-3.** The oxygenation-erythropoietin (EPO) negative feedback mechanism. The number of circulating red cells determines the amount of oxygen delivered from the lungs to other tissues. In the renal cortex, a specific subset of interstitial cells produce EPO when they perceive hypoxia. The EPO is immediately secreted into the blood and acts in the marrow to prevent the programmed death (apoptosis) of erythroid progenitor cells. Those erythroid progenitors that survive the EPO-dependent period of differentiation mature into reticulocytes (irregularly shaped anucleate cells in marrow and blood) and subsequently into erythrocytes. Increased numbers of erythrocytes resulting from increased plasma EPO levels deliver more oxygen to the kidneys and thereby lower the amount of EPO produced as renal hypoxia is relieved.

The same cells that sense hypoxia are the ones that produce EPO.<sup>32</sup> The mechanism for sensing hypoxia in cells involves a family of specific transcription factors, hypoxia-inducible factors (HIFs).<sup>33,34</sup> HIFs have two components, HIF- $\alpha$  and HIF- $\beta$ , which form a complex that binds to a hypoxia-inducible transcription enhancer located in the region of various genes that include *EPO*, vascular endothelial growth factor (*VEGF*), and genes encoding several of the glycolytic enzymes.<sup>35</sup> In the case of *EPO*, HIF-2 $\alpha$  is the family member that binds to a 120-bp enhancer 3' to the human *EPO* polyadenylation signal<sup>36,37</sup> as shown in Fig 2-4(B). HIF-1 $\beta$  is constitutively produced, and its intracellular levels are not influenced by hypoxia. HIF- $\alpha$  components are constitutively produced, but under normoxic conditions, they are essentially undetectable because they are rapidly degraded by the ubiquitin-proteasome pathway,<sup>38</sup> shown in Fig 2-4(A). However, when an EPO-producing cell experiences hypoxia, this rapid degradation ceases and intracellular HIF-2 $\alpha$  levels promptly increase, as in Fig 2-4(B). Polyubiquitination of HIF-2 $\alpha$  depends upon the von Hippel-Lindau protein (pVHL) interacting with those HIF-2 $\alpha$  molecules that have hydroxylation of two specific proline residues.<sup>39–41</sup> Hydroxylation of a specific asparagine residue<sup>42,43</sup> in HIF-2 $\alpha$  prevents its interaction with the p300 member of the HIF transcription complex, thereby preventing the formation of the active complex. These hydroxylations are directly linked to the oxygenation of the EPO-producing cell because the two non-heme iron-containing hydroxylases, which catalyze these proline and asparagine hydroxylation reactions respectively, use molecular oxygen as a substrate.<sup>35</sup> Under

normoxic conditions, the hydroxylations and subsequent ubiquitination and interference with transcription complex formation proceed, but with hypoxia they do not. These posttranslational regulations of HIF-2 $\alpha$  levels and activity are the key components in controlling *EPO* gene transcription. Components of this complex other than HIF-2 $\alpha$  and HIF-1 $\beta$  include hepatocyte nuclear factor-4 (HNF-4) and the protein p300.<sup>44–46</sup> Once hypoxia reaches the threshold that triggers *EPO* transcription, the resultant *EPO* messenger RNA is translated into the EPO glycoprotein, which is immediately secreted.<sup>31</sup> When an individual cell is triggered to produce EPO, it does so in an all-or-nothing manner.<sup>32,47</sup> Thus, EPO concentrations in the blood increase sharply within 2 hours after loss of blood, hemolysis, or a sudden decrease in atmospheric oxygen.

The kidney cells that produce EPO are a subset of cortical interstitial cells adjacent to proximal tubules<sup>48,49</sup> and appear to be fibroblasts<sup>50,51</sup> (Fig 2-3). In mild anemia, small foci of the EPO-producing cells are present in the inner cortex. In moderate anemia, the EPO-producing cells are present in larger areas within the inner half of the cortex. In severe anemia, they are present throughout the renal cortex.<sup>47</sup> These progressive increases in the areas of EPO production in the kidney correspond to increasing areas of renal cortical hypoxia that are a function of oxygen supply from the blood and local oxygen utilization by rapidly metabolizing cells, such as the adjacent proximal tubular epithelium.<sup>47,52</sup> Thus, the rapid increase in EPO production after blood loss or hemolysis is not due to increased production by each EPO-producing cell but rather to the recruitment to active EPO production of increased numbers of cells with the potential to produce EPO.<sup>47</sup> The number of cells actively producing EPO and the resultant plasma EPO levels increase exponentially with a linear decrease in hematocrit. This exponential increase characterizes most anemias except for those involving patients with renal disease or malignancies.<sup>53</sup>

### Interaction of Erythropoietin and Erythroid Progenitor Cells

EPO is carried through the blood to the marrow, where it binds to the specific transmembrane glycoprotein erythropoietin receptor (EPO-R).<sup>54</sup> The mature, fully glycosylated EPO-R is displayed on the surface of erythroid progenitor cells at the CFU-E stage and persists through the late basophilic erythroblast stage with an average of approximately 1000 surface receptors per cell<sup>55,56</sup> (Fig 2-2). The EPO-R is structurally homologous with receptors for numerous hematopoietic growth factors and cytokines including granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, thrombopoietin, the interleukins, growth hormone, and prolactin.<sup>57</sup> The binding of EPO to EPO-Rs leads to three major events: 1) homodimerization and conformational alterations of EPO-Rs, 2) initiation of intracellular signaling by the EPO-Rs, and 3) endocytosis of the EPO/EPO-R complexes, which are subsequently proteolyzed.<sup>45,55,58–61</sup> Dimerization and structural changes of EPO-Rs after EPO binding induce both signaling and

**Figure 2-4.** Induction of erythropoietin (EPO) gene transcription by hypoxia. (A) In cells capable of producing EPO, two components of hypoxia-inducible factor (HIF-2 $\alpha$  and HIF-1 $\beta$ ) are constitutively produced under normoxic conditions. However, the molecular oxygen present in the EPO-producing cells under normoxic conditions is used to hydroxylate two prolines and one asparagine in HIF-2 $\alpha$ . The prolyl hydroxylations (P-OH) lead to recognition by von Hippel-Lindau protein (pVHL), which targets HIF-2 $\alpha$  for polyubiquitination (Poly Ub) by ubiquitin ligase. The ubiquitinated HIF-2 $\alpha$  is rapidly degraded in proteasomes. Asparaginyl hydroxylation (N-OH) inhibits the association of the HIF-2 $\alpha$  with the p300 member of the HIF transcription complex, providing another means of blocking

the transcription of *EPO*. (B) When EPO-producing cells are hypoxic, HIF-2 $\alpha$  is not hydroxylated and accumulates because it is not degraded by the ubiquitin-proteasomal pathway. The HIF-2 $\alpha$  forms heterodimers with HIF-1 $\beta$ . Because the asparagine hydroxylation of HIF-2 $\alpha$  has not occurred when the EPO-producing cells are hypoxic, these heterodimers associate with two other components of the HIF transcription complex, hepatocyte nuclear factor-4 (HNF-4) and p300. The HIF transcription complex binds to the hypoxia-inducible enhancer 120 bp 3' to the *EPO* polyadenylation signal and increases *EPO* promoter activity with a resultant increase in *EPO* transcription and accumulation of EPO messenger RNA accumulation.

endocytosis. The endocytosis and intracellular degradation of the EPO/EPO-R complexes appear to be the normal mechanisms for clearance of EPO from the blood.<sup>62,63</sup>

Like the other hematopoietic growth factor-cytokine receptors, EPO-Rs have no intrinsic enzyme activity,<sup>57</sup> but they interact with several signal transduction pathways through Janus tyrosine kinase-2 (JAK2). JAK2 is physically associated with the cytoplasmic portion of EPO-Rs, where it chaperones EPO-Rs to the surface of the erythroid cell and is the initial enzyme activated by the conformational changes in the EPO-Rs produced by the binding of EPO.<sup>64,65</sup> JAK2 is activated by phosphorylation. In turn, activated JAK2 phosphorylates tyrosines in EPO-Rs and initiates signal transduction pathways that include signal

transduction and activator of transcription-5 (STAT5), RAS-raf-MAP kinase, and phosphoinositol-3 kinase/Akt kinase (protein kinase B).<sup>45,55,58-61</sup> In addition to activating these pathways that appear to lead to increased erythroid cell numbers, JAK2 also activates SHP-1 and SHP-2 phosphatases and suppressors of cytokine signaling-3 (SCOS-3) that control the phosphorylation state of the EPO-Rs and ultimately cease EPO-R signaling.<sup>66-68</sup>

### Effects of Erythropoietin on Erythroid Progenitor Cells

EPO has been proposed to be an inducer of proliferation and terminal differentiation, but the only effect of EPO on erythroid progenitor cells that has been well documented is the prevention of programmed death (apoptosis). Promotion of survival

**Figure 2-5.** Model of erythropoiesis based on suppression of programmed cell death (apoptosis) by erythropoietin (EPO) and heterogeneity in EPO dependence among erythroid cells. Between the (A) Normal erythropoiesis with an average survival rate of 40% in each of the EPO-dependent generations. Normal erythropoiesis produces about 250 billion new erythrocytes daily, despite the fact that a minority of all potential erythroid cells survive the EPO-dependent period. (B) Elevated EPO levels as found after acute blood loss or hemolysis increase average survival rates to 57% in each EPO-dependent generation. Daily erythrocyte production is increased three times the normal amount. (C) Decreased EPO levels as found in renal failure decrease average survival rate to 28% in each EPO-dependent generation. Daily erythrocyte production is one-third of normal.

(D) Ineffective erythropoiesis with high EPO levels increases rates of apoptosis caused by a pathologic process such as folate or vitamin B<sub>12</sub> deficiency. High EPO levels in response to decreased erythrocyte production expand surviving cells in the early EPO-dependent generations, but the increased rates of apoptosis in the late EPO-dependent and post-EPO-dependent stages decrease daily erythrocyte production to one-third of normal. (E) Iron-deficient erythropoiesis with elevated EPO levels resulting in a similar increase to an average of 57% survival as seen in (B), but in the post-EPO-dependent period, when hemoglobin is synthesized, heme-regulated inhibitor (HRI) prevents apoptosis by inhibiting protein synthesis. The inhibited protein synthesis decreases the size of erythrocytes produced and reduces daily erythrocyte production to three-fourths of the normal numbers.

by EPO through the prevention of apoptosis has been found in several different systems, including CFU-Es from various hematopoietic tissues<sup>69-72</sup> and in knockout mice that are either *EPO* null or *EPO-R* null.<sup>73,74</sup> These studies all indicate that erythroid progenitor cells in CFU-E through basophilic erythroblast stages are dependent upon EPO for their survival. How EPO signaling prevents apoptosis is unknown, but one key modulator of apoptosis, the anti-apoptotic protein Bcl-X<sub>L</sub>, has been implicated in erythroid cell survival.<sup>75,76</sup> Bcl-X<sub>L</sub>, however, does not mediate the anti-apoptotic effect of EPO on CFU-Es and proerythroblasts, but prevents the apoptosis of later stage erythroblasts.<sup>77</sup>

During the period of EPO dependence, individual erythroid cells in the same stage of differentiation from the same hematopoietic tissue display wide variation in degree of dependence on EPO for survival.<sup>78</sup> Some of the erythroid cells need very low levels of EPO,

such as those in the plasma of patients with chronic renal failure. Other erythroid cells need very high levels of EPO, such as those in patients with acute blood loss or hemolysis. Thus, this broad spectrum of EPO requirements covers the more than 1000-fold range of EPO concentrations found in plasma under various physiologic and pathologic conditions. The mechanism responsible for this heterogeneity in EPO dependence is not known, but it does not appear to be caused by differences in either the numbers of EPO-Rs or the EPO-binding affinities of EPO-Rs in the dependent progenitors.<sup>78</sup>

A model that incorporates the wide range of plasma EPO levels and the wide heterogeneity in EPO dependence among the EPO-responsive cells of the hematopoietic tissues has been proposed to explain the regulation of erythrocyte production by EPO in various physiologic and pathologic conditions.<sup>79</sup> In a version of this model in Fig 2-5, erythroid progenitor cells enter

an EPO-dependent period of differentiation (left of the dotted line in the figure) that extends from the CFU-E through the early erythroblast stages and encompassing three generations of cells. In Fig 2-5, the proportion of total cells that survive in a generation is shown immediately under the population. The surviving cells are represented by circles, each of which contains a large black dot representing an intact nucleus. The cells lost to apoptosis are shown by circles, each of which contains an X. The number of surviving cells in a generation results in twice that number for the total cells in the subsequent generation. Most cells reaching the CFU-E stage need more EPO than the low levels found in normal plasma to sustain them through the EPO-dependent period of differentiation. As a result, the approximately 250 billion erythrocytes produced daily by a normal, healthy adult are the progeny of a minority of all the erythroid progenitor cells that reach the CFU-E stage, shown in Fig 2-5(A).

When blood loss, hemolysis, or decreased atmospheric oxygen is encountered, plasma EPO increases, allowing the survival of many of EPO-dependent progenitors that would die by apoptosis under normal conditions. This enhanced survival increases reticulocyte production within a few days after encountering blood loss or decreased atmospheric oxygen. The increased reticulocytosis leads to increasing erythrocyte numbers until oxygen delivery recovers to normal, and then plasma EPO levels decline toward normal. In pathologic states of decreased oxygen delivery, such as lung disease or cardiac diseases with right-to-left shunts, the persistently increased EPO levels allow greater-than-normal survival of EPO-dependent cells such that the total number of erythrocytes is maintained in the polycythemic range. Conversely, when plasma EPO levels fall below normal because of decreased production in chronic renal disease, many erythroid progenitor cells that would survive the EPO-dependent period of differentiation under normal conditions die by apoptosis, resulting in anemia from decreased reticulocyte production, shown in Fig 2-5(C). Treatment of patients with renal failure with exogenously administered EPO rescues the erythroid progenitor cells that need normal plasma levels of EPO to survive.

## Nutritional Requirements for Erythropoiesis

Although erythropoiesis is finely regulated by the oxygenation-EPO feedback mechanism, the erythropoietic process is frequently limited by an insufficient supply of three essential nutrients. These nutrients are folate, vitamin B<sub>12</sub>, and iron. Although all proliferating cell populations need folate and vitamin B<sub>12</sub>, the large number of erythrocytes that must be produced each day results in a large DNA synthesis requirement for erythropoiesis. Although iron also is needed by all proliferating cell populations, the erythroblasts need much more iron than any other cell type because they produce hemoglobin. When any of these three nutrients is not present in sufficient amounts for the erythroid cell population of the marrow, production of erythrocytes decreases, and anemia occurs. Through the hypoxia

feedback mechanism, these anemias increase EPO production,<sup>53</sup> but increased EPO can only partially compensate for the decreased erythropoiesis caused by the specific nutrient deficiency. Administration of the deficient nutrient, however, results in resolution of anemia in each of the deficiency states.

Folate deficiency results in decreased intracellular levels of all folate coenzymes in the erythroid progenitor cells. Deficiency of vitamin B<sub>12</sub> results in trapping of folate in the methyltetrahydrofolate form, making it unavailable in the methylenetetrahydrofolate form required for thymidine synthesis or the formyltetrahydrofolate form required for purine synthesis.<sup>80</sup> As a result, vitamin B<sub>12</sub> deficiency, like folate deficiency, leads to decreased intracellular levels of the specific folate coenzymes needed for de novo synthesis of all of the deoxynucleotides used in DNA synthesis, except for deoxycytidine.<sup>81</sup> The inability to synthesize DNA caused by an inadequate supply of thymidine and purines causes accumulation of erythroid progenitors in the S phase of the cell cycle, which is rapidly followed by the induction of apoptosis.<sup>82,83</sup> The stages of erythroid differentiation that appear to be most susceptible to this apoptosis are at the end of the EPO-dependent stage and the beginning of the period of hemoglobin synthesis. EPO-induced expansion of the EPO-dependent population at the CFU-E and proerythroblast stages leads to the presence of even greater numbers of these progenitor cells that subsequently undergo apoptosis just as they are beginning to produce hemoglobin.<sup>84</sup> The resultant clinical disease is megaloblastic anemia. The prominent feature of megaloblastic anemia is ineffective erythropoiesis, shown in Fig 2-5(D). In ineffective erythropoiesis, progenitor cells in the EPO-dependent period expand in response to increased EPO levels. The number of reticulocytes formed, however, is less than normal because of the increased rates of pathologic apoptosis in the EPO-dependent and post-EPO-dependent periods of differentiation. The increased death of erythroid cells in ineffective erythropoiesis is recognized clinically by increases in iron turnover, serum bilirubin, and serum lactate dehydrogenase.

Erythroid progenitor cells are the greatest consumers of iron in the body. Iron uptake is mediated through transferrin receptors and tightly regulated by a complex intracellular system such that erythroid progenitor cells synthesize large amounts of hemoglobin without having an excess of iron, heme, or globins in the cells.<sup>85</sup> Two-thirds of the body's iron is in the hemoglobin of circulating erythrocytes, and iron deficiency almost always arises from blood loss. Two milliliters of blood contain 1 mg of iron, which is the amount normally absorbed each day from the diet. The iron absorption rate can be increased only slightly, so that chronic blood loss of just a few milliliters per day leads to iron deficiency. With iron deficiency anemia, serum EPO levels are elevated<sup>53</sup> and the number of CFU-Es in the hematopoietic organs are increased while the numbers of erythroblasts in the marrow and the circulating reticulocytes are decreased.<sup>86</sup> However, unlike megaloblastic anemia, ineffective erythropoiesis does not occur, and serum bilirubin and lactate dehydrogenase levels remain normal. The iron-deficient erythroid cells are

spared from apoptosis by one of the regulators of protein synthesis, heme-regulated inhibitor (HRI).<sup>87</sup> HRI is a protein kinase that phosphorylates eukaryotic translation initiation factor-2 $\alpha$  (eIF-2 $\alpha$ ), thereby inhibiting translation of globin (and other proteins) in erythroblasts. When free heme is present in the erythroid cells, it binds HRI and inhibits its phosphorylation of eIF-2 $\alpha$ , thereby permitting active globin (and other) protein translation. Conversely, when erythroblasts are iron-deficient, they produce much less heme and HRI phosphorylation of eIF-2 $\alpha$  is uninhibited, leading to greatly decreased rates of protein synthesis. This decreased protein synthesis results in a much slower rate of erythrocyte production and microcytosis.<sup>87</sup> The effect of iron deficiency and HRI on erythropoiesis is shown in Fig 2-5(E).

### **Influence of Pathologic States on Erythropoiesis**

The erythropoietic process can be influenced by diseases that are intrinsic to the erythropoietic cells or that secondarily affect the erythropoietic cells. Among the intrinsic diseases are several that decrease the number of erythropoietic cells. These include myelodysplasia, myeloid leukemia, aplastic anemia, pure red cell aplasia, and Fanconi anemia. Increased apoptosis of hematopoietic cells or failure to differentiate, in the case of acute leukemia, are considered the mechanisms of population reduction in these diseases. Conversely, polycythemia vera results in increased numbers of erythropoietic progenitor cells that have an increased sensitivity to EPO.<sup>88</sup> This increased sensitivity to EPO has been found to be caused by mutations in the JAK2 kinase that is responsible for the signaling of the EPO-R.<sup>89</sup> Indeed, the large majority of patients with polycythemia vera have a specific mutation in JAK2 kinase that keeps it in a constitutively active state. Because JAK2 also functions in the signaling of other hematopoietic growth factors, other hematopoietic lineages are involved in polycythemia vera as well as in other myeloproliferative disorders such as essential thrombocythemia and idiopathic myelofibrosis.<sup>89</sup> In patients with polycythemia vera the EPO feedback mechanism shown in Fig 2-3 is functional as demonstrated by lower-than-normal EPO levels, but the erythroid progenitor cells in the EPO-dependent stages in polycythemia vera survive much better with the low EPO levels than do normal erythroid progenitors with normal EPO levels.

Diseases that can secondarily decrease erythropoiesis include those that directly displace the hematopoietic cells in the marrow, such as metastatic neoplasms, lymphoid neoplasms, and myelofibrosis. However, the most common cause of secondary inhibition of erythropoiesis is anemia of chronic disease. This anemia occurs in chronic infections, neoplasms, and inflammatory diseases, and the prominent factor in its pathophysiology is excessive iron sequestration by macrophages. The major source of iron for erythropoiesis is macrophages, which store and process absorbed iron and recycled iron from the breakdown of

senescent erythrocytes.<sup>86</sup> Macrophages export iron to plasma transferrin, which delivers it to the erythroblasts. The release of iron from the macrophages occurs through ferroportin, a membrane transport protein. Ferroportin also mediates the passage of iron from duodenal enterocytes into the plasma where it is carried by transferrin. The expression of ferroportin is regulated by hepcidin, a 25-amino acid hormone produced in the liver.<sup>90</sup> Hepcidin production is induced by increased plasma iron and by cytokines produced in inflammation.<sup>90</sup> Hepcidin binds to ferroportin on the plasma membranes of macrophages and duodenal enterocytes, thereby inducing the internalization and degradation of the ferroportin.<sup>90</sup> Thus, increased hepcidin decreases ferroportin expression, resulting in the inhibition of iron export into the plasma by the macrophages and enterocytes. Therefore, as a result of hepcidin induction, less iron is available to erythroblasts and the erythropoietic process is suppressed.

Although iron sequestration by macrophages plays a major role, other direct and indirect effects of inflammatory cytokines on the erythropoietic cells have been reported in the anemia of chronic disease. Another indirect effect is decreased EPO production by the kidneys (relative to the degree of anemia), while direct effects on erythroid cells include suppressed growth and increased apoptosis induced by inflammatory cytokines such as interferon- $\gamma$ , tissue necrosis factor- $\alpha$ , and interleukin-1.<sup>91,92</sup> Although the anemia of chronic disease may partially respond to high doses of exogenously administered EPO, resolution of the anemia requires effective treatment of the primary disease responsible for increased cytokine production.

### **Summary**

Erythropoiesis is a component of the larger process of hematopoiesis, in which a pluripotent HSC gives rise through proliferation and differentiation to all the mature cells of the blood and the immune system. Within the erythroid differentiation process, the rate of erythrocyte production is regulated by EPO. EPO acts by increasing the number of erythroid progenitors that can survive during a specific period when they are dependent on EPO for the prevention of apoptosis. Levels of EPO are controlled by oxygen delivery and utilization in the renal cortex, where hypoxia induces EPO production. This oxygen-EPO feedback mechanism results in finely controlled rates of erythrocyte production. This mechanism responds promptly to physiologic changes such as blood loss or changes in atmospheric oxygen. In pathologic conditions, it provides compensatory changes in the rates of erythrocyte production that partially correct the abnormal oxygen delivery to the peripheral tissues. Although the use of EPO in clinical medicine is routine for patients with the anemia of renal disease, further research is needed to understand the intracellular signaling by the EPO-R that leads to increased erythroid cell survival in disorders such as myelodysplasia and the anemia of chronic disease. Understanding of these EPO-related mechanisms as well as the roles of HRI in preventing apoptosis of

iron-deficient erythroblasts and hepcidin in inducing the anemia of chronic disease will facilitate treatment of these various anemias.

## Regulation of Oxygen Delivery by Red Cells and Red Cell Substitutes

**Christopher P. Stowell**

Director, Blood Transfusion Service, Massachusetts General Hospital, and Assistant Professor of Pathology, Harvard Medical School, Boston, Massachusetts, USA

The maintenance of tissue levels of  $O_2$  adequate to support aerobic respiration depends on four processes. The mechanics of breathing draw  $O_2$  into the alveolar space and expel  $CO_2$ . These respiratory gases are exchanged between the alveoli and the red cells in the pulmonary capillaries followed by transport of the oxygen-rich red cells to the peripheral circulation. In the last process,  $O_2$  diffuses along a concentration gradient from the red cells, through the blood vessel wall, into the tissue, and eventually to the mitochondria, where its reduction along the respiratory chain drives the generation of energy in the form of adenosine triphosphate (ATP). The body stores of  $O_2$  are small relative to the rate of consumption and cannot be drawn down too far before weakening the concentration gradients that are key determinants of tissue oxygenation. Disruption of any one of these processes impairs cellular oxygenation; hence, they are tightly regulated by multiple, overlapping systems that operate on the systemic, regional, and tissue levels. This chapter focuses on the regulation of the last phase of this process, the transport of oxygenated red cells to the periphery and delivery of oxygen to tissues.

### Regulation of Systemic Oxygen Delivery

Some of the quantitative aspects of systemic oxygen dynamics are reviewed in Chapter 9, which points out that the amount of oxygen delivered is a function of the unit volume of blood flow (related to cardiac output) and the oxygen content of blood, which is determined by the concentration of hemoglobin and the degree to which it is saturated with  $O_2$ . Ordinarily, the amount of oxygen delivered to the periphery exceeds what is required to sustain metabolic activity. Under resting conditions, only about 25% of all delivered  $O_2$  is consumed; hence, blood returning to the heart remains approximately 75% saturated. Even if delivery decreases because of reduced cardiac output or hemoglobin concentration,

or consumption increases because of exercise or fever, more oxygen can be extracted from the blood. However, at some threshold the tissues can no longer extract more oxygen and consumption becomes supply limited. To avoid reaching this point, systemic oxygen delivery is protected by regulation of the cardiac output, as well as the level and function of erythrocytic hemoglobin.<sup>1</sup> In normovolemic anemia, decreased blood viscosity contributes to facilitated venous return with increased preload and decreased afterload.<sup>2</sup> Anemia also results in increased synthesis of 2,3-diphosphoglycerate (2,3-DPG) in the red cell, which increases the hemoglobin  $P_{50}$  and facilitates oxygen release. In addition, blood flow is redistributed to tissues with increased metabolic needs (eg, heart and muscle in exercise) and diverted from tissues whose activity can be reduced or whose baseline oxygen extraction ratio is low (eg, splanchnic beds). Overlapping regulatory systems sensitive to blood volume, pressure, and oxygen levels trigger hemodynamic and metabolic responses that serve to maintain blood flow and oxygen delivery to the periphery. (See Table 3-1.)

### Central Nervous System Regulation of Hemodynamics

The central nervous system (CNS) regulates hemodynamic responses to hypovolemia and hypotension by increasing cardiac output and vascular tone and shunting blood flow away from such tissues as the skin and gut. Cardiac output is increased because of increases in both heart rate and stroke volume in the awake patient<sup>3</sup> but stroke volume alone in the anesthetized patient.<sup>4</sup> This regulatory response is initiated in part by vascular mechanoreceptors sensitive to stretch. High-pressure baroreceptors are located in the carotid bodies and the aortic arch, and low-pressure receptors are found in the heart and lungs.<sup>5,6</sup> The carotid sinus baroreceptors are located in the adventitia of the internal carotid artery, close to its juncture with the common carotid artery. Stretching of the arterial wall distorts sensory nerve endings and activates ion channels, causing membrane depolarization and the generation of an action potential proportionate to the degree of stretch. In the aortic arch, this signal transduction appears to be mediated by KCNQ  $K^+$  channels,<sup>7</sup> a group of widely distributed, multimeric ion channels that play a major role in determining neuronal excitability as well as in the

**Table 3-1.** Systemic Control of Blood Flow

| Type of Control | Input                                                 | Effector Organ                      | Output                                     |

epileptic and arrhythmia syndromes that result from their malfunction.<sup>8</sup> Afferent impulses from the carotid mechanoreceptors are transmitted via sensory fibers of the carotid sensory nerve that travel with the glossopharyngeal nerve and project to the nucleus of the solitary tract in the medulla.<sup>5</sup> This nucleus also receives signals from the mechanoreceptors in the aortic arch and heart via nodose and vagal afferents, respectively. The baroreceptive neurons of the solitary tract nucleus in turn activate parasympathetic neurons of the dorsal vagal nucleus and the nucleus ambiguus. They also inhibit the sympathoexcitatory neurons of the rostral ventrolateral nucleus of the medulla.<sup>5,9</sup> Thus, activation of the mechanoreceptors by increased stretch (increased blood volume or pressure) stimulates parasympathetic effects and inhibits sympathetic effects—resulting in decreased heart rate, vasodilation, and distribution of blood to skin and skeletal muscle. The neurons of the rostral ventrolateral nucleus are themselves sensitive to PO<sub>2</sub>, which shuts down a K<sup>+</sup> channel and causes an increase in the spontaneous discharge rate.<sup>10,11</sup> In addition, there is evidence that 1) nitric oxide (NO) acts as a neurotransmitter in the CNS, generally attenuating sympathetic tone by interacting with baroreceptor afferent inputs,<sup>12</sup> and 2) NO from S-nitrosothiol (SNO) adducts in red cells regulates the ventilatory response to hypoxia in the nucleus of the solitary tract.<sup>13</sup>

The carotid bodies also contain oxygen sensors that detect systemic hypoxia and quickly stimulate breathing and raise blood pressure via activation of the autonomic nervous system.<sup>14</sup> The O<sub>2</sub> chemoreceptor tissue in the carotid body includes two cell types. Type I, or glomus, cells are of neural crest origin and produce various neurotransmitters. Type II, or sustentacular, cells play a supportive role and resemble glial cells. It is thought that the Type I cells act as the O<sub>2</sub> sensors and trigger afferent nerve activation, which is transmitted to the CNS where it acts via autonomic control of respiratory rate and blood pressure. Although all cells respond to hypoxia, these responses usually evolve over a period of minutes to hours and require prolonged exposure to hypoxic conditions.<sup>15</sup> The carotid body, however, responds within seconds to decreases in the arterial PO<sub>2</sub> even as small as 20 mm Hg with excitation of the afferent nerves. This increased level of excitation is maintained if hypoxia persists and shows little adaptation.<sup>16</sup> The identities of the molecular elements of the O<sub>2</sub> sensor in Type I cells

are not clear, but candidates include several heme-containing proteins that use molecular O<sub>2</sub>, including cytochrome *a*<sub>3</sub>, nitric oxide synthase, heme oxygenase 2, and nicotinamide adenine dinucleotide phosphate oxidase.<sup>17–19</sup> Type I cells also express several O<sub>2</sub>-sensitive K<sup>+</sup> channel proteins which are inhibited by hypoxia.<sup>20,21</sup> There is evidence that multiple heme-containing proteins, may function as O<sub>2</sub> sensors, each sensitive to a different dynamic range of PO<sub>2</sub>. These proteins interact with O<sub>2</sub>-sensitive K<sup>+</sup> channel proteins (the “chemosome” hypothesis) to rapidly transduce the signal.<sup>22–24</sup> Hypoxia leads to depolarization of Type I cells and release of neurotransmitters. The major neurotransmitter that mediates afferent nerve activation by hypoxia is ATP. Paradoxically, ATP also acts on the Type I cells in an autocrine fashion to inhibit the hypoxia-stimulated increase in intracellular Ca<sup>++</sup> concentration,<sup>25,26</sup> and may release other inhibitory neurotransmitters as well.<sup>27,28</sup> It has been suggested that the release of both excitatory and inhibitory neurotransmitters functions as a “push-pull” mechanism to prevent over-excitation and signal extinction of the afferent nerves. This mechanism may also explain the lack of adaptation in the presence of persistent hypoxia.<sup>29</sup>

### Humoral Regulation of Blood Volume

Both atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP) are produced in myocytes; ANP largely in the atria and BNP in the ventricle.<sup>30</sup> ANP is stored in perinuclear granules and released in response to increased atrial distension or pressure, as well as several neurotransmitters. BNP is not stored in granules but rather is synthesized and released episodically.<sup>31</sup> Volume expansion or pressure overload of the ventricular wall prompts synthesis of precursor forms of BNP that are processed and released.<sup>32</sup> Acting through receptor guanylate cyclases, these peptides have pleomorphic effects that generally contribute to peripheral vasodilation, natriuresis, and diuresis. BNP acts to inhibit the release of both antidiuretic hormone and aldosterone.<sup>33</sup> Acting in concert with sympathetic nerve input, it also has direct effects on the kidney, stimulating glomerular filtration, natriuresis, and diuresis.<sup>34,35</sup> In vascular smooth muscle cells, BNP, acting via the receptor guanylate cyclase and the Rho kinase system, stimulates dephosphorylation of myosin light chain, which promotes vasodilation.<sup>36</sup>

Blood volume is also regulated directly by the kidney. The renin axis is stimulated by a baroreceptor mechanism as well as the macula densa system. The cells of the macula densa respond to decreases in luminal NaCl concentration by stimulating the secretion of renin from the juxtaglomerular cells of the kidney. The secretion of renin initiates a proteolytic cascade beginning with the cleavage of angiotensinogen from the liver to produce angiotensin I. Angiotensin I itself is cleaved by angiotensin-converting enzymes (found in the lung and other tissues) to angiotensin II, and then angiotensin III. Both angiotensins II and III stimulate the secretion of aldosterone and thereby reduce diuresis.<sup>37</sup> The ability of the cells of the macula densa to sense NaCl levels depends on the function of the luminal  $\text{Na}^+/\text{K}^+/\text{2Cl}^-$  cotransporter,  $\text{NKCC2}$ .<sup>38,39</sup> The affinity of this cotransporter for  $\text{Cl}^-$  is low; hence, uptake is very sensitive to small changes in  $\text{Cl}^-$  concentration. Prostaglandins have been implicated as mediators of macula-dependent renin secretion,<sup>40</sup> partly on the basis of observations of impaired renin responses in the presence of COX-inhibitors and in COX-2 knockout mice.<sup>41-43</sup> Within the kidney, local production of endothelin activates NO secretion, which not only affects vasomotor tone and blood flow but also promotes sodium excretion as well.<sup>44</sup> In addition, increased intraluminal pressure is sensed by an as-yet-unidentified structure (possibly the juxtaglomerular cells themselves), which also acts through the release of prostacyclin ( $\text{PGI}_2$ ) to modulate renin release.<sup>45</sup>

Vascular volume is also regulated by the control of vasopressin over water metabolism. Arginine vasopressin (AVP) is synthesized as a prohormone in the magnocellular neurons in the supraoptic and paraventricular nuclei of the hypothalamus and transported to axon termini in the posterior pituitary gland.<sup>46</sup> There, the prohormone is processed to AVP and released constitutively at low levels. The magnocellular neurons receive input from cardiovascular control centers in the medulla that receive impulses from the baroreceptors of the carotid bodies and the aortic arch. AVP secretion is stimulated when blood pressure decreases, markedly so in hypovolemic shock. The magnocellular neurons also are innervated by osmoreceptor centers in the anterior hypothalamus that trigger AVP release when plasma osmolality increases. AVP release is also stimulated by prostaglandins, angiotensin II, and norepinephrine through  $\alpha_1$ -receptors, but inhibited by NO, ANP, and norepinephrine binding to  $\alpha_2$ - and  $\beta$ -receptors.<sup>47,48</sup>

AVP binds to a family of receptors on a variety of tissues including vascular smooth muscle and the kidney, where it exerts pressor and antidiuretic effects, respectively.<sup>49</sup> Binding of AVP to  $\text{V}_1$  receptors on vascular smooth muscle cells activates phospholipase C and stimulates the production of inositol triphosphate and diacylglycerol through the  $\text{G}_{q/11}$  pathway.<sup>50</sup> These second messengers in turn increase protein kinase C activity, leading to increased intracellular  $\text{Ca}^{++}$  concentration and contraction of the actin-myosin complex. AVP also binds to  $\text{V}_2$  receptors on the distal convoluted tubule and collecting ducts of the kidney where, via a cyclic adenosine monophosphate (cAMP)-dependent

pathway, it leads to insertion of Aquaporin-2 water channel proteins into the membrane of the luminal surface of the collecting ducts, enhancing the reabsorption of water.<sup>51</sup>

Although not as actively regulated as the above systems, blood volume is also influenced by the balance between the hydrostatic and oncotic forces at the capillary level. The movement of water and proteins across the capillaries provides for a relatively passive, but significant, mechanism for regulating intravascular volume.

### Erythropoiesis—Regulation of Oxygen Content

Oxygen delivery can also be enhanced by increasing the amount of oxygen delivered. This can be accomplished quickly through red cell transfusion, or physiologically, although more slowly, through erythropoiesis. The production of erythropoietin by cortical interstitial cells of the kidney in response to hypoxia is covered in more detail in Chapter 2. Upregulation of the transcription of the erythropoietin gene occurs rapidly after the onset of hypoxia, and is mediated by hypoxia inducible factor-1 $\alpha$  (HIF), which forms a transcription factor complex with other proteins.<sup>52</sup> Although the increase in erythropoietin production in response to hypoxia is prompt, the increase in the hematocrit is not seen for several days. Thus, this adaptation represents a long-term adjustment.

---

## Regulation of Regional Oxygen Delivery

Blood flow to different organs is tailored to their levels of metabolic activity at rest, and actively altered to meet episodic physiologic needs, such as exercise or digestion. Blood flow is controlled by a mix of intrinsic and extrinsic systems. The local, intrinsic control mechanisms that operate in all organs facilitate the appropriate matching of oxygen delivery to metabolic need, while central control mechanisms make it possible to prioritize the distribution of blood flow among different organs and to preserve flow to critical organs such as the brain and heart. (See Table 3-2.)

### Coronary Circulation

Blood flow through the coronary circulation is greatest in the left ventricle, about half of that level in the right ventricle, and only a quarter of the left ventricular rate in the atria. Myocardial  $\text{O}_2$  consumption can increase by about five-fold during peak work, but is matched by a comparable increase in blood flow.<sup>53</sup> Even at rest, the myocardium extracts approximately 70% of the  $\text{O}_2$  delivered, which is much higher than any other resting tissue; thus, increased metabolic demands must be met by increased blood flow.<sup>54</sup> In the resting state, only about half of the myocardial capillary beds are open to perfusion in the resting state<sup>55</sup>; however, in hyperemia, additional capillary beds are recruited to augment flow.<sup>56</sup> Although the myocardial vasculature receives low-density innervation from the autonomic nervous system, blood flow is governed chiefly by intrinsic or metabolic regulatory mechanisms.<sup>57</sup> During sympathetic stimulation of heart rate and cardiac

CNS = central nervous system

work, the weak sympathetic signal for vasoconstriction is overridden by intrinsic factors that increase blood flow to meet elevated O<sub>2</sub> demands. Similarly, while vagal release of acetylcholine would be expected to stimulate vasodilation, the decreased metabolic demands of the myocardium under parasympathetic influence leads to vasoconstriction, as intrinsic systems for matching blood flow and cardiac activity supersede autonomic input.

The nature of metabolic flow regulation of the coronary circulation is still unclear.<sup>58</sup> Several models have been proposed to account for the autoregulatory behavior of the coronary circulation. It was recognized early that hypoxemia and hypercapnia both produce vasodilation, and in a synergistic manner.<sup>59</sup> Prostaglandin-mediated vasodilation in response to low PO<sub>2</sub> levels has been shown to play a role in epicardial arterioles, but it is probably not a major factor in the regulation of coronary blood flow in hypoxia.<sup>60,61</sup> Hypercapnia (or the associated acidosis) has also been suggested to trigger autoregulatory responses from the arteriolar wall, or the subjacent myocardium via such mediators as adenosine, NO, or ATP-dependent K<sup>+</sup> channel activity.<sup>62</sup> However, while NO and ATP-dependent K<sup>+</sup> channel activity may contribute to vasomotor tone in the resting coronary arteries, none of these three mediators are responsible for local metabolic control during exercise.<sup>57</sup> It has also been hypothesized that release of ATP by red cells responding to hemoglobin desaturation<sup>63</sup> or NO released from S-nitroso-hemoglobin<sup>64</sup> might mediate a vasodilatory response in the coronary circulation.

The myocardial circulation is also unique in that flow varies with the mechanical activity of the heart, with most flow occurring during diastole; during systole, blood flow through the coronary capillaries comes to a virtual standstill. Blood flow is also unevenly distributed throughout the myocardium.<sup>65</sup> Compression forces are highest near the endomyocardium, and diminish progressively toward the epicardium.<sup>66</sup> To compensate, the internally located arterioles are more dilated than those nearer the epicardium. One consequence of this local

adaptation is that the subendomyocardial arterioles have less capacity to compensate for increased myocardial activity or anemia by further vasodilating, making this tissue particularly vulnerable to ischemia. The very high rate of O<sub>2</sub> utilization also makes the myocardium particularly sensitive to interruptions in blood flow. O<sub>2</sub> reserves are quickly depleted and within minutes the myocardium must switch to anaerobic glycolysis—thus generating lactic acid and, as ATP stores are drawn down and not replenished, inorganic phosphate. This further impairs muscle contraction. One protective feature of the myocardial circulation in some mammals, including humans, is the existence of collateral circulation, and the ability to stimulate its growth in response to decreased blood flow.

### Cerebral Circulation

About 15% of the cardiac output perfuses the brain, which, at rest, extracts approximately 35% of the delivered O<sub>2</sub>. Because gray matter has a much higher rate of oxidative metabolism than white, it receives a disproportionate fraction of the blood flow. The maintenance of ion homeostasis and membrane potentials is energy intensive and consumes a large proportion of the ATP generated by the neurons, which depend on a constant supply of O<sub>2</sub> and glucose. The O<sub>2</sub> reserves of the brain are very limited so that even brief periods of ischemia can produce hypoxia and irreversible cell damage because glycolysis cannot meet the energy demands of the neuron.

Cerebral blood flow is subject to both extrinsic and intrinsic regulation, although the latter is dominant, as is the case with the coronary circulation. Unlike other tissues, however, the brain also has the ability to control blood flow to other organs through autonomic output, and thus to protect its own blood supply. Extrinsic, autonomic innervation of resistance vessels in the brain has relatively weak effects on blood flow, and the blood-brain barrier excludes many humoral vasoactive molecules. Sympathetic input serves chiefly to shift the autoregulatory

curve to higher pressures, thereby protecting the brain from sympathetic-driven increases in blood pressure.<sup>67</sup> The parasympathetic system probably plays little part in autoregulation but has been implicated in ischemia and migraine.<sup>68</sup>

Cerebral resistance vessels and perivascular astrocytes both receive input directly from intrinsic CNS neurons (the neurovascular unit) located in the nucleus basalis, locus coeruleus, and raphe nucleus, which modulate vascular tone.<sup>67</sup> The projections of these intrinsic neurons contain acetylcholine, nitric oxide synthase (NOS), norepinephrine or 5-hydroxytryptamine, depending on their source. Perivascular astrocytes respond to these transmitters, as well as glutamate,  $\gamma$ -aminobutyric acid and ATP, and their endfeet are particularly rich in noradrenergic receptors, NOS,  $\text{Ca}^{++}$ -activated  $\text{K}^+$  channels, and purinergic receptors. These astrocytes release various vasoactive molecules such as ATP, adenosine, and NO, and exert both vasoconstrictive and vasodilatory influences via the release of 20-hydroxyeicosatetraenoic acid, or prostaglandin E2 and epoxyeicosatrienic acid, respectively.<sup>69</sup> The level of NO appears to influence which of these vasoactive molecules is produced. Astrocytes also release  $\text{K}^+$  via a  $\text{Ca}^{++}$ -activated channel that causes hyperpolarization of smooth muscle cells and may be responsible for their relaxation, although its role in functional hyperemia is not completely understood.<sup>70,71</sup>

The autoregulatory mechanisms of the brain maintain adequate cerebral blood flow over a wide range of arterial blood pressures (between 60 and 140 mmHg) and can adapt to even higher pressures in the face of chronic hypertension or acute sympathetic stimulation. These cerebral autoregulatory mechanisms also adapt to the considerable spatial and temporal heterogeneity of oxygen requirements<sup>72</sup> as reflected in the wide variation in tissue  $\text{PO}_2$  and hemoglobin  $\text{O}_2$  saturation throughout the brain demonstrated by studies using blood oxygen-dependent functional magnetic resonance imaging.<sup>73</sup> Increases in regional brain neural activity that increase metabolic demands trigger increased blood flow, probably by producing a temporary decrease in tissue  $\text{PO}_2$ .<sup>74-76</sup> Short-term responses to changes in cerebral  $\text{PO}_2$  appear to be mediated by  $\text{O}_2$ -sensitive  $\text{K}^+$  channels that are reversibly inhibited by hypoxia.<sup>77,78</sup> Gene transcription and protein synthesis may also be downregulated, the latter through inhibition of the function of eukaryotic initiation factors 1 and 2, as well as eukaryotic elongation factor 2,<sup>79-81</sup> thereby limiting the metabolic demands of the neurons.<sup>82</sup> Adaptation to persistent reduction in  $\text{O}_2$  supply requires changes in gene expression. Several  $\text{O}_2$ -sensitive transcription factors have been shown to respond to hypoxia, leading to changes in gene expression among them HIF, nuclear factor  $\kappa\text{B}$ , activator protein-1, and early growth response protein-1; however, the HIF system appears to play the central role in responses to changes in tissue  $\text{PO}_2$ . Among the scores of HIF-regulated genes are those that affect the regulation of vascular tone, angiogenesis, erythropoiesis, cell metabolism, and pH regulation.<sup>83</sup>

The cerebral circulation is also distinctive from others in its responsiveness to levels of  $\text{CO}_2$ . In fact, it appears to be even more sensitive to changes in arterial and tissue  $\text{PCO}_2$  than  $\text{PO}_2$ .<sup>84</sup>

Even small increases in the  $\text{P}_a\text{CO}_2$  stimulate vasodilation of cerebral arterioles.<sup>85</sup> Hypercapnic vasodilation may be mediated through effects on tissue pH, which decreases as the  $\text{PCO}_2$  rises. Because neuronal function is markedly impaired by increased  $\text{H}^+$  concentration, maintenance of constant pH is a critical process. There is also evidence that hypercapnia triggers closing of ATP-sensitive  $\text{K}^+$  channels.<sup>86</sup>

## Pulmonary Circulation

In contrast to the circulation through the brain and heart, the pulmonary circulation is a low-pressure, high-flow-rate system. Pulmonary pressures and resistances are only about a fifth of those found in the systemic circulation, although the entire blood volume circulates through the lungs approximately every minute. Ordinarily, only about 500 mL of blood are in the pulmonary vasculature. However, the vasculature can accommodate much larger volumes, particularly in the pulmonary veins, without a marked increase in resistance, thereby protecting the lungs from edema in the event of reduced left ventricular function or volume overload.<sup>87</sup>

Unlike the coronary and cerebral circulations, blood flow through the lungs is affected by both extrinsic and intrinsic factors and is highly responsive to its environment. Sympathetic innervation increases pulmonary vascular tone, although parasympathetic stimulation has little effect.<sup>88</sup> Some regulatory molecules also increase vascular tone, including angiotensin, serotonin, and prostaglandin F. Others, such as bradykinin and prostaglandin E1, reduce pulmonary resistance.

Hypoxic pulmonary vasoconstriction is a paradoxical but distinctive feature of the pulmonary vasculature.<sup>89</sup> Precapillary arterioles respond to the relative hypoxia of underventilated regions of the lung by constricting, thereby reducing flow and diverting it to better oxygenated alveoli. Pulmonary hypertension is prevented by the capacity of other vascular beds to absorb the diverted volume; however, widespread hypoxia may result in pulmonary hypertension.<sup>90</sup> The mechanism for hypoxic pulmonary vasoconstriction is not completely understood. Hypoxia has been shown to stimulate a small increase in the intracellular concentration of  $\text{Ca}^{++}$  in the smooth muscles of the pulmonary arteries. The effect of these small changes in  $\text{Ca}^{++}$  on smooth muscle actin-myosin contraction may be enhanced by "sensitizers" such as the Rho kinase signal transduction system.<sup>89,91</sup> It has also been observed that under conditions of hypoxia, NO consumption by red cells increases because of formation of hemoglobin  $\text{Fe}^{++}\text{NO}$ , which may potentiate other vasoconstrictive influences operative in this pulmonary reflex.<sup>92</sup> The pulmonary vasoconstrictive response to hypoxia is enhanced by metabolic acidosis<sup>93</sup> but muted by metabolic and respiratory alkalosis. This response is also decreased by various medications, including nitroprusside and some inhalational anesthetics, and in turn produces a decrease in the  $\text{P}_a\text{CO}_2$ .<sup>94</sup>

Circulation of blood through the lungs serves other purposes in addition to respiratory gas exchange with the alveoli and metabolic support of lung tissue. The lungs are also the site of the removal or inactivation of various vasoactive molecules

(eg, vasopressin, norepinephrine, acetylcholine), mediators of inflammation (eg, bradykinin, leukotrienes, prostaglandins E and F), and some medications (eg, propranolol, lidocaine, fentanyl) that in turn may have effects on vascular tone and blood flow. In addition, circulation of blood through the pulmonary bed serves to filter the venous return before its distribution through the arterial tree.

### **Skeletal Muscle Circulation**

At rest, the skeletal muscles of the body receive about 20% of the cardiac output. Skeletal muscle is heterogeneous, consisting of phasic fibers (glycolytic, rapid twitch) and tonic fibers (oxidative, postural). The majority of blood flow goes to the tonic fibers when the body is at rest, which is reflected in the higher density of the capillary beds around these muscle bundles. During exercise, however, the increased metabolic demands of the phasic fibers may be met with up to a 20-fold increase in blood flow.<sup>95,96</sup> Because most of the capillary beds are perfused at rest, increased flow is achieved through arteriolar dilation and increased red cell flux through the capillaries.<sup>97-99</sup> The hematocrit in the capillaries may rise from 10% to 15% at rest to 40% to 50% during hyperemia.<sup>99,100</sup> Given the striking ability to increase flow to actively exercising muscle, central cardiovascular control is required to prevent systemic hypotension and inadequate flow to other tissues.<sup>101,102</sup> Muscle can also extract more O<sub>2</sub>, increasing from a baseline oxygen extraction ratio of 25% to 30% to as much as 90%.

As is the case for the myocardium, blood flow in skeletal muscle is episodically interrupted by contraction and compression of the arterial vasculature, although red cells are still present in the capillaries during contraction and oxygen extraction continues, albeit at a reduced rate.<sup>103</sup> During periods of relaxation, the dilation of the arterioles and the opening of capillary beds also compensate for interruptions in flow. Indeed, there is evidence suggesting that contraction can activate a mechanosensitive response by the vascular endothelium or smooth muscle that stimulates vasodilation.<sup>104,105</sup> When contraction is sustained, however, tissue O<sub>2</sub> is quickly depleted, anaerobic glycolysis generates lactic acid, and ischemic pain is experienced.

Unlike the myocardium, blood flow to skeletal muscle is controlled by both extrinsic and intrinsic factors.<sup>106</sup> The arterioles in skeletal muscle are densely innervated with sympathetic nerves that maintain vascular tone and a tonic state of partial vasoconstriction. Arteriolar vasomotor tone is controlled centrally via reflex changes in autonomic output accompanying volition to exercise and in response to the arterial baroreflex. Additional sympathetic stimulation can produce greater vasoconstriction. In exercise, however, central autonomic sympathetic signals are overridden by intrinsic cues that trigger vasodilation. This occurs despite the fact that skeletal muscle also invokes the exercise pressor reflex, which augments blood pressure and heart rate through increased sympathetic outflow from the brainstem.<sup>107</sup> Mechanical<sup>108</sup> and/or chemical muscle receptors stimulated by muscle activity relay impulses to the dorsal horn of the spinal cord.<sup>109</sup> These impulses project onto many of the same nuclei in

the medulla that mediate the baroreflex pathway, among them the solitary tract nucleus and the rostral ventrolateral nucleus.<sup>110</sup>

Two other mechanisms have been implicated in the control of sympathetic output during exercise. Stimulation of the otoliths and vestibular system of the inner ear (by motion for example) enhances sympathetic activity of skeletal muscle and has been shown to produce vasoconstriction in the muscles of the forearm and calf.<sup>111,112</sup> In addition, elevated or reduced muscle temperature, respectively, increase or decrease sympathetic outflow during forearm exercise.<sup>113,114</sup>

### **Renal Circulation**

The kidneys receive about 20% of the cardiac output, a volume that considerably exceeds the flow required for perfusion. In part, the high flow reflects the metabolic demands of the kidney. Tubular reabsorption of sodium is an energy-intensive activity, consuming large amounts of O<sub>2</sub>. In addition, the kidneys require high flow to maintain hydrostatic pressure, which is the driving force for glomerular filtration. Renal blood flow is autoregulated to maintain a relatively constant rate of glomerular filtration over a wide range of arterial pressures by balancing the tone of the afferent and efferent arterioles serving the glomeruli. Two intrinsic systems interact to control blood flow through the kidneys.<sup>115</sup> The smooth muscle of the renal afferent arterioles responds to systemic arterial pressure by constricting when pressures increase and dilating as pressures decrease, ensuring constant blood flow. This myogenic response functions rather slowly, and does not compensate for fluctuations in systemic pressures of short duration (seconds).<sup>116</sup> The tubuloglomerular feedback mechanism is based on the macula densa responding to changes in blood flow with the release of vasoactive mediators, including adenosine, ATP, and NO, from the juxtaglomerular apparatus, in addition to renin as described above.<sup>117-119</sup> These vasoactive mediators affect local flow.

### **Splanchnic Circulation**

The circulation to the organs of the splanchnic bed is much more subject to central control than the circulation in other areas of the body. This circulation is characterized by dual control by organ-specific factors as well as the CNS. The arterioles of the splanchnic organs are particularly well innervated by sympathetic nerves but are also highly sensitive to the vasoconstrictors vasopressin and angiotensin II. These signals are capable of triggering intense vasoconstriction and reduction of flow under circumstances when blood must be diverted to other organs, as occurs in exercise or hemorrhage. In the absence of such demands, blood flow to the abdominal organs responds to local cues. Following meals, the metabolic needs of the digestive organs to support the secretion of acids and digestive enzymes or the adsorption and transport of nutrients, trigger increased blood flow to these tissues. This blood flow can double over a period of several hours following meals. The increased flow is largely achieved by opening capillary beds that were previously underperfused.<sup>120</sup> Gastrointestinal hormones and neuropeptides

released by cholinergic stimulation play a role in stimulating postprandial blood flow as do local mediators, including prostaglandins,<sup>121</sup> adenosine,<sup>122</sup> and NO.<sup>123</sup> Long chain fatty acids stimulate hyperemia of the proximal small intestine,<sup>124</sup> while bile acids evoke increased blood flow to the distal ileum.<sup>125</sup> Glucose has the most marked hyperemic effect of any of the nutrient stimulators of blood flow.<sup>126</sup>

The liver receives about 75% of its blood supply through the portal vein, which provides relatively deoxygenated blood. The remainder, which comes from the hepatic artery, is comparatively oxygen-rich. Blood flow from these two sources is controlled reciprocally to prevent congestion of the hepatic sinusoids, which could cause excessive filtration of water and plasma proteins through their highly permeable barriers.<sup>127</sup> A hyperdynamic splanchnic circulation with extensive portal-systemic shunting is typical of cirrhotic patients and plays a role in the development portal hypertension. The process is thought to be initiated by arterial vasodilation and has been related to NO overproduction.<sup>128</sup>

## Regulation of Oxygen Delivery in the Microcirculation

### The Microcirculation

The primary function of the microcirculation is to serve as a platform for the exchange of respiratory gases, nutrients, by-products of metabolic activity, and heat. The microvascular unit is composed of a reticulum of blood vessels with diameters less than 250 microns that lie between the arteries and the veins.<sup>1</sup> These beds of small vessels are dense in tissues with high metabolic activity and relatively sparse in tissues whose energy demands are modest. The arterioles arborize into a network of vessels that progressively decrease in caliber to form the terminal arterioles, with diameters of around 10 microns. The capillaries, which consist of a single layer of epithelial cells, have diameters of 3 to 10 microns, and drain into the postcapillary venules, and then to the venules.

Oxygen is delivered to the tissues by both convective and diffusive forces. Convection (blood flow) brings oxygenated blood to the microvascular unit. As oxygen is transferred from the incoming blood to the tissue, a longitudinal O<sub>2</sub> concentration gradient is created parallel to the direction of flow as more O<sub>2</sub> is extracted from the blood.<sup>129</sup> A second, radial, O<sub>2</sub> concentration gradient exists between the blood and the tissue surrounding the vessel, which is the driving force for O<sub>2</sub> diffusion into the tissue.<sup>130-132</sup> However, oxygen exchange in the microvascular unit involves more than the simple transfer of O<sub>2</sub> from red cell to tissue. Most O<sub>2</sub> is extracted from the blood at the level of the arterioles, particularly in skeletal muscle, with much of it being consumed by the arteriolar wall<sup>132</sup> to support smooth muscle activity and endothelial cell metabolism, including synthesis of NO, which requires molecular O<sub>2</sub>.<sup>133,134</sup> The O<sub>2</sub> concentration in the capillaries is generally near equilibrium with the surrounding

tissue so there is no gradient to drive O<sub>2</sub> into the tissues at that level.<sup>133</sup> The arterioles also serve as a source of O<sub>2</sub> to deoxygenated red cells flowing through capillaries<sup>135,136</sup> and the capillaries themselves exchange O<sub>2</sub> as well.<sup>136-138</sup> The extensive diffusion of O<sub>2</sub> among all of these elements of the microvascular unit is thought to be the basis for relatively homogeneous tissue oxygenation despite the considerable heterogeneity of blood flow through the capillaries.<sup>139</sup>

Under unstressed conditions, there is considerable temporal and spatial variability in blood flow through the capillary beds of the microcirculation. Depending on the tissue, only a quarter to a third of the capillaries are perfused at any time. When metabolic demands increase, however, a greater number of capillaries are perfused, increasing the effective area for O<sub>2</sub> exchange. Blood flow is actively regulated at the level of the resistance vessels as well as by changes in the vascular tone of the microvascular unit. Vasodilation is associated with decreased O<sub>2</sub> consumption by the arterial wall, which reflects decreased demand by smooth muscle, and thus a decreased O<sub>2</sub> gradient across the arterial wall.<sup>130</sup> More arterial O<sub>2</sub> is therefore available to the adjacent tissue.<sup>130,140-143</sup> A direct relation exists between intravascular PO<sub>2</sub>, arterial wall oxygen consumption, and microvascular tone.<sup>140,142,143</sup>

### Regulation of Microcirculatory Blood Flow

Blood flow through the microcirculation is controlled largely by intrinsic mechanisms, including pressure flow autoregulation, active hyperemia, and reactive hyperemia.<sup>144</sup> Pressure flow autoregulation refers to the ability of a tissue to maintain relatively constant blood flow over a wide range of systemic arterial blood pressures, vasodilating in response to elevated pressures and contracting when mean arterial pressure decreases. The effectiveness of this pressure-activated response is variable, but is generally robust in metabolically active tissues that must protect their oxygen supply. Active hyperemia is the ability of a tissue to meet metabolic demand by varying blood flow and the number of perfused capillaries, and is characteristic of tissue with episodic energy demands, such as skeletal muscle and the gastrointestinal tract.<sup>145</sup> Reactive hyperemia is the transient increase in blood flow, above baseline levels, which occurs after release of blood flow occlusion. The period of reactive hyperemia is usually proportional to the period of reduced flow, presumably reflecting the intensity of the hypoxic driver. All of these autoregulatory responses have been attributed to myogenic or metabolic mechanisms, although elements of both probably contribute to all of these phenomena.

The myogenic theory is based on the observation that vascular smooth muscle contracts when the tension or stretch of the arteriolar wall is increased and relaxes when tension drops. Smooth muscle cells respond to increased intraluminal pressure/stretch by depolarizing. This depolarization leads to activation of L-type voltage gated Ca<sup>++</sup> channels, Ca<sup>++</sup>-dependent activation of myosin light chain kinase, and actomyosin contraction.<sup>146</sup> This intrinsic, myogenic response explains pressure flow autoregulation and reactive hyperemia, but cannot account for active hyperemia, or responses to increased metabolic demand.

The metabolic theory is based on the coupling of flow to the level of  $O_2$  consumption of the tissue, and the observation that many metabolic by-products, such as  $CO_2$ ,  $O_2$ ,  $K^+$ ,  $H^+$  and adenosine, have vasoactive effects. According to this paradigm, tissue  $PO_2$  levels are read by an oxygen sensor of unknown identity. This sensor modulates the release of mediators of vascular tone including endothelin, NO, prostaglandins, and others. The sensor might be in the tissue itself, although the very rapid adjustments to flow and its sensitivity to intravascular  $PO_2$  are not entirely consistent with this location. It has also been suggested that the vessel walls—particularly the arterioles, which are the sites of  $O_2$  consumption and transfer—and/or red cells may serve as the sensors.<sup>147</sup>

Endothelial cells play a key role in integrating and conducting local vasoregulatory stimuli.<sup>148</sup> These cells act as signal transducers in their own right (eg, releasing NO in response to changes in shear stress)<sup>149</sup> but also serve as conduits to communicate signals along blood vessels through intercellular connections formed with adjacent endothelial cells.<sup>150</sup> Gap junction channels composed of connexins link endothelial cells to one another as well as to smooth muscle cells.<sup>151</sup> Six connexin subunits, proteins with four transmembrane-spanning domains, combine to form a hemichannel. Alignment of hemichannels on adjacent cells produces a complete gap junction. Through these connections, endothelial cells transmit signals as far as 1 mm, reaching resistance arterioles and influencing vasoactivity,<sup>152,153</sup> thereby accommodating increased flow through one capillary bed without diverting blood from another.<sup>148</sup> This property is called the conducted vasomotor response.

Endothelial cells exert their vasoregulatory effects through at least four mediators: endothelin, NO, prostaglandins, and endothelium-derived hyperpolarizing factor.

### Endothelin Regulation of Microcirculatory Blood Flow

Endothelin is a vasoconstrictor (usually) secreted by endothelial cells in response to a wide variety of signals.<sup>154</sup> Endothelial cells synthesize three isoforms of endothelin, of which endothelin-1 (ET-1) is the most important in terms of effect on vascular tone.<sup>155</sup> It is present in particularly large quantities in the pulmonary vasculature where its release is stimulated by hypoxia, but it is found throughout the vascular tree.<sup>156</sup> Endothelin is synthesized as preproendothelin-1 and then processed to big-ET-1 and ET-1 by ET-converting enzymes, a family of multiple metalloproteases.<sup>157</sup> ET-1 is secreted at low levels constitutively, primarily toward the basolateral side of the endothelial cells, and so acts principally as a local mediator rather than as a circulating hormone. ET-1 secretion is stimulated by vasoconstrictors (angiotensin II, vasopressin, norepinephrine), thrombin, several inflammatory cytokines, and physicochemical factors (low shear stress, hypoxia). Its release is inhibited by vasodilators such as NO, prostaglandins  $E_2$  and  $I_2$ , ANP, BNP, and bradykinin, as well as high levels of shear stress.<sup>158</sup>

ET-1 binds to one of two different G protein coupled receptor types found on the smooth muscle of blood vessels, the atrium,

and the ventricle. Binding of ET-1 to endothelin A receptors stimulates vasoconstriction via several signal transduction pathways.<sup>159</sup> Activation of the phospholipase C and 1,4,5-inositol triphosphate pathways elevates intracellular  $Ca^{++}$  concentration, which stimulates myosin light chain phosphorylation and contraction. ET-1 binding also inhibits myosin light chain phosphatase through activation of the Rho/Rho kinase pathway. Finally, ET-1 enhances phosphorylation of thin-filament associated protein through activation of c-Src, Janus tyrosine kinase, and protein tyrosine kinase, which stimulates extracellular signal-regulated kinases 1 and 2 (ERK1/2).<sup>160</sup>

Endothelin B receptors also mediate contraction of smooth muscle; however, they are found predominantly on endothelial cells.<sup>158</sup> When ET-1 binds to B receptors on endothelial cells, it stimulates release of NO and prostacyclin and produces a vasodilatory response in the adjacent smooth muscle. Exogenous endothelin administered to rats has been shown to have an initial vasodilatory (hypotensive) effect followed by a prolonged vasoconstrictive (hypertensive) effect, reflecting the dual nature of the A and B receptors.<sup>161</sup> ET-1 also stimulates production of vascular endothelial growth factor and potentiates the effects of platelet-derived growth factor and transforming growth factor- $\beta$ .

### Nitric Oxide Regulation of Microcirculatory Blood Flow

NO, or endothelium-derived relaxing factor, is synthesized from L-arginine and molecular oxygen by the enzyme NOS in a number of tissues but most notably in the vascular endothelium. The three isoforms of NOS (endothelial, inducible, and neuronal) are all activated in response to several mediators, including acetylcholine, bradykinin, ATP, and adenosine diphosphate (ADP), via G protein coupled receptors on the endothelial cell membrane that increase the level of intracellular  $Ca^{++}$ . NOS is a dimeric enzyme with a catalytic heme group and a zinc-thiolate domain, which is primarily structural.<sup>162</sup> It is localized principally in the caveolae of the plasmalemma and is inhibited by the major scaffold protein, caveolin-1, to which it is bound. When intracellular levels of  $Ca^{++}$  increase, calcium binds to calmodulin, which in turn displaces NOS and permits it to become catalytically active.<sup>163</sup>

In the vessel wall, NO released by endothelial cells diffuses to smooth muscle where it binds to guanylate cyclase coupled receptors and stimulates cyclic guanosine monophosphate (cGMP) synthesis.<sup>164,165</sup> The increase in cGMP level activates protein kinase G and produces muscle relaxation by opening  $K^+$  channels and/or decreasing the responsiveness of the contractile machinery to  $Ca^{++}$ ,<sup>166</sup> as well as modulating mitochondrial respiration.<sup>167</sup> Most vascular endothelial cells constitutively secrete low levels of NO, with the notable exceptions of the cerebral and coronary vessels.

In response to hypoxia, NO released by endothelial cells produces vasodilation, which results in redistribution of blood flow and the opening of more capillary beds.<sup>168</sup> Another factor influencing the production of NO (and endothelin) is shear stress, a property of a moving fluid that is influenced directly by its viscosity. Endothelial cells respond to decreases in shear stress

that occurs because of reduction of either flow velocity or blood viscosity (eg, anemia). In response to reduced shear stress, endothelial cells downregulate NO production and release, and increase endothelin release, resulting in vasoconstriction.<sup>169</sup> In animal models of hemorrhagic shock or isovolemic hemodilution, restoration of mean arterial pressure and capillary perfusion was better achieved with asanguinous fluids with higher viscosity compared to those with lower viscosity.<sup>170,171</sup> These effects were shown to be mediated by NO production based on direct measurement of NO by microelectrode and their abrogation by the presence of the NOS inhibitor N-nitro-L-arginine methyl ester, or in NOS-deficient mice.<sup>172</sup> In the same animal systems, equivalent restoration of microvascular flow was achieved with red cells whether they contained oxyhemoglobin or methemoglobin. These results suggest that the maintenance of blood viscosity, rather than oxygen delivery, was primarily responsible for successful maintenance of tissue perfusion.<sup>173,174</sup>

NO has wide-ranging effects beyond the vascular wall. In addition to its influence on vascular smooth muscle, NO also modulates systemic hemodynamic responses to hypovolemia, anemia, and hypoxia.<sup>175</sup> The vascular-dependent effects of NO on the heart include regulation of coronary tone, thrombogenicity, and angiogenesis. In addition, NO affects myocardial cell excitation-contraction coupling, mitochondrial respiration, and responses to autonomic input. Low levels of NO have a positive inotropic effect, while high levels have a negative inotropic effect. Negative chronotropic effects are mediated through the neuronal form of NOS in the cardiac ganglia, and the endothelial form in the myocardium.<sup>175</sup> NO released into the vascular lumen inhibits platelet aggregation and adhesion as well as leukocyte adhesion to the endothelium by interfering with the function of the CD11/CD18.<sup>162,176</sup>

### Prostaglandin Regulation of Microcirculatory Blood Flow

Prostaglandins are another set of molecular signals that endothelial cells release to modulate the activity of vascular smooth muscle. Arachidonic acid is released from the plasma membrane through the action of phospholipase A<sub>2</sub> and then metabolized to various eicosanoids by COX and other enzymes.<sup>177</sup> The COX-1 isoform is expressed in endothelial cells of the vascular wall and is responsible for a key step in the pathways that lead to the synthesis of both vasodilators [such as prostacyclin (PGI<sub>2</sub>), prostaglandin E<sub>2</sub> (PGE<sub>2</sub>), and prostaglandin D] and vasoconstrictors (such as prostaglandin F<sub>2</sub> and thromboxane). The major products in endothelial cells, however, are the vasodilators PGI<sub>2</sub> and PGE<sub>2</sub>. COX-2 is an inducible form of the enzyme that is also expressed by endothelial cells in inflammatory states and, in vitro, by prolonged periods (hours) of shear stress, stretch, hypoxia, or exposure to inflammatory cytokines, growth factors, or ET-1. Expression of COX-2 in response to these stimuli also leads to secretion of PGI<sub>2</sub>; however, it is not clear that there is a role for COX-2 in unstressed conditions.<sup>178</sup>

PGI<sub>2</sub> diffuses from the endothelial cell to the smooth muscle. The surface membrane of the smooth muscle cell expresses

a family of eicosanoid receptors.<sup>179</sup> The IP and EP<sub>2</sub> receptors for PGI<sub>2</sub> and PGE<sub>2</sub>, respectively, mediate vasodilation, whereas the TP receptors for thromboxane produce vasoconstriction. PGI<sub>2</sub> binding to the G-protein-coupled IP receptor activates adenylate kinase and increases cAMP levels. cAMP stimulates protein kinase A activity, which opens K<sup>+</sup> channels and causes membrane hyperpolarization; this, in turn, closes voltage-sensitive Ca<sup>++</sup> channels. The decrease in intracellular Ca<sup>++</sup> concentration results in relaxation of the smooth muscle cell and vasodilation.<sup>166</sup>

PGI<sub>2</sub> release is stimulated by bradykinin and hypoxia.<sup>178</sup> Conversely, hyperoxia has been shown to inhibit synthesis and release of vasodilator prostaglandins from endothelial cells and permit vasoconstriction, an effect that is independent of NO.<sup>180</sup>

### Endothelium-Derived Hyperpolarizing Factor in the Regulation of Microcirculatory Blood Flow

Endothelium-derived hyperpolarizing factor (EDHF) is a term used to define an as-yet-unidentified molecule (or process) that originates with the endothelial cell and produces smooth muscle relaxation, independently of NO or prostaglandins.<sup>152</sup> EDHF causes hyperpolarization of the smooth muscle membrane by activating K<sup>+</sup> channels that, in turn, close voltage-sensitive Ca<sup>++</sup> channels and elicit relaxation, as described for NO and PGI<sub>2</sub>. The mechanism whereby the endothelial cell produces this hyperpolarization of the smooth muscle cell membrane has not been completely worked out. The one step of the process that is well understood is the response of endothelial cells to agonists such as ATP. ATP increases the concentration of intracellular Ca<sup>++</sup> via activation of phospholipase C and inositol triphosphate-gated Ca<sup>++</sup> channels.<sup>181</sup> Several mechanisms have been proposed to explain how endothelial cells induce hyperpolarization of the smooth muscle cell membrane. One proposal is that the increase in endothelial cell intracellular Ca<sup>++</sup> leads to the synthesis and release of epoxyeicosatrienoic acids that open large-conductance, calcium-activated K<sup>+</sup> channels in the smooth muscle membrane, causing hyperpolarization.<sup>182,183</sup> K<sup>+</sup> itself, released from activated endothelial cells, may activate the inwardly rectifying K<sup>+</sup> channel (K<sub>ir</sub>) or Na/K ATPase in the smooth muscle cell, producing hyperpolarization.<sup>184,185</sup> It has also been suggested that the gap junctions between endothelial cells and smooth muscle cells either transmit the EDHF or propagate the hyperpolarizing current from cell to cell.<sup>186,187</sup> Finally, H<sub>2</sub>O<sub>2</sub> (produced by superoxide dismutase from the superoxide ion generated by endothelial cell NO) has been shown to activate several K<sup>+</sup> channels and elicit hyperpolarization.<sup>188</sup>

The physiologic role for EDHF is not completely understood.<sup>152</sup> EDHF-like dilations have been demonstrated in a wide variety of arteries and arterioles in vitro and in vivo. It is particularly prominent in smaller vessels, and may even supersede NO in some tissue beds. These observations suggest that EDHF may be a significant factor in regulating flow through the microcirculation. EDHF may also play a role in conducted vasomotor response, a property of microcirculatory beds that is

**Figure 3-1.** Endothelial cells receive inputs from various local and systemic sources, which they coordinate into a cohesive response with outputs to the smooth muscle cells of the vascular wall, other endothelial cells, and in some cases, nerve termini and other accessory cells. They play a central role in the regulation of blood flow and oxygen delivery through the microcirculation. NO = nitric oxide; EDHF = endothelium-derived hyperpolarizing factor.

retained even when the production of prostaglandin and NO are inhibited.<sup>189,190</sup>

### Coordination of Endothelial Control Mechanisms

Endothelial cells play an integrative role in the regulation of blood flow and the microvascular level (Fig 3-1). They are the recipients of myriad inputs including neurotransmitters, growth factors, hormones, vasoactive peptides, respiratory gases, nucleotides, and cytokines, as well as mechanical stimuli such as shear stress, stretch, and gravity. They are in physical contact with other endothelial cells, smooth muscle cells, nerve endings and, in some tissues, accessory cells such as astrocytes in the CNS. The endothelial cells also send out signals of their own, including endothelin, NO, prostaglandins, EDHF, adenosine,  $K^+$ , and others. The endothelial cell integrates all of this input and translates it into a coherent response that functions to adjust vascular tone. The relative contribution of the four main endothelial signals is not uniform through the vascular tree; NO serves as the major vasodilator in conduit arteries and EDHF is the major vasodilator in arterioles.<sup>191</sup> In addition, NO tonically inhibits EDHF responses as well as prostaglandin output. These complex interactions provide for a stable but responsive platform for oxygen delivery in the dynamic environment of the microcirculation.

### The Red Cell as a Regulator of Microcirculatory Blood Flow

It has been hypothesized that the red cell, or the hemoglobin therein, is a regulator of hypoxic vasodilation.<sup>192</sup> As hemoglobin deoxygenates, it undergoes a conformational change during the transition from the relaxed (R) to the tense (T) state; hence, it

could function as an oxygen sensor in the physiologically relevant  $PO_2$  range. Several models have been proposed to explain how the conformational change accompanying hemoglobin deoxygenation could be translated into a signal for vasodilation.

One model couples the R-T transition to release of ATP from the red cell, which then binds to purinergic receptors on endothelial cells, stimulating a vasodilatory response.<sup>193-196</sup> The model is supported by observations of increased levels of ATP in venous blood after hypoxia, the secretion of ATP from hypoxic red cells in vitro, the effect of ATP on vasomotor tone, and the retrograde propagation of the vasodilatory signal from the capillaries to the precapillary arterioles.<sup>194</sup> The conformation-induced release of ATP from red cells is mediated by the cystic fibrosis transmembrane conductance regulator.<sup>197</sup>

The second set of models proposes that the release of NO from the red cell in response to hemoglobin deoxygenation and the R-T transition is responsible for the vasodilatory effect. One mechanism of vasodilation is based on the release of NO from S-nitrosylated hemoglobin as it deoxygenates.<sup>198-200</sup> Although free NO has a very short half-life, NO adducts to cysteine thiols in proteins, while readily reversible, are quite stable. The S-nitrosothiol adducts can exchange with the free NO pool or other SNO adducts (transnitrosation) and in that manner can be transported far from the site of origin.<sup>201,202</sup> NO binds to the heme group of deoxygenated hemoglobin, but transfers to the  $\beta$ -93 cysteine upon reoxygenation<sup>202</sup> and has been shown to be released in hypoxia.<sup>203</sup> The anion exchange 1 macrocomplex may facilitate the exchange of gases, including NO, across the red cell membrane.<sup>204</sup> A number of experimental observations of the enhancement of hypoxic vasodilation in the presence of red cells have also been reported, consistent with a role in regulating blood flow.<sup>165,194,205-206</sup>

A second mechanism to explain NO release from red cells is based on the observation that hemoglobin has an intrinsic, allosterically regulated enzymatic activity that reduces nitrite anion ( $\text{NO}_2^-$ ) to NO.<sup>207-209</sup> Deoxyhemoglobin has more unliganded heme groups than the oxygenated form and can bind more  $\text{NO}_2^-$ ; however, the reduction rate constants are higher for oxyhemoglobin-mediated reduction. Maximal  $\text{NO}_2^-$  reduction therefore occurs where there is a mix of oxygenated and deoxygenated heme groups in the same molecule, which occurs around the  $P_{50}$ .<sup>209</sup> The reaction consumes a proton, hence hypoxia (or hemoglobin deoxygenation to levels of 40% to 60%; ie, around the  $P_{50}$ ) and acidosis would be expected to favor the generation of NO by this route. Exogenous  $\text{NO}_2^-$  has been shown to stimulate vasodilation in model systems,<sup>207-209</sup> experimental animals, and humans.<sup>210-213</sup> It is not clear if the  $\text{NO}_2^-$  pool operates as an independent source of NO, or in fact acts as a source of Fe bound NO, which is then transferred to  $\beta$ -93 cysteine and eventually released from the red cell.<sup>198,214</sup>

### The Microcirculation in Disease

As pointed out in Chapter 9, there is a critical point at which the rate of oxygen delivery is no longer adequate to support metabolic needs (oxygen consumption). It has been shown in stressed animals (eg, inflammation, sepsis) that this point occurs at higher ratios of  $\text{O}_2$  delivered to  $\text{O}_2$  consumed, even when the latter is not elevated, suggesting that the ability to extract  $\text{O}_2$  from the blood is impaired in these pathologic states. Inadequate tissue oxygenation when gross oxygen delivery is adequate may reflect disordered microcirculation.<sup>215</sup> Shunting of  $\text{O}_2$  from arterioles to venules has been described in sepsis and systemic inflammatory states, as has reduced tissue oxygenation when flow rates are high and red cell transit times through the arterioles and capillaries are too brief for effective  $\text{O}_2$  off-loading.<sup>216</sup> Shunting of  $\text{O}_2$ -rich blood around capillary beds also occurs when there is a decrease in the fraction of capillaries perfused, as has been demonstrated to occur in models of sepsis<sup>217-220</sup> and shock,<sup>221</sup> with increased  $\text{O}_2$  extraction by those capillaries that do remain open.<sup>222</sup> It has been suggested that the increased heterogeneity (maldistribution) of blood flow and resulting tissue hypoxia that occurs in sepsis and systemic inflammatory states is an early step leading to organ failure.<sup>221,223,224-227</sup> As a result, several approaches to microvascular resuscitation have been advocated combining volume replacement, inotropes, vasodilating drugs, and restrained use of vasopressors.<sup>228</sup> NO and prostacyclin in particular have been studied in human sepsis, and these vasodilators have been found to achieve some improvement in tissue perfusion and oxygen extraction.<sup>229,230</sup>

Capillary underperfusion in disease is thought to be the result of both vessel occlusion and impaired regulation of blood flow. One factor contributing to capillary occlusion is endothelial cell edema, which can be seen in sepsis.<sup>231</sup> In addition, the activated and immature leukocytes characteristic of systemic inflammation are less malleable and may mechanically occlude capillaries. Or, the leukocytes may interact with upregulated adhesion molecules on endothelial cell membranes, impeding

their progress through the microcirculation.<sup>232</sup> Red cells also exhibit reduced deformability in sepsis<sup>233-235</sup> perhaps related to overproduction of NO.<sup>234</sup> They also bind to endotoxin-exposed endothelial cells in vitro, suggesting that they, too, might occlude the microvasculature.<sup>236-238</sup>

Finally, disseminated intravascular coagulation could also occlude vessels with microthrombi.<sup>239</sup>

Arteriolar dysfunction also contributes to impaired blood distribution through the capillary beds in pathologic states. Arterioles exhibit abnormal responses to vasoregulatory signals in animal models of sepsis.<sup>240,241</sup> In addition, it has been shown that communication between endothelial cells is disrupted by lipopolysaccharide in vitro, and in animal model systems.<sup>241-244</sup> Impaired intercellular communication may be mediated by abnormal tyrosine phosphorylation of connexin 43, one of the gap junction proteins.<sup>245,246</sup> Excess NO production seen in inflammatory states is associated with endothelial cell and smooth muscle cell injury and may be responsible for defective arteriolar responses to regulatory cues, which results in the abnormal distribution of blood flow seen in these pathologic conditions.<sup>247</sup>

### Red Cell Transfusion and the Microcirculation

The effects of red cell transfusion on the microcirculation are just beginning to be understood. Direct assessment of microvascular function in patients is difficult, although minimally invasive techniques are becoming more widely available for this application. The analytic tools that have been used in the clinical setting include the  $\text{O}_2$  microelectrode, near infrared spectroscopy (NIRS), orthogonal polarizing spectroscopy (OPS), and blood oxygen-dependent function magnetic resonance imaging (BOLDfMRI).<sup>248</sup> The use of these techniques to assess the impact of red cell transfusion in humans has been limited.

#### $\text{PO}_2$ Microelectrodes

Direct measurements of tissue  $\text{PO}_2$  by microelectrode used in an observational study to assess brain tissue oxygenation in patients with subarachnoid hemorrhage or traumatic brain injury showed that the transfusion of one unit of Red Blood Cells (RBCs) increased tissue  $\text{PO}_2$  without changing the cerebral perfusion pressure.<sup>249</sup> However, transfusion of one or two RBC units to patients after coronary artery bypass grafting did not raise the  $\text{PO}_2$  in the deltoid muscle as measured by microelectrode.<sup>250</sup>

#### Near Infrared Spectroscopy

NIRS measures the degree of hemoglobin deoxygenation in the blood vessels in the sampled tissue and has been used widely as a monitoring tool in trauma,<sup>251,252</sup> sepsis,<sup>253,254</sup> brain injury and surgery,<sup>255,256</sup> and cardiac surgery.<sup>257-259</sup> NIRS has also been used to investigate the impact of blood loss on tissue oxygenation. Donation of 450 mL of whole blood was found to be associated with only a small decrease in cerebral blood oxygen saturation.<sup>260</sup> During removal of 740 mL of whole blood from research subjects, there was a correlation between  $\text{O}_2$  saturation levels measured in the cerebrum and calf muscle with the volume of

blood loss.<sup>261</sup> Similar results were obtained in acute normovolemic hemodilution.<sup>262</sup>

A few studies have investigated the effect of RBC transfusion on tissue oxygenation as assessed by NIRS. In a study in the neonatal intensive care unit (ICU), preterm neonates with symptomatic anemia were found to have higher fractional oxygen extraction, as determined by measurement of cerebral cortex tissue hemoglobin saturation by NIRS. When they received RBC transfusions, these infants showed a decrease in oxygen extraction to the levels seen in asymptomatic, anemic infants, and nonanemic infants.<sup>263</sup> NIRS monitoring of low-birthweight infants showed improvement in cerebral cortex oxygenation following RBC transfusion.<sup>264</sup> Both tissue oxygenation and cerebral blood flow improved when anemic, preterm infants received RBCs.<sup>265</sup> Intraoperative transfusion of 84 RBC units to 29 adult patients were monitored by NIRS. RBC transfusion was associated with improved cerebral and peripheral (calf muscle) oxygen saturation readings that correlated with the increase in hemoglobin level.<sup>266</sup> Decreases in cerebral blood oxygen saturation were noted in a high proportion of elderly patients undergoing abdominal surgery that correlated with the degree of blood loss; the decreases were correctable by RBC transfusion.<sup>267</sup> Notably, these changes in oxygenation were present in the absence of any decrease in blood pressure or other clinical signs of anemia.

### Orthogonal Polarizing Spectroscopy

Orthogonal polarizing spectroscopy assesses blood flow through the microcirculation.<sup>268,269</sup> It generates an image of the microcirculation based on the differential absorption and scattering of light, which distinguishes between patent blood vessels that contain red cells and vessels (including tissue) that do not. This technique can assess tissue perfusion in a manner that correlates with fractional capillary density. There are some limitations to OPS—chiefly, that the most suitable monitoring site in adults is the mucosa of the mouth (sublingual placement is common) and that it cannot be used on internal organs, except intraoperatively. It has been validated in animal systems and also against conventional capillary microscopy in human nail skinfold.<sup>270,271</sup> Altered microcirculation was demonstrated by OPS in patients with severe sepsis, and the changes were more severe in nonsurvivors.<sup>227,272,273</sup> Improvement in microcirculatory blood flow as assessed by OPS was also more strongly associated with good outcome than other changes in hemodynamic parameters or serum lactate levels.<sup>274</sup> Transfusion of 10 to 15 mL/kg of RBCs to anemic, preterm infants was shown to increase functional capillary density in blood vessels of the upper arm as measured by OPS.<sup>275</sup> The change was due to the perfusion of additional capillary beds because it was also shown that vessel diameter, red cell velocity, and flow rate did not change. Sublingual OPS was used to assess the effect of RBC transfusion in septic patients.<sup>276</sup> RBC transfusion resulted in increased hematocrit, mean arterial pressure, and calculated oxygen delivery; however, microvascular perfusion was unchanged, and was found to show considerable inter-patient variability.

### Blood Oxygen-Dependent Function Magnetic Resonance Imaging

BOLDfMRI detects changes in the ratio of oxyhemoglobin to deoxyhemoglobin. It has been used extensively to determine tissue oxygenation and blood flow in many tissues including brain,<sup>277</sup> kidney,<sup>278</sup> heart,<sup>279</sup> muscle,<sup>280</sup> and tumors.<sup>281</sup> It has not yet been used to assess hemorrhage or transfusion, but offers the advantage of being able to query any organ noninvasively.

### Animal Models

Direct assessment of the impact of RBC transfusion on the microcirculation has been studied more extensively in experimental animal systems. In a hemorrhagic shock model in rats, resuscitation with human red cells was associated with improved oxygenation of the mesenteric microcirculation as measured by O<sub>2</sub>-dependent quenching of palladium-porphyrin phosphorescence.<sup>282</sup> Similar results were obtained when this system was adapted to an isovolemic exchange model.<sup>283</sup> Experiments in the hamster skinfold system, where the microvascular circulation is visualized directly and can be coupled with O<sub>2</sub> level determination using palladium-porphyrin phosphorescence, showed better maintenance of microvascular blood flow and tissue oxygenation after exchange transfusion with fresh RBC units, than with units that had been stored for 28 days.<sup>284</sup> In a hemorrhagic shock model in the same hamster skinfold system, however, the same improvements in the microcirculation were obtained with fresh RBC units whether or not they contained functional hemoglobin or methemoglobin, suggesting that the rheologic effects of RBC transfusion were more important than the ability of the red cells to off-load O<sub>2</sub>.<sup>174,285</sup>

### Effect of RBC Storage Changes on the Microcirculation

During storage, RBC units undergo several changes. It has been suggested that these changes affect their ability to deliver O<sub>2</sub>. Although there has been considerable interest in defining the clinical impact of these storage changes, clinical studies and experiments in animal model systems have yielded conflicting results. Several observational studies in cardiac surgery, trauma, and ICU patients have shown an association between prolonged storage time and poor clinical outcomes<sup>284,286-290</sup>; however, several other studies, including a pilot randomized, controlled trial in ICU patients, have not found deleterious effects after the transfusion of longer storage RBC units.<sup>277,276,291-294</sup> The effect of the storage changes on the microcirculation is also being evaluated.

Among the characteristic changes that red cells undergo during storage is alteration of their shape from a biconcave disc to an echinocyte with protrusions from which lipid vesicles are shed. This shape change is associated with loss of deformability<sup>295,296</sup> and increased osmotic fragility that results in hemoglobin loss to the plasma-anticoagulant-preservative phase.<sup>297</sup> Given the ability of hemoglobin to scavenge NO, RBC units with free hemoglobin could trigger vasoconstriction and impede blood flow. In fact, there is evidence that hemoglobin scavenging of NO contributes to vaso-occlusive crisis in sickle cell disease.<sup>298</sup> Reduced red cell deformability might also impede flow as a result of impaired

transit through small vessels, although this effect has been shown to be mitigated by the shunting of rigid or misformed red cells to larger diameter vessels in the microcirculation.<sup>299</sup> Stored red cells have been shown to adhere to endothelial cell layers in vitro and to small vessels in rat muscle, suggesting another mechanism whereby transfused red cells could occlude the microcirculation.<sup>300</sup> Candidate adhesion molecules include the Lutheran and LW antigens,<sup>301</sup> and the thrombospondin receptor, CD36.<sup>300</sup>

Levels of 2,3-DPG decrease during red cell storage. The loss of this allosteric modifier is reflected in a decrease in the hemoglobin  $P_{50}$  from 29 mm Hg to approximately 20 mm Hg. After transfusion, the red cell replenishes its 2,3-DPG over a period of 24 hours.<sup>302</sup> Increased  $O_2$  affinity has been suggested to impair oxygen off-loading. No effect of experimentally altered  $P_{50}$  on global parameters of oxygen dynamics or the microcirculation was apparent in several studies in experimental animals.<sup>303–305</sup> Conversely, in three studies in rats, tissue oxygenation (as assessed by palladium-porphyrin phosphorescence or microelectrode) and/or functional capillary density (as assessed by intravital microscopy) showed that tissue oxygenation and capillary perfusion were not as well maintained by transfusion of RBC units that had been stored for various periods and were presumably deficient in 2,3-DPG.<sup>283,306,307</sup> Transfusion of red cells from mice with a low-affinity hemoglobin variant (hemoglobin Presbyterian) conferred a survival advantage in a mouse LPS-challenge sepsis model.<sup>308</sup> The behavior of hemoglobin-based oxygen carriers (HBOCs) is different than that of intraerythrocytic hemoglobin. In two animal model systems, high-affinity hemoglobin preparations preserved functional capillary density and tissue oxygenation better than preparations formulated with lower-affinity hemoglobin.<sup>309,310</sup> High oxygen affinity is thought to balance the enhanced propensity of the HBOCs, which are much smaller than red cells, to facilitate diffusion of  $O_2$  to the vessel wall and thereby avoid triggering autoregulatory vasoconstriction and impaired blood flow through the microcirculation.<sup>311</sup>

ATP levels in stored RBC units decrease to around 60% of initial levels after 5 weeks of storage, and are restored a few hours after transfusion, a process that involves the uptake of adenosine.<sup>312</sup> ATP levels do correlate with posttransfusion red cell survival, but only at levels below 50%, which is usually reached only after the standard storage period of 42 days.<sup>313</sup> However, restoration of ATP levels in stored RBC units improved tissue oxygenation in a model system,<sup>283</sup> suggesting that ATP plays a role, whether as an energy source for a metabolic process or as a vasodilator, in oxygen delivery.

It has recently been observed that red cell levels of SNO-hemoglobin decline rapidly during storage, decreasing by 70% within a day of collection.<sup>314</sup> These SNO-depleted red cells failed to induce vasodilation in isolated rabbit aorta rings or to promote blood flow through canine coronary arteries in vivo; however, these properties could be restored by re-nitrosolating the red cells by exposure to NO in solution. This change may explain, in part, the experimental observations of the failure of RBC transfusion to improve global and/or microcirculatory parameters of oxygenation.

## Red Cell Substitutes

Investigators have long sought a substitute for red cells that would successfully imitate its oxygen delivery capabilities. Interest in the development of materials that could be used to deliver  $O_2$  to tissues in place of red cells was initially stimulated in the 1980s by concerns about the adequacy of the blood supply and transfusion-transmitted infectious diseases. This interest has been sustained primarily because of the clinical potential for an effective red cell substitute and secondarily because of the insights into oxygen delivery and its regulation that have been gained through the study of these materials.<sup>315–317</sup> The search for a red cell substitute has led to the investigation of three different classes of oxygen carriers: modified hemoglobin, perfluorocarbon emulsions, and liposome-encapsulated hemoglobin. The development of the latter remains in the preclinical stage,<sup>318</sup> but several perfluorocarbon- and hemoglobin-based substitutes have advanced to the level of Phase III trials.

### Hemoglobin-Based Oxygen Carriers

Cell-free hemoglobin is an obvious candidate for a red cell substitute and has a number of desirable attributes, the first of which is its ability to carry high concentrations of  $O_2$  and  $CO_2$ . The absence of the red cell membrane eliminates the complications created by the presence of blood group antigens. The purification procedures remove other cell components that could produce undesirable effects, and a variety of processes are used to eliminate or inactivate infectious agents. In its purified form, hemoglobin solutions are quite stable and can be stored for much longer periods than RBC units and under more permissive conditions (eg, room temperature). However, hemoglobin is a highly active molecule, and in its unmodified state, has the potential of producing a number of deleterious effects.<sup>319</sup> These toxicities have been responsible for the failure of several candidate oxygen carriers in clinical trials and were recently addressed at a symposium sponsored by the National Heart, Lung, and Blood Institute. The symposium identified areas of particular concern requiring more research to sustain future development.<sup>320</sup> In an effort to eliminate or mitigate some of these potential toxicities, all of the HBOCs being studied make use of hemoglobin preparations that have been chemically modified.

One problem with free hemoglobin in plasma is that it dissociates into  $\alpha\beta$  dimers and is rapidly cleared by glomerular filtration. Not only does the hemoglobin leave the bloodstream too rapidly to be clinically useful, but also it is toxic to the renal tubular cells.<sup>321</sup> Various modifications have been made to all HBOCs under study; these changes have had the effect of increasing the plasma half-life and eliminating nephrotoxicity. Three types of modifications have been used to achieve these ends: intramolecular stabilization of the hemoglobin tetramer; intermolecular cross-linking (polymerization of the tetramer); and surface conjugation of hemoglobin with other macromolecules such as polyethylene glycol (PEG).

A second concern with the hemoglobin molecule is its vasoactivity. The hypertensive effects of cell-free hemoglobin have been observed in animals<sup>322,323</sup> and humans<sup>324</sup> and are attributed, in part, to NO scavenging by the heme iron and the resulting vasoconstriction.<sup>325</sup> In addition, the HBOCs are not S-nitrosylated, like hemoglobin in red cells, and therefore lack the vasodilatory activity of the intact red cell.<sup>326</sup> However, in-vitro S-nitrosylation of a pegylated hemoglobin was recently shown to enhance its ability to promote vasodilation of the coronary arteries in dogs undergoing open-chest surgery.<sup>327</sup> Other factors that play a role in the vasoactivity of HBOCs are the effects of their low viscosity<sup>328</sup> on vascular tone.<sup>329,330</sup> Delivery of O<sub>2</sub> by the substitute may also exert local vasoconstrictive effects by triggering an O<sub>2</sub>-sensitive autoregulatory response.<sup>331,332</sup> The degree of vasoactivity varies among the different HBOC compounds and is generally more prominent in preparations based on a hemoglobin species with small molecular radius (eg, stabilized hemoglobin tetramer) compared to a species with a large radius (eg, pegylated hemoglobin).<sup>333</sup>

Hemoglobin in solution auto-oxidizes to methemoglobin, which does not carry O<sub>2</sub>, thence to irreversibly altered metabolites including free radicals,<sup>334</sup> which could have deleterious effects on tissues exposed to them. Methemoglobin formation has been measured in all of the HBOCs studied to date and found to be <15% in all, with little tendency to accumulate during storage.<sup>335</sup> The possibility that HBOCs might be immunogenic is low but is being assessed in the various clinical trials.<sup>336</sup> Human hemoglobin is a poor immunogen, but chemically modified human hemoglobin, or bovine hemoglobin, which has 90% sequence homology with the human form, could conceivably be more highly immunogenic. Surface modification with macromolecules such as PEG and polyoxyethylene may shield hemoglobin from the immune system and reduce the frequency or magnitude of the response.<sup>337</sup>

The HBOCs under development have been based on hemoglobin from three sources: human, from outdated donor RBC units; bovine; and recombinant technology. Seven HBOCs, four of them based on human hemoglobin, have been studied in clinical trials, as have two HBOCs based on bovine hemoglobin and one using a recombinant human hemoglobin. (See Table 3-3.) Only three remain under active development, although a newer product based on lyophilized human hemoglobin, OxyVita (OxyVita, New Windsor, NY), is in preclinical testing.<sup>338</sup>

PolyHeme (Northfield Laboratories, Evanston, IL) is a preparation consisting of a glutaraldehyde polymerized human hemoglobin that has been pyridoxylated and extensively purified to remove residual hemoglobin tetramers.<sup>339</sup> (See Table 3-4.) It is being developed as an alternative to RBC use in surgery and trauma.<sup>340,341</sup> Trauma patients who received PolyHeme required fewer transfusions of banked blood.<sup>340</sup> Northfield recently completed a pivotal Phase III clinical trial of the use of PolyHeme as an early intervention in trauma.<sup>342</sup> The study was controversial for its waiver of individual informed consent, which has occasionally been used in clinical studies in trauma patients, as well as for the

study designs, which called for continued use of the study material even after patients arrived at the hospital and could have received banked blood. Although there was a trend for excess 1-day and 30-day mortality in the treatment arm, the differences were not statistically significant. Myocardial infarction was reported more frequently in patients receiving PolyHeme ( $p < 0.05$ ).

The Biopure Corporation (Cambridge, MA) uses glutaraldehyde to polymerize bovine hemoglobin followed by extensive purification and virus inactivation steps to produce a substitute with less than 3% hemoglobin tetramers (Hemopure). The Biopure Corporation is the first to have obtained licensure for a blood substitute product. In 1997, a veterinary formulation of their HBOC, Oxyglobin, was licensed by the Food and Drug Administration (FDA) for use in animals and in 2001, Biopure announced that Hemopure had been approved for clinical use in South Africa. This product has been studied principally for perioperative use as a “bridge,” delaying the need for banked RBCs until the patient has been stabilized and blood loss curtailed.<sup>343-345</sup> Biopure has reported in abstract form on the safety and efficacy of Hemopure in Phase II and III trials in orthopedic surgery, where it was shown to reduce the use of allogeneic RBCs<sup>346</sup>; however, the firm has announced that it is in the process of designing several Phase II trials in nonsurgical applications.<sup>347</sup>

Hemospan (Sangart, San Diego, CA) is a pegylated human hemoglobin designed specifically with a large molecular radius and high oxygen affinity to mitigate the diffusive transfer of O<sub>2</sub>, which is thought to trigger the vascular autoregulatory response responsible for the vasoactivity characteristic of many of the other HBOCs.<sup>310,348,349</sup> This product has undergone Phase I and II clinical testing in Europe where it was found to have minimal hypertensive effects.<sup>350,351</sup> A Phase II clinical trial in patients undergoing radical retropubic prostatectomy is being mounted in the United States and a Phase III trial in orthopedic surgery is open in Europe.<sup>352</sup>

### Perfluorocarbon-Based Oxygen Carriers

The perfluorocarbons (PFCs) are a class of compounds consisting of linear or cyclic carbon backbones that are highly substituted with fluorine.<sup>353</sup> Most of the PFCs are liquid at room temperature and are highly soluble for respiratory gases including O<sub>2</sub>, N<sub>2</sub>, and CO<sub>2</sub>. The amount of gas that can be dissolved into a PFC is directly proportional to its ambient partial pressure. Theoretically, at a high enough PO<sub>2</sub>, a PFC could contain the same amount of O<sub>2</sub> as blood. PFCs are not miscible in water, however, and must be prepared as emulsions for most biologic applications. The need to prepare the PFCs as emulsions decreases the O<sub>2</sub>-carrying capacity; therefore, patients must receive supplemental oxygen when a PFC emulsion is used.

PFC emulsions are cleared by the reticuloendothelial system (RES), as are the HBOCs, but eventually are exhaled via the lungs. The half-lives in the RES of some of the first PFCs studied were quite prolonged, but the newer PFCs have half-lives in the RES on the order of a few days. The impact on the RES of the ingestion of large amounts of PFCs or the emulsifying

**Table 3-5.** Perfluorocarbon Red Cell Substitutes Reaching Clinical Trials\*

| Product (Manufacturer)         | Perfluorocarbon              | Trial Level                 | Application                             |
|--------------------------------|------------------------------|-----------------------------|-----------------------------------------|
| Fluosol-DA (Green Cross/Alpha) | Perfluorodecalin             | Phase II (discontinued)     | Acute blood loss                        |
|                                | Perfluoropropylamine         | Approved (withdrawn)        | PTCA                                    |
| Oxygent (Alliance)             | Perflubron                   | Phase II                    | CABG—ANH Ortho surgery—acute blood loss |
|                                |                              | Phase III (discontinued)    | Cardiac surgery, surgery—ANH            |
| Imagent GI (Alliance)          | Perflubron                   | Approved (withdrawn)        | GI imaging                              |
| Imavist (Alliance)             | Perflubron                   | Phase III (discontinued)    | Cardiac ultrasound                      |
| Liquivent (Alliance)           | Perflubron (neat)            | Phase Ib/II                 | Liquid ventilation—IRDS                 |
|                                |                              | Phase II/III (discontinued) | Liquid ventilation—pedi and adult ARDS  |
| Oxyfluor (HemaGen/PFC)         | Perfluorodichlorooctane      | Phase II (discontinued)     | Surgery, neuro-protectant/bypass        |
| Oxycyte (Synthetic Blood Int.) | Perfluoro-t-butylcyclohexane | Phase IIb                   | Acute brain injury                      |

\*Information current as of May 2008.

PCTA = percutaneous transluminal coronary angioplasty; CABG = coronary artery bypass graft; ANH = acute normovolemic hemodilution; GI = gastrointestinal; IRDS = infant respiratory distress syndrome; ARDS = acute respiratory distress syndrome.

agents remains to be determined. The clearance rate of PFC emulsions from the circulation increases as the emulsion particle sizes decrease. Thus, reproducibly and predictably preparing emulsions with the appropriate distribution of particle sizes is one of the technical challenges that the developers of these materials have faced. The plasma half-lives of the PFC emulsions that have been studied for clinical use are approximately 12 to 24 hours, which compare favorably with the half-lives of the HBOCs.

Two PFC emulsions underwent clinical trials in the 1990s but development of both has been discontinued. (See Table 3-5.) Two new products are in preclinical or clinical testing. One, PherO<sub>2</sub> (Sanguine, Pasadena, CA) is a reformulation of perfluorodecalin, one of the constituent PFCs in Fluosol, a product licensed in the 1980s for use in percutaneous transluminal coronary angioplasty to perfuse the vascular bed distal to the balloon, but which saw off-label use as a transfusion equivalent.<sup>354</sup> Synthetic Blood

International (Costa Mesa, CA) announced that its PFC product, Oxycyte, was more effective at increasing brain oxygen levels in patients with traumatic brain injury than either 50% or 100% O<sub>2</sub>. The firm has announced plans for a Phase IIb study in 200 patients with traumatic brain injury.<sup>355</sup>

### Red Cell Substitutes: Summary

Although the various preparations that have been studied share the ability to transport oxygen, they are quite distinct from one another and certainly very different from red cells. If the compounds are to be used to best advantage, transfusion medicine specialists will need to be familiar with the capabilities and liabilities of the substitutes that find their way into the clinical arena. The development of these substitutes has shed considerable light on the mechanisms of oxygen delivery and its regulation, and forced reconsideration of some long-held assumptions. In order to adequately fulfill the role of consultant, the transfusion

medicine specialist will need an even greater understanding of the physiology of red cell transfusion and oxygen delivery.

## Conclusion

A constant supply of oxygen to the tissues is essential to sustain the basic energy-producing machinery of the cell. Homeothermic organisms have evolved multiple, interlinked regulatory systems to ensure that oxygen delivery to the periphery meets the specific metabolic requirements of each tissue and is coordinated with the function of other systems.

## Red Cell Metabolism and Preservation

**Bjarte G. Solheim<sup>1</sup> & John R. Hess<sup>2</sup>**

<sup>1</sup> Professor Emeritus, Institute of Immunology, Rikshospitalet University Hospital of Oslo, Oslo, Norway

<sup>2</sup> Professor, Blood Bank, University of Maryland Medical Center, Baltimore, Maryland, USA

A human red cell, mature and released from the marrow, lacks a nucleus and mitochondria. It has a life span of 120 days, after which it is removed from the circulation in the natural course of aging. It can neither use oxygen for the extraction of energy, nor synthesize proteins or nucleotides. Its primary functions—transporting oxygen from the lungs to the tissues and carrying carbon dioxide back to the lungs—do not require the expenditure of energy. However, maintaining hemoglobin in an optimal state for delivery of oxygen and keeping a normal cell morphology do require active metabolism, and are prerequisites for function and successful transfusion.

During standard storage at 4°C, significant and, in part, reversible changes in red cell morphology and metabolism occur. One striking example is the change in red cell shape (Fig 4-1), which can be reversed to a large extent by metabolic rejuvenation of the cells. In order to optimize storage with the development of optimal strategies, it is essential to understand basic principles of red cell metabolism.

Another example of a reversible change is the binding of oxygen. As detailed in Chapter 3, hemoglobin flips between a taut (low oxygen affinity) state (T) and a relaxed (high oxygen affinity) state (R). Therefore, the process of oxygenation causes the hemoglobin molecule, like the lungs, to “breathe.” However, oxygenation and deoxygenation of hemoglobin are not isolated events, because parallel to the intrasubunit and tetrameric conformational movements related to the T and the R states are changes in the binding of hemoglobin to its other ligands [hydrogen ions, carbon dioxide, chloride ions, 2,3-diphosphoglycerate (2,3-DPG), band 3 in the cell membrane, and nitric oxide]. Together with the influence of temperature, these ligands are mutually interactive in determining the conformational state of hemoglobin, and thus its oxygen affinity.

Results obtained in the past decade by several research groups indicate that many intermolecular interactions may be

missed when hemoglobin is considered by itself without taking into account the cellular milieu in which it performs its main biological function.<sup>2,3</sup> Thus, interaction of hemoglobin and band 3 is influenced by conformational changes that accompany ligand binding to hemoglobin, which modulates the function of band 3, the glycolytic pathway, and the structural architecture of the red cell membrane-cytoskeletal system (Fig 4-2). Human red cells move rapidly through the tissue and lung capillaries (transit time of 0.3-1 second). Cells in the tissue surrounding the microcapillary endothelium signal their requirement for oxygen by release of carbon dioxide and protons. To satisfy this requirement, oxygen must be released from red cells in the vicinity of the cells that signal their need for it.<sup>3</sup> Thus, red cell carbon dioxide uptake and oxygen release must be completed within the brief time during which the red cell traverses the capillary and is in contact with endothelial cells. Moreover, the close contact of hemoglobin, band 3, and carbonic anhydrase in the cell membrane promotes the production of bicarbonate with release of protons. The release of protons via the Bohr effect (see Chapter 3) in turn releases oxygen from hemoglobin where it is needed in the tissues. In the following section, red cell metabolism is discussed taking into account intermolecular interactions of importance for the primary function of hemoglobin, which is the transport of oxygen and carbon dioxide.

---

### Metabolism

#### Metabolism of Glucose

Under physiologic circumstances, the energy that the red cell requires is derived through the breakdown of glucose to lactate or pyruvate. The sequence of reactions is generally known as the glycolytic or the Embden-Meyerhof pathway.<sup>4</sup> This pathway is phylogenetically very old, and the sequence of reactions is the same in bacteria, yeast, and vertebrates. Except for the exaggerated production of 2,3-DPG (also known as 2,3-bisphosphoglycerate) in the red cell, the pathway is the same in all tissues.

**Figure 4-1.** Scanning electron micrographs showing representative red cells in various stages of shape change typical of prolonged storage.<sup>1</sup> The cells progress from discocytes (A), through several stages of echinocytes (B-D), to spherocytes (E), and finally to spherocytes (F). Scores based on the visual appearance (shown in the lower right of the individual images) can be assigned to several hundred individual stored cells and averaged to produce a morphology score for the unit. Such scores decrease in a linear manner during storage but can be substantially reversed by rejuvenation.

**Figure 4-2.** Schemata of red cell components.

In the past, it was believed that oxygen transport by hemoglobin and metabolism were cytosolic functions, and that the membrane and cytoskeleton merely enclosed them. It is now recognized that the attachments of the membrane to the cytoskeleton from band 3, through ankyrin (An) and proteins 4.2 and 4.1 to spectrin, and from glycophorin C through protein 4.1 and actin (Ac) to spectrin are destabilized by 2,3-diphosphoglycerate (2,3-DPG). 2,3-DPG released from deoxyhemoglobin (d-Hb) binds to band 3 and partially detaches the membrane from the cytoskeleton, allowing lateral movement of membrane structures. This could have implications for red cell flexibility in peripheral capillaries. Other abbreviations: O-Hb = oxygen-hemoglobin.

The reactions of the glycolytic pathway are shown in Fig 4-3. In a sequence of reactions, the six-carbon sugar glucose is phosphorylated, isomerized to fructose phosphate, phosphorylated again, and cleaved into three-carbon sugars. The three-carbon sugars are again phosphorylated. Finally, the carbohydrate-bound phosphate that has been gained is transferred to adenosine

diphosphate (ADP), producing the high-energy compound, adenosine triphosphate (ATP). The synthesized ATP is used by ATPases for the pumping of ions against concentration gradients, for the phosphorylation of membrane proteins and lipids, and very importantly for the phosphorylation of glucose in the glycolytic pathway.<sup>5</sup>

**Figure 4-3.** The glycolytic pathway with the pentose and 2,3-DPG shunts of red cell metabolism. ATP = adenosine triphosphate; ADP = adenosine diphosphate; HK = hexokinase; NADP<sup>+</sup> = nicotinamide adenine dinucleotide phosphate, oxidized form; NADPH = nicotinamide adenine dinucleotide phosphate, reduced form; 6-PGD = 6-phosphogluconate dehydrogenase; P = phosphate; G-6-PD = glucose-6-phosphate dehydrogenase; PFK = phosphofructokinase; TPI = triosephosphate isomerase; NAD<sup>+</sup> = nicotinamide adenine dinucleotide, oxidized form; NADH = nicotinamide adenine dinucleotide, reduced form; GAPD = glyceraldehyde-3-phosphate dehydrogenase; PGK = phosphoglycerate kinase; DPGM = diphosphoglycerate mutase; DPGP = diphosphoglycerate phosphatase; MPGM = monophosphoglycerate mutase; PK = pyruvate kinase; LDH = lactate dehydrogenase.

### The 2,3-DPG Shunt (Rapoport-Luebering Shunt)

Production of 2,3-DPG is the function of a shunt that branches from the main glycolytic pathway after the formation of 1,3-diphosphoglycerate (1,3-DPG) and returns to it with the formation of 3-phosphoglycerate (3-PGA) (Fig 4-3). The pathway consists of the formation of 2,3-DPG from 1,3-DPG, followed by the dephosphorylation of 2,3-DPG to 3-PGA (Fig 4-4). Both reactions are catalyzed by the same enzyme and are balanced at physiologic pH.<sup>6</sup> At higher pH, the enzyme acts only as a mutase, moving phosphate in 1,3-DPG from position 1 to position 2 in the molecule; at low pH it acts only as a phosphatase, transforming 2,3-DPG to 3-PGA. As the 2,3-DPG shunt bypasses one of the two ATP-making steps in glycolysis, 2,3-DPG is made at the expense of ATP. In storage systems, a high pH can shut down ATP production, while a lower than physiologic pH leads to a burst of ATP production driven by the breakdown of 2,3-DPG.

The production of large quantities of 2,3-DPG is a unique feature of glycolysis in the red cell. Red cells contain approximately equimolar amounts of hemoglobin and 2,3-DPG. Binding of 2,3-DPG to the  $\beta$  subunits of deoxyhemoglobin serves to stabilize the T (low oxygen affinity) state of hemoglobin and thus shifts the oxygen equilibrium curve to the right (favoring dissociation of oxygen). In the R (high oxygen affinity) state, approximately 80% of 2,3-DPG is “free,” while in the T state over 80% of 2,3-DPG is bound to hemoglobin.<sup>7</sup> In the “free” state 2,3-DPG at physiologic concentrations modulates

properties of the red cell membrane.<sup>2</sup> It binds directly to band 3 and thereby interferes negatively in the interactions between protein 4.1, 4.2, ankyrin, and band 3.<sup>8</sup> In addition, 2,3-DPG releases spectrin from the membrane skeleton, and interferes negatively in the interactions between spectrin-actin-protein 4.1 and the glycophorin C complex.<sup>2,9,10</sup> This decreases the number of connecting links between the cell membrane and the cytoskeleton and increases lateral mobility of integral membrane proteins.<sup>11</sup> The rise and fall of 2,3-DPG concentrations with each pass through the circulatory system, therefore, results in repetitive destabilization and restabilization of the membrane-cytoskeleton architecture (Fig 4-2). “Free” 2,3-DPG increases cell flexibility by weakening the links between the membrane and the cytoskeleton, and facilitates gas exchange by allowing the red cell to slip into narrow capillaries and splenic sinusoids. However, further experiments are needed to clarify the physiologic implications of the interactions of 2,3-DPG, cell membrane proteins, and the cytoskeleton.

### The Pentose Shunt (Hexose Monophosphate Shunt)

Under normal, steady-state conditions, most glucose is metabolized in red cells by way of the glycolytic pathway, but there is another important metabolic pathway called the pentose shunt or hexose monophosphate shunt (Fig 4-3). Some of the glucose-6-phosphate (G-6-P) formed when glucose is phosphorylated in the hexokinase reaction may enter this pathway. Glucose-6-phosphate dehydrogenase (G-6-PD)

**Figure 4-4.** Regulation of the formation and breakdown of 2,3-DPG. The steady-state concentration of 2,3-DPG is governed by the rate of its formation from 1,3-diphosphoglycerate and by its breakdown to 3-phosphoglycerate. Both reactions are catalyzed by the same multifunctional enzyme modulated by a variety of substances. Formation of 2,3 DPG by the mutase (DPGM) is enhanced by substances to the right of the upward arrow, and reduced by those to the right of the downward arrow. Similarly, arrows indicate substances modulating the breakdown of 2,3 DPG by the phosphatase (DPGP). GAP = glyceraldehyde-3-P; 3 PGA = 3-phosphoglycerate; 2 PGA = 2-phosphoglycerate; PEP = 2-phosphoenolpyruvate.

catalyzes the oxidation of G-6-P to 6-phosphogluconolactone, reducing nicotinamide adenine dinucleotide phosphate (NADP) to NADPH. After hydrolysis of the lactone to 6-phosphogluconic acid, another oxidative step reduces additional NADP to NADPH, and releases carbon dioxide from the six-carbon compound, forming the pentose sugar ribose-1-phosphate. After a series of rearrangements, two normal intermediates of the main glycolytic pathway—fructose-6-phosphate and glyceraldehyde-3-phosphate—are formed and rejoin the main metabolic stream.

The pentose shunt is important to the red cell primarily as a source of NADPH. It is this reduced nucleotide that maintains glutathione (GSH) in its reduced form. Reduced GSH is important for the elimination of peroxide, protection of protein sulfhydryl (SH) groups and detoxification processes. The pentose shunt also plays an important role for the red cell by providing ribose-5-phosphate needed for the production of phosphoribosyl pyrophosphate (PRPP), an essential substrate for the synthesis of adenine nucleotides required for ATP synthesis (see below).

### Alternative Substrates for Red Cell Metabolism

Glucose is the natural substrate for human red cell energy metabolism, but red cells are also capable of metabolizing other sugars (ie, fructose, mannose, galactose, and the three-carbon sugar dihydroxyacetone). However, none of these other sugars have proven to be useful in the design of blood preservatives.

The presence in red cells of the enzyme nucleoside phosphorylase makes it possible for red cells to use nucleosides such as inosine to support ATP synthesis:

In this reaction, ribose-1-phosphate is formed without the expenditure of ATP. Ribose-1-phosphate is then readily converted to fructose-6-phosphate by the pentose shunt, which feeds into the glycolytic pathway leading to the generation of ATP. In the rejuvenation of red cells (see later) inosine allows ATP-depleted red cells to prime their metabolic pump (the glycolytic pathway). It has not been possible to include inosine in blood preservatives because the product of its metabolism, hypoxanthine, is rapidly converted to uric acid in the body. Because many patients who receive blood transfusions have impaired liver function or may already have hyperuricemia because of hereditary or acquired factors, a blood component that increases plasma uric acid level cannot be considered safe.<sup>12</sup>

### Regulation of Energy Metabolism

#### Rate of Glucose Metabolism

In general, metabolic regulation is dependent on protein synthesis, which, in turn, is regulated by increasing or decreasing the rate of DNA transcription or the translation of messenger RNA. Red cells do not have this option. Instead, the rate of glucose metabolism is regulated by feedback mechanisms. However, in spite of extensive studies, our understanding of the control of glucose metabolism by red cells is still incomplete.

The N-terminal cytoplasmic domain of band 3 binds hemoglobin, cytoskeletal proteins, and glycolytic enzymes.<sup>13</sup> Based on current evidence, de Rosa et al<sup>2</sup> point out that interaction between hemoglobin in the T state and band 3 causes a release of glycolytic enzymes, which results in increased activity of the main glycolytic pathway. On the other hand, hemoglobin in the R (highly oxygenated) state is associated with increased activity of the pentose shunt because the enzymes of the main glycolytic pathway show reduced activity when bound to band 3.<sup>14</sup>

The rate of glucose metabolism by red cells is influenced by many factors other than enzyme activity. Negative feedback mechanisms seem to be involved in the glycolytic pathway and 2,3-DPG is involved in several. Both hexokinase and phosphofructokinase are inhibited by hydrogen ions. Thus, one of the principal reasons for the markedly slow rate of glycolysis during blood storage is the accumulation of lactic acid in whole blood or the acidity of first-generation additive solutions.

### 2,3-DPG Concentration

The concentration of 2,3-DPG depends on the rate of its formation and degradation. Many effectors determine whether the mutase or the phosphatase activity of the diphosphoglycerate mutase/phosphatase predominates (Fig 4-4). The hydrogen ion concentration is one of the most important physiologic modulators. At low pH, phosphatase activity is stimulated and mutase activity is inhibited. Thus, high pH favors 2,3-DPG maintenance and production during storage at the expense of ATP formation, whereas low pH leads to the rapid loss of 2,3-DPG with an increase in ATP production. Modulation of red cell metabolism by pH has been the principal means used to retard the decline of 2,3-DPG levels that occurs during liquid storage of red cells (see later). After depletion during storage, 2,3-DPG levels in transfused red cells return to 50% of normal in 7 hours and to almost 95% at 72 hours.<sup>15</sup>

### Pentose Shunt Activity

The rate of the pentose pathway is influenced by the availability of NADP and the level of NADPH. Under oxidative stress NADPH is oxidized to NADP and the activity of the pentose pathway increases, which is consistent with the observation of increased pentose shunt activity when hemoglobin is in the R state.

### Adenosine Triphosphate

In the red cells, ATP is synthesized by the glycolytic pathway, but its regulation is complex. ATP is used in a number of different metabolic pathways—particularly by the kinases, which phosphorylate sugars (ie, hexokinase, phosphofructokinase) and proteins, and by ATPase-driven ion pumps (ie,  $\text{Na}^+/\text{K}^+$ -ATPase,  $\text{Mg}^{2+}$ -ATPase, and  $\text{Ca}^{2+}$ -ATPase). Moreover, red cell membrane shape and rigidity are controlled by the ATP-dependent cytoskeleton.

ATP is in equilibrium with ADP and adenosine monophosphate (AMP). As the level of ADP increases, some is converted to AMP. AMP, in turn, is deaminated in the AMP-deaminase reaction. The total red cell pool of adenine decreases during storage, which leads to the depletion of ATP if adenine is not added to the anticoagulant and/or the additive solution.

### Guanine Nucleotides

Red cells contain and turn over guanine nucleotides, which perform at least two functions in red cells. First, guanine nucleotides play a role in the signal transduction of membrane shear into secretion of local vasodilators cyclic AMP and ATP.<sup>16</sup> Second, high concentrations of guanosine triphosphate (GTP) inhibit red cell transglutaminase, a primitive coagulation system that also interacts with the cytoplasmic domain of band 3 and with protein 4.1.<sup>17</sup> The GTP concentration is reduced when red cells age so that transglutaminase, which has a Factor XIII-like activity, can facilitate the removal of senescent red cells by binding them to fibrin clots.

### Synthetic Processes

Red cells are able to assemble only a limited repertoire of important molecules from simpler precursors. They retain the capacity to synthesize nucleotides through a “salvage pathway” and to

synthesize GSH from its precursor amino acids. Adenine is able to enter the erythrocyte and purine nucleotides are synthesized through the adenine phosphoribosyl transferase reaction:

This reaction is critical in blood storage. The beneficial effect of addition of adenine to stored blood depends on it. PRPP, one of the substrates for the formation of AMP in this reaction, is synthesized from pentose-phosphate formed in the pentose shunt. Guanine nucleotides form in an analogous reaction and are catalyzed by a different enzyme, hypoxanthine-guanine phosphoribosyl transferase. Red cells also actively synthesize a number of other small molecules, including reduced glutathione, NAD, and S-adenosyl-L-methione.<sup>5</sup>

### Membrane Metabolism

The red cell membrane is composed of a phospholipid bilayer containing cholesterol molecules and membrane proteins.<sup>18</sup> The phospholipids are disposed with a predominance of phosphatidylcholine and sphingomyelin in the outer leaflet and phosphatidylinositol, phosphatidylethanolamine, and phosphatidylserine (PS) in the inner leaflet. Loss of phospholipid asymmetry results in exposure of PS, which is an important apoptotic marker on the red cell surface. Exposure of PS on the outer cell surface promotes red cell removal from the circulation, while the surface glycoprotein CD47, which decreases during storage, inhibits phagocytosis.<sup>19</sup> The phospholipid asymmetry is maintained by the ATP-dependent flippase (aminophospholipid translocase) activity. This activity counteracts phospholipid scrambling, which moves PS from the inner to the outer cell surface. Flippase activity decreases during storage, but can be corrected by rejuvenation of the red cells.<sup>20</sup> Phospholipid scrambling is normally low during storage, but can be enhanced by photodynamic treatment for pathogen inactivation.<sup>21</sup>

Maintaining the iron of hemoglobin in a reduced state is a prerequisite for effective oxygen transport. The enzyme involved is methemoglobin reductase, which reduces  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$  by oxidizing the reduced form of nicotinamide adenine dinucleotide (NADH) to NAD. Protection of the SH groups of hemoglobin and membrane proteins from oxidation is also a crucial function. This is accomplished by maintaining adequate amounts of reduced GSH by oxidation of NADPH to NADP. The oxidation of GSH to GSSG catalyzed by peroxidase reduces  $\text{H}_2\text{O}_2$  to  $\text{H}_2\text{O}$  and  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$ . Adequate levels of ATP, NADH, NADPH, and 2,3-DPG for these metabolic functions are secured by the glycolytic pathway with its pentose and 2,3-DPG shunts. In addition, the synthesis of NAD and NADP from nicotinic acid must also occur.

Membrane proteins such as glycophorin and band 3 extend through the lipid membrane. Branches of carbohydrates anchored to membrane proteins protrude from the outer surface of the membrane. The inner surface of the membrane is lined by the cytoskeleton, which is anchored to the membrane through the N-terminal cytoplasmic domain of band 3. The tetrameric form of band 3 binds ankyrin and constitutes with proteins 4.1

and 4.2 a major attachment site for spectrin. A second attachment site for spectrin involves actin and protein 4.1 in the glycoporphin C complex. Both attachments (Fig 4-2) are weakened when the concentration of “free” (non-hemoglobin-bound) 2,3-DPG is increased; this could be of importance for cell flexibility and gas delivery.<sup>2</sup> Membrane shape and deformability are controlled by the ATP-driven cytoskeleton. Because some capillaries in the microcirculation have a diameter of only half that of a red cell, loss of flexibility and deformability is a serious storage lesion responsible for removal of rigid cells (Fig 4-1).

The red cell membrane also contains a number of transport proteins such as the glucose transporter,  $\text{Ca}^{2+}$ -ATPase, the  $\text{Na}^{+}$ - $\text{K}^{+}$ -ATPase, the GSSG (oxidized glutathione) transport ATPases, and amino acid transporters, in addition to various other transport channels.

A prime metabolic activity of the red cell is maintaining osmotic stability through the activity of its membrane pumps, which are ATP driven. The  $\text{Na}^{+}$ - $\text{K}^{+}$ -ATPase is highly sensitive to changes in temperature and scarcely functions at 4°C. During storage in the cold, sodium diffuses into the cells and potassium leaks out until a new equilibrium is reached. The leakage of potassium is further increased by irradiation. Increased potassium content in plasma or in the additive solution of stored Red Blood Cell (RBC) units presents a potential hazard to neonates, although under most other circumstances it can be ignored.<sup>15</sup> Citrate in plasma increases potassium toxicity, while reducing red cell supernatant volume results in less potassium leakage before equilibrium is reached. Studies performed over 30 years ago indicate that restoration of potassium after transfusion is slow, and can take more than 6 days.<sup>15</sup> Surprisingly, there are no reports on restoration of potassium after transfusing RBC units with modern anticoagulant and additive solutions.

Although the macromolecules of the membrane are produced by red cell precursors, some of the components of the membrane are metabolically quite active. For example, cholesterol in the membrane exchanges readily with cholesterol in the plasma, phosphatidylinositol undergoes active phosphorylation, and some proteins are phosphorylated by protein kinases and dephosphorylated by phosphatases. These reactions may influence the functional status of membrane components, but their importance is not yet fully understood.

## Summary

In the circulation, red cells metabolize glucose by the glycolytic pathway with its pentose and 2,3-DPG shunts. The energy gained provides ATP to maintain ion and glucose concentration gradients between the plasma and erythrocyte and to secure red cell deformability. It also secures NADH to keep hemoglobin in the reduced state and NADPH to protect SH-groups on hemoglobin and membrane proteins. Finally, the production of 2,3-DPG is important for the optimal dissociation of oxygen from hemoglobin while the rise and fall of non-hemoglobin-bound 2,3-DPG with each pass through the circulatory system induces repetitive changes in the membrane-cytoskeleton architecture,

which could have implications for red cell flexibility and gas transport.

## Red Cell Preservation in Transfusion Medicine

### General Considerations and Principles

RBCs are the most commonly transfused blood components, and their use in a variety of physical circumstances and clinical conditions has shaped their development as products. As an example, the US military's need to reduce the weight and breakage of blood bottles during shipment led to the development and adoption of plastic blood bags.<sup>22</sup> This led to closed-system component production and, fortuitously, exposure of red cells to the plasticizer diethylhexyl phthalate (DEHP), which reduced hemolysis during storage.<sup>23</sup> Arguments between blood bankers, who wanted to remove the plasma to make albumin and coagulation factors, and surgeons, who wanted to keep the plasma so the blood could flow quickly in trauma patients, led to the development of additive solutions.<sup>24</sup> Again, there were unforeseen consequences; the removal of plasma led to better RBC storage and reduced transfusion reactions. Regulatory agencies have also played a role. The US Food and Drug Administration (FDA) recognizes that 4 million patients a year receive RBCs and that the product must be safe for all.<sup>25</sup> Adding antibiotics to blood bags to prevent bacterial contamination, which kills five patients a year in the country, may seem like a beneficial advance. However, the agency must consider the accompanying risk of exposing millions of patients to allergenic and toxic drugs, with the probability of greater harm than good being achieved.

As a result of many competing forces, the development and adoption of new RBC storage technology has been slow.<sup>26</sup> Five major improvements occurred in the last 50 years: 1) the addition of phosphate, 2) the use of plastic bags, 3) the addition of adenine, 4) the development of additive solutions, and 5) the use of leukocyte reduction, which reduces hemolysis. The reasons for this slow progress have had to do with the perception of little need for change, limited investment in change, lack of understanding of the red cell storage lesion, poor developmental strategies, and conservative regulatory stances.<sup>27</sup>

For 60 years, it has been a societal goal that RBC transfusion should be available, safe, effective, and cheap.<sup>24</sup> Making red cells readily available requires 1) the ability to take liquid units out of the refrigerator and administer them immediately to critically ill or injured patients and 2) the ability to find rare units in frozen national or international inventory. Storage systems contribute to blood safety by isolating individual units in closed systems and reducing product breakdown and bacterial growth through cold storage. A major goal of storage systems is to maintain effectiveness by preserving the lifespan and function of fresh red cells to the greatest extent possible. Keeping blood components inexpensive remains a goal, but the social costs of unsafe blood are high, and the costs of additional testing have added significantly to production costs. At the present time, the costs of RBC units are

rising (see Chapter 1), and controlling those costs has been one factor in limiting progress on storage systems.

### A Short History of RBC Storage Systems

Rous and Turner developed the first red cell storage solution in 1916, a simple mixture of citrate and glucose.<sup>28</sup> It was used initially to store rabbit red cells for heterophil agglutination testing for syphilis, but when the cells appeared to be intact 4 weeks later, they were reinfused back into the donor rabbits, raising the hematocrit without increasing the reticulocyte count or bile in the urine.<sup>29</sup> A year later, Robertson used the Rous-Turner solution to build the first successful blood bank in the Harvard Medical Unit attached to the British Expeditionary Force in France.<sup>30</sup>

The major problem with the Rous-Turner solution was that it could not be heat sterilized, because the sugar caramelized; thus, there was a risk of bacterial contamination from the open mixing of the ingredients and addition of the solution to the bottles. In 1943, Loutit and Mollison solved this problem by lowering the pH of the solution to 5.0 to make acid-citrate-dextrose (ACD) solution.<sup>31</sup> ACD could be autoclaved in sterile vacuum bottles and was used as the standard blood collecting solution in the United States and Britain for many years. It was made first to be used at a 1:4 ratio with collected whole blood and later concentrated to be used at a 1:7 ratio, as is now standard, to reduce the dilution of the blood.

During research on why red cells seemed to do better in the lower volume ratio of the anticoagulant-nutrient solution, it became clear that the cells passively lose phosphate. This loss could be prevented by adding phosphate to the solution.<sup>31</sup> Citrate-phosphate-dextrose (CPD) in a 1:7 volume ratio, 63 mL for 450 mL of whole blood, preserved red cells slightly better than the older ACD.<sup>32</sup> CPD became the standard anticoagulant in the United States, but ACD persisted in Europe. Both were used for 21-day storage with recovery of 70% to 80% of the red cells 24 hours after reinfusion to their original donor.

At about the same time, Gabrio and colleagues recognized that nucleotides were important for red cell metabolism, but almost a decade passed before researchers determined that adenine was the critical intermediate.<sup>33-36</sup> In 1968, Shields formulated a mixture of CPD and adenine, CPDA-1, and showed that it markedly improved whole blood storage.<sup>37</sup> However, during the subsequent 11 years that the FDA debated the safety of adenine, plastic bags revolutionized blood banking, and this excellent whole blood storage solution turned out to work less well with the red cells left behind when plasma was removed.<sup>38</sup> Beutler and West went on to show that the higher the hematocrit of red cells in concentrates, the lower the red cell ATP concentrations and the in-vivo recovery.<sup>39</sup> The obvious answer was to add back more volume and nutrients in the form of an "additive solution," but the initial attempt to do this with a solution of bicarbonate, adenine, glucose, and phosphate (BAGP), did not work.<sup>40</sup> CPDA-1 was finally licensed as a 5-week storage solution in 1979, but only after Hogman had developed a simple additive solution of saline,

adenine, and glucose (SAG) that also worked for 5-week storage but without the adverse effects associated with the high pH.<sup>41</sup> SAG went on to immediate use in Sweden.

The use of SAG was associated with 1% hemolysis by the end of 5 weeks of storage, so mannitol was subsequently added (SAG-M) as a "membrane stabilizer."<sup>42</sup> This reduced the hemolysis by more than 50%. Drawing whole blood into CPD, making component products, and storing the concentrate with an additional 100 mL of SAG-M (CPD/SAG-M) is the standard RBC storage system in Europe. Minimal variants of this basic solution, additive solution-1 (AS-1) and additive solution-5 (AS-5), are widely used in the United States. Also used is a more substantial variant using citrate and phosphate in the place of mannitol (AS-3 or SAG-CP). All of the variants appear to be equivalent and provide about 80% recovery with about 0.3% hemolysis after 6 weeks of storage.<sup>26</sup>

The most important limits of the first generation of additive solutions are the loss of membrane with resulting loss of deformability and viability that occur with prolonged storage. The progressive loss of 2,3-DPG may also be important in some situations, although the clinical impact is not well understood. More advanced additive solutions have been demonstrated in principle in small human trials, but only one is licensed and only in a few countries.<sup>26</sup> They appear to hold the potential for 7 to 8 weeks of storage, but are considered to be attractive more for their ability to improve recovery, reduce membrane loss, and improve 2,3-DPG and/or ATP concentrations for all stored RBCs.

### Collection and Separation Procedures

The volume of whole blood removed for storage, processing, and transfusion was historically 450 mL (a pint) in Western countries. For some newer collection systems, this amount has been increased to 500 mL (a half-liter) to increase the collection with each donation and to offset the losses associated with leukocyte reduction by filtration. Products derived from either collection volumes, whether leukocyte-reduced or not, are considered one unit. The inter-donor differences in hematocrit and platelet count are sufficiently great that the yields of red cells, platelets, and plasma in components prepared from donor units of either collection volume show considerable overlap. Some have argued for a more standard definition of a unit, perhaps based on grams of hemoglobin, but it would make blood collection more difficult and wasteful.<sup>43</sup>

As noted above, the volume of anticoagulant-nutrient solution is normally 1/7th the volume of the collected blood, 63 mL for a 450-mL collection and 70 mL for a 500-mL collection. This volume ratio has been a standard for more than 50 years and was used with the anticoagulant-nutrient solutions ACD-A, CPD, and CPDA-1. There has long been a question of whether the first few drops of blood to enter the collection system are injured by their sudden immersion in the acid anticoagulant, but the red cells seem to tolerate this process with minimal hemolysis or loss of viability.<sup>44,45</sup> At the end of collection, venous blood with a pH of about 7.35 has been mixed with anticoagulant-nutrient solution with a pH of 5.0 to 5.6 with a resulting pH about 7.05 in the

mixture. The high buffer capacity of the hemoglobin molecule limits the effects of the acidic primary collection solution.

Whole blood in anticoagulant-nutrient solution was licensed for storage for 3 or 5 weeks, but has now been largely replaced by separately stored blood components. Making components from whole blood not only serves more patients but also improves the storage of the individual blood elements. Red cells are best stored cold, platelets at room temperature, and plasma, frozen. Removing the white cells also improves RBC storage by removing a cell population with high energy requirements and potential for damaging red cells by released enzymes.<sup>46</sup>

Schemes for separating whole blood into components are based on centrifugation. The standard “platelet-rich plasma” method used in the United States involves performing a low-speed “soft” spin to sediment the red cells against the pole of the bag opposite the connections to the satellite bags and then squeezing off the supernatant platelet-rich plasma from the top of the bag into the first satellite bag with pressure applied to the sides of the base of the bag. Thus, typically, 500 mL of whole blood with a hematocrit of 42%, consisting of 210 mL of red cells and 290 mL of plasma, is collected into 70 mL of anticoagulant-nutrient solution, increasing the volume in the bag to 570 mL and reducing the hematocrit to 36%. Removing most of the supernatant plasma will increase the hematocrit in the bag to 80% to 90%, consisting of the original 210 mL of red cells and the remaining 22 to 45 mL of plasma/anticoagulant-nutrient solution mixture. Of the original 290 mL of plasma and 70 mL of anticoagulant-nutrient solution, about 90% is removed in this initial separation process. In Europe an initial hard spin is generally preferred in order to harvest buffy coat for the production of platelets and increase the volume of the separated plasma. As noted above, the red cells do better if most of the plasma volume and anticoagulant-nutrient solution are replaced.

Recently, separation of whole blood into plasma and RBC by using a hollow-fiber filtration system has been described.<sup>47</sup> Red cell parameters were similar to those obtained when routine centrifugation methods were used, and the filter did not cause hemolysis. Levels of plasma Factor VIII and Factor XI were slightly reduced with this prototype; however, there was no evidence of activation of the coagulation or complement systems and filters that do not interact with coagulation factors can be made.

### Anticoagulant-Nutrient Solutions

Anticoagulant-nutrient solutions were developed from ACD to CPD to CPDA-1. This path is the result of the discovery of the critical nutrients for red cells during prolonged storage: dextrose, phosphate, and adenine. The recognition that RBC concentrates occasionally ran out of glucose led to development of CP2D, with twice the amount of glucose in CPD, and a never-licensed CPDA-2 with a third more glucose than CPDA-1.<sup>48,49</sup> The molar contents of the five licensed anticoagulant-nutrient solutions are shown in Table 4-1. Note that all of the anticoagulant-nutrient solutions are acidic, reducing the pH of the stored blood below 7.2 and leading to the rapid depletion of 2,3-DPG as it enters the glycolytic pathway.

**Table 4-1.** Compositions and Properties of Some of the Common Acid Citrate Preservative Solutions

|                                                | ACD-A | ACD-B | CPD  | CPDA-1 | CP2D |

ACD = acid-citrate-dextrose (two formulations, A and B); CPD = citrate-phosphate-dextrose; CPDA-1 = citrate-phosphate-dextrose-adenine; CP2D = CPD with double dextrose.

The amounts of the nutrients in the anticoagulant-nutrient solutions are critical depending on the intended storage times. There is enough glucose in whole blood to keep the red cells healthy for 4 days. Whole blood, stored in citrate alone for up to 4 days, was considered the safest form of storage before autoclavable solutions containing sugar were developed. The high glucose content of CP2D is necessary because it is used with an additive solution that does not contain sufficient glucose, AS-3. Phosphate exists at 1 to 1.3 mM/L in plasma, but needs to be present at higher concentrations in the nutrient solution to passively diffuse against the high concentrations in the red cells when 2,3-DPG breaks down. Adenine is needed for storage only beyond 3 weeks and is an ingredient of all of the additive solutions.

In emergencies in remote locations, it may be necessary to collect fresh whole blood before new supplies of fully tested components are available. Under these circumstances, drawing whole blood into the primary collection bag containing the anticoagulant-nutrient solution and holding the whole blood at room temperature for up to 24 hours is associated with good short-term preservation of function of the blood components.<sup>50</sup> The national blood services of Finland and Israel collect all of their whole blood on one day and process it on the next, holding it at 20°C overnight in the anticoagulant-nutrient solution before separating it into components.<sup>51,52</sup>

### Additive Solutions

The first widely used additive solution, SAG, represented an attempt to replace the volume and sugar lost with plasma removal and add the adenine necessary for storage beyond 3 weeks.<sup>41</sup> It was made with normal saline with 4.5% w/v glucose and 2 mM/L of adenine. Stored RBCs had good viability for 5 weeks but 1% hemolysis. In screening a large number of compounds for additives that would reduce the hemolysis, mannitol was identified as a compound that both reduced hemolysis and had an excellent safety record with intravenous infusion. The addition of 30 mM mannitol (SAG-M) reduced

hemolysis and increased the osmolarity of the solution further.<sup>42</sup> The solutions are made acidic to a pH of about 5.6 with hydrochloric acid to allow the glucose to be heat sterilized, but the solutions have essentially no buffer capacity so they do not make the RBC units much more acidic than they were when separated from plasma. SAG-M and its close relatives, AS-1 and AS-5, are the most widely used additive solutions.

Other widely used first-generation additive solution systems include CP2D/AS-3 in the United States and Canada, and CPD/MAP (mannitol, adenine, phosphate) in Japan.<sup>53</sup> Table 4-2 provides a comparison of the ingredients and concentrations of the more common of these first-generation additive solutions.

Second-generation additive solutions started with attempts to rebalance the final suspending solution and a search for additional nutrients for the RBC units. With BAGP, Beutler attempted to preserve both ATP and 2,3-DPG by raising the pH.<sup>40</sup> However, raising the pH substantially above 7.2 led to high concentrations

of 2,3-DPG at the expense of ATP and no improvement in storage function. The composition of a representative group of second-generation additive solutions are shown in Table 4-3.

The pH of red cells during storage is very important. Above pH 7.2, the bifunctional enzyme diphosphoglycerate mutase/phosphatase converts almost all 1,3-DPG into 2,3-DPG, depriving the cell of new ATP.<sup>54</sup> Below a pH of about 6.4, the activities of the initial enzymes of glycolysis, hexokinase and phosphofructokinase, are too low to support ATP production. In this narrow pH range between 7.2 and 6.4, hemoglobin, the mineral salts in the suspension, and bicarbonate all serve to buffer the protons produced by glycolysis. The approximately 60 g of hemoglobin present in an RBC unit can buffer about 8 mEq of protons in that pH range.<sup>55</sup> However, conventional first-generation acidic additive solutions, which result in an initial pH of 7.0, fail to take advantage of a quarter of that pH range and buffer capacity. Adding 20 mM/L of phosphate delivers 2 mM in the 100 mL of additive solution and buffers about 1 mM of additional protons. Adding 20 mM/L of bicarbonate again delivers 2 mM to the final RBC suspension, which will be protonated to make carbonic acid and converted to carbon dioxide and water by red cell carbonic anhydrase. The resulting solution will buffer 2 mM of protons as the carbon dioxide diffuses out of the plastic bag. Attention to formulation and pH balance in the design of second-generation additive solutions can almost double the amount of ATP energy available to stored red cells by depressing diphosphoglycerate mutase activity while sustaining glycolysis.

Finding additional critical nutrients has been less successful. The only approved second-generation solution is phosphate, adenine, glucose, guanosine, and saline (PAGGS)-mannitol.<sup>56</sup> Guanosine was added because GTP was detected in red cells and known to decrease during storage. However, guanosine nucleotides play only a minimal role in critical events in red

**Table 4-2.** Compositions (in mM/L) of the Common Licensed First-Generation RBC Additive Solutions

BAGP-M 5 bicarbonate-adenine-glucose-phosphate-mannitol, the original additive solution developed by Beutler; PAGGS-M 5 phosphate-adenine-glucose-guanosine-saline-mannitol, licensed in Germany; PAGGG-M 5 phosphate-adenine-glucose-guanosine-(sodium) gluconate-mannitol, developed by de Korte as a chloride-free variant of PAGGS-M; ErythroSol-1 and -2 developed by Hogman; EAS-81 5 developed by Hess and Greenwalt.

cell storage (inhibiting the primitive coagulation enzyme transglutaminase) and the solution worked only modestly better than first-generation additive solutions with a 74.6% 24-hour in-vivo recovery after 7 weeks in the only published series.

As ingredients were added to advanced additive solutions, the salt concentration was generally reduced to maintain osmotic balance. Reducing the chloride concentration in the suspending solutions caused intracellular chloride to passively leave the red cells, but this can occur only if other anions countered the flow, and phosphate, bicarbonate, and hydroxyl ions are the only available anions.<sup>57</sup> The influx of these anions initially increases the intracellular pH, but eventually the pH falls. PAGGG-M, in which the sodium chloride is replaced by sodium gluconate, is an example of an attempt to take advantage of the “chloride shift” phenomenon to maintain red cell 2,3-DPG.<sup>58</sup>

The ErythroSol solutions were developed by Hogman based on the ideas of using the “chloride shift” to increase the intracellular pH while using a more alkaline final suspending solution and additional phosphate to simultaneously maintain ATP.<sup>59</sup> ErythroSol-1 used half-strength citrate (0.5 CPD) and had problems with incomplete anticoagulation in blood collected from donors with low (but acceptable) hematocrit levels. ErythroSol-2 uses full strength CPD and an alkaline additive solution made with disodium phosphate. In both systems the glucose was placed in a separate bag from the rest of the additive solution during manufacture and sterilization and added only at the time of RBC component production. The original description of ErythroSol-2 suggested that the optimal pH had been determined to preserve both ATP and 2,3-DPG.<sup>60</sup> However, the study needs confirmation because only 10 units were stored in the ErythroSol-2. The natural variability in donor hematocrit means that some units with low red cell content have low buffer capacity and, therefore, become overly alkaline. The solution can achieve successful 7-week storage. Merely increasing the pH of conventional additive solutions to increase the 2,3-DPG causes the ATP concentrations to fall.<sup>61</sup>

The experimental additive solution-81 (EAS-81) was the end result of work by Hess and Greenwalt that reexamined the use of bicarbonate as a buffer to prevent erythro-apoptosis by maintaining high concentrations of red cell ATP and limited hemolysis with mannitol and hypotonic conditions.<sup>54</sup> Formulating the solutions to get the starting pH as close as possible to 7.2 preserves the 2,3-DPG concentrations for 2 weeks.<sup>62</sup> The buffering provided by the bicarbonate probably allows RBC storage for at least 8 weeks based on six recovery measurements.<sup>62</sup>

Finally, increasing the volume of these advanced additive solutions increases the buffering capacity and allows greater storage time. With 300 mL of additive solutions, Hess and colleagues were able to achieve storage times of 10 to 12 weeks, but the higher volume and lower storage hematocrit probably make such solutions inappropriate for clinical use, especially in infants and massively transfused trauma patients.<sup>63</sup>

### **Additional Factors Influencing RBC Quality** **Temperature and Time Lapses during Collection and Component Preparation**

Whole blood is collected at body temperature and must be maintained at room temperature if platelets are to be prepared from the collection. By present US regulations, whole blood must be separated into its components in 8 hours if platelets and Fresh Frozen Plasma are to be manufactured. If only RBCs and frozen plasma are to be made, the whole blood can be held on ice for up to 24 hours. The problems with holding blood at room temperature are twofold. Red cells metabolize glucose at higher rates when warm, producing more lactate and protons that reduce the pH and further slow metabolism. In addition, labile coagulation factors are lost. Attempts to validate the 24-hour warm hold for 6-week RBC storage using first-generation additive solutions have not been successful. However, in Israel and Finland, where this system is used, RBCs are rarely stored for that long because the national blood services are efficient and supply lines are short.

As noted above, fresh whole blood is occasionally collected in emergencies on the battlefield or in isolated locations such as Pacific Island nations and stored at room temperature. Based on the above experience and experimental data, blood probably maintains reasonable functionality for 24 to 72 hours if maintained between 19 and 25°C.<sup>52</sup> However, such use can be recommended only in the most urgent of situations.

### **Temperature and Time Lapses during Storage**

RBCs that have been allowed to rewarm to greater than 10°C during storage are considered unfit for transfusion and are destroyed per FDA regulations. This has led to the wide use of the “30-minute rule,” meaning that units are discarded if they have been off ice for more than 30 minutes. Experimental work has shown that glucose is metabolized about 10 times as fast at 25°C as at 4°C and that RBCs stored at 25°C lose viability 10 times as fast. Thus, a day of storage at room temperature would reduce the in-vivo recovery equivalent to 10 days of 4°C storage.<sup>64,65</sup> The regulation is very conservative with regard to temperature but it is also intended to prevent bacterial overgrowth in contaminated units.

### **Storage Containers**

Polyvinyl chloride bags plasticized with DEHP are the standard RBC storage containers. The presence of the DEHP reduces hemolysis by 4-fold during storage by intercalating into the red cell membrane.<sup>66</sup> Other plasticizers, such as butyryl-n-trihexyl citrate, work almost as well, but are more expensive (~5% more for a multibag set with leukocyte filter) and have an unusual smell when initially unwrapped.

While questions about the safety of DEHP have been raised, they are based on very limited animal testing and must be balanced against the obvious safety value of being able to visually inspect the contents of blood bags and reduce RBC losses by extending shelf-life. The general trend in Europe to avoid the slowly degradable plasticizer, DEHP, has resulted in the

introduction of butyryl-n-trihexyl citrate plasticized multibag systems in Sweden, Spain, and Norway.

Leukocyte Reduction

Leukocyte reduction improves RBC storage by removing a highly metabolically active blood component that would make the bag more acidic sooner. White cells also secrete cytokines, and when they die after exposure to the cold, they release proteolytic, glycolytic, and lipolytic enzymes that damage the red cell surface. On the other hand, some red cells are damaged in the filters, and typically 15 to 35 mL of blood is lost in the filters, depending on filter size and whether whole blood or concentrated red cells are being leukocyte reduced. Red cells from donors with sickle cell trait and mild thalassemia may also clog filters. Leukocyte reduction improves the red cell 24-hour in-vivo recovery by several percent according to the best estimates.<sup>46</sup>

Washing

Washing RBCs in saline to remove the plasma causes small losses of red cells in the bag transfers, as well as loss of the supporting nutrients, glucose, phosphate, and adenine. Because the cells are used soon after washing, generally within 6 to 24 hours, only the glucose loss is physiologically important. There is still a small amount of glucose inside the washed red cells, but it is metabolized quickly especially if the cells are not promptly refrigerated. In the absence of glucose, metabolism stops and the cells are very susceptible to oxidative stress and erythro-apoptotic changes.

Irradiation

During storage at 4°C, red cells lose potassium. This potassium collects in the supernatant fluid in the closed storage bag at a rate of about 1 mEq/day until equilibrium is reached between intra- and extracellular concentrations, usually at about 60 to 70 mEq/L depending on the storage hematocrit (Table 4-4). Gamma irradiation in doses of 2500 cGy, given to prevent graft-vs-host disease, damages the red cell membranes and increases this rate of potassium loss to approximately 1.5 mEq/day; however the reinfused red cells have normal in-vivo survival.<sup>67</sup> The current FDA regulation that irradiated RBCs expire 28 days after irradiation limits the potential maximum potassium concentration by limiting the period of potassium loss. Nevertheless, care must be taken in all situations when large volumes of older, high-potassium RBC units are used to prime cardiopulmonary bypass, dialysis, or apheresis circuits and then administered at high flow rates into the central circulation.

Pathogen Reduction

Pathogen reduction systems developed so far require additional manipulation of and stresses on the stored red cells that are system specific. Examples from two such proposed systems are illustrative. Diethanolamine (DEA) was proposed as a red cell permeable nucleic acid cross-linker with broad pathogen killing potential and minimal direct red cell toxicity. However,

**Table 4-4.** Effect of Storage Duration on Characteristics of RBC Concentrates in AS-1

|                      | 35 Days<br>(n = 25) | 42 Days<br>(n = 10) | 49 Days<br>(n = 10) | 56 Days<br>(n = 10) |

Unpublished data obtained from the US Food and Drug Administration under the Freedom of Information Act. ATP = adenosine triphosphate; Hb = hemoglobin.

the system required exposure of the cells to DEA for 20 hours at room temperature and extensive secondary washing to reduce the remaining amounts of this carcinogenic chemical. When the time- and temperature-related decrease in red cell pH was added to the effects of washing with large volumes of acidic solutions and storage in an acidic additive solution, red cell recovery suffered.<sup>68</sup> Riboflavin, a photoactive oxidizer, has also been proposed as a highly red cell permeable molecule for pathogen reduction in conjunction with ultraviolet light. However, red cells are so optically dense that the units must be diluted and transferred to large bags only a few millimeters thick for photo-treatment, and the photo-treatment must be done above a critical temperature. The bag transfers all involve losses of red cells, the choice of diluent fluid is important, and the hemoglobin and other optically active molecules in the red cells are also damaged by the light exposure. The red cells need additional energy to attempt to correct the damage. Finally, the reconstituted and treated red cells need to be stored in an additive solution that is balanced to maximize their life span.

Functionality

Since the discovery of the effect of 2,3-DPG on the oxygen affinity of hemoglobin, it has been common to discuss the functionality of stored red cells in terms of their 2,3-DPG content.<sup>69</sup> This is an oversimplification for several reasons. First, while it is clear that low 2,3-DPG can affect oxygen delivery in animal models at critically low hemoglobin concentrations, these concentrations are well below standard transfusion triggers.<sup>70</sup> Second, 2,3-DPG works in red cells by binding and stabilizing deoxyhemoglobin. This moves the base of the oxygen-hemoglobin dissociation curve to the right and increases the P50, but most oxygen transport occurs at the top of the binding curve which is relatively unaffected, and even in critical situations, the arterial PO<sub>2</sub> is higher than the P50. However, 2,3-DPG may play an important role in red cell membrane transport and cytoskeleton architecture because of its interaction with attachment points between the cell membrane and the cytoskeleton, and the interaction of deoxyhemoglobin with band 3. These interactions, the critical importance of oxygen transport, and the retrospective data that

suggest an association between adverse patient outcomes and increased storage time of banked RBCs, drives continuing efforts to reduce 2,3-DPG depletion during storage with modern additive solutions. Until that is achieved, it is recommended in some countries, such as Norway, to use RBCs in SAG-M, not older than 10 days, for the transfusion of intensive care patients.

Probably more important for normal red cell function is the loss of membrane, cell deformability, and ATP secretion that occurs with storage. Direct observation of the flow characteristics of fresh, stored, and stored rejuvenated RBCs suggests that ATP secretion in response to decreased shear, by which red cells dilate small vessels to maintain their forward flow, is most important.<sup>71</sup> Membrane deformability, which is regulated by the ATP-modulated cytoskeleton, is very important for the passage of red cells through capillaries half their diameter. Maintaining high ATP concentrations is, therefore, an important function of modern additive solutions.

### Rejuvenation

Red cell loss of viability during storage is different from red cell senescence in the body. In the body, red cells undergo cumulative oxidative damage that leads to reduced enzyme activities and cross-linking of cytoskeletal components. These are essentially irreversible processes and are ultimately associated with macrophage clearance of old red cells, possibly mediated by phosphatidyl serine exposure or neoantigen formation. The changes that lead to loss of viability during storage are largely reversible by a process called “rejuvenation.” Hogman showed that rejuvenating red cells at the end of 6 weeks of storage in SAG-M increased their 24-hour in-vivo recovery from 77% to 89%.<sup>72</sup>

This rejuvenation is a strictly metabolic recharging of red cells at the end of their storage period. Such cells have a low pH as well as low ATP and 2,3-DPG concentrations. They can be rejuvenated by incubation in a high pH solution of phosphate, inosine, pyruvate, and adenine (PIPA, Rejuvesol, Cytosol Laboratories, Braintree, MA) for 2 hours. Such incubation increases their ATP and 2,3-DPG concentrations and increases their in-vivo recovery, probably by allowing them to internalize negatively charged membrane phospholipids that would otherwise signal clearance by macrophages. Return of the normal distribution of phospholipids also prevents red cells from participating in plasma coagulation reactions. Rejuvenation does not reverse the oxidative damage to band 3 of the cell membrane. However, the fact that RBC can be rejuvenated at the end of storage by increasing their pH and ATP suggests that improved storage could be achieved by a method designed to maintain pH and ATP. This is the fundamental idea behind second-generation additive solutions.

### Frozen Storage of RBCs

RBCs can be frozen, and in the frozen state they are stable for long periods—Valeri has reported storage of 37 years.<sup>73</sup> Four methods of freezing RBCs have been extensively tested, two have been developed for practical use, and one remains in common use.<sup>74</sup>

During red cell freezing, water turns to ice and the salt concentration of the remaining intracellular water increases, drawing in more water and expanding the cell. Under normal circumstances, this leads to cell rupture. Rupture can be prevented by freezing the cells so rapidly that water does not have time to enter, or by diluting the total cellular water with a cryoprotectant so that not enough water enters to rupture the cell. While several cryoprotectants can work, glycerol is the standard material used because of its cost and safety. The two systems for RBC cryopreservation that have been developed for clinical use both use glycerol. One system uses a “low” glycerol concentration of about 20% and rapid cooling by plunge freezing in liquid nitrogen; the other uses a “high” glycerol concentration of about 40% and slow cooling in  $-80^{\circ}\text{C}$  freezers. The low glycerol frozen RBCs must be maintained in the vapor phase of liquid nitrogen whereas the high glycerol frozen RBCs are stable at temperatures below  $-65^{\circ}\text{C}$ . The high cost of maintaining liquid nitrogen freezers and the difficulty of transporting products frozen in liquid nitrogen limit the utility of the low glycerol system. High glycerol frozen RBCs can be transported on dry ice. When the RBCs are thawed, the glycerol must be removed promptly to prevent it from poisoning the red cell metabolism and to protect the recipient because the glycerol-loaded red cells would swell and rupture if placed directly into the bloodstream. Thus, once thawed, the RBCs must be deglycerolized by washing in a set of graded salt solutions. In the past, the glycerolization and deglycerolization of RBCs for freezing were open manual processes, so the thawed RBCs had to be used within 24 hours or discarded.

The recent partial automation of a closed system for glycerolizing and deglycerolizing RBCs now allows them to be kept after thawing in the liquid state for 2 weeks.<sup>75</sup> RBCs collected in any of the standard licensed systems can be frozen up to 6 days after collection and stored for up to 10 years. The deglycerolized RBCs are then stored in AS-3. Net losses of red cells in the freeze-thaw-wash process are approximately 5% to 15%, and the 24-hour in-vivo recovery of infused red cells is about 78% after 2 weeks. Frozen RBCs entail substantial costs for processing and storage, probably four times that of a standard liquid unit, so only for the rarest blood units is there an advantage for frozen inventory.

Other systems of freezing and freeze-drying have been demonstrated, but are associated with greater than 1% hemolysis and so would require a washing step before administration. This limitation prevents their use in emergency medicine, and they are too costly and labor intensive to compete with glycerol frozen RBCs.<sup>74</sup>

### Validation of RBC Storage Systems

RBC storage systems have historically been validated by demonstrating that the stored cells do not hemolyze during storage and that they circulate normally after reinfusion. Measures of normal circulation have included increments in recipient hemoglobin, and determining the recovery and in-vivo half life of the transfused red cells. Transfused red cells have been counted using differential agglutination, radioactive tracer labeling, and flow-cytometric differential counting.

Chromium-51 labeling has been the standard method used in the United States for 50 years. There is a published standard method, but only a handful of laboratories perform the measurement, and a recent attempt to gather a decade's experience identified only 900 measurements.<sup>76</sup> Chromium-51 labeling persists in the United States because it is the only validated method compatible with autologous red cell reinfusion, and the infectious disease risks of allogeneic RBCs are considered unacceptable for storage system development work. The methods of red cell labeling have been the subject of an excellent review.<sup>77</sup>

When performing chromium-51 labeling, it is important to recognize that red cells from different donors may have very different 24-hour in-vivo recovery values. In a typical study of a modern additive solution with an 84% mean recovery, individual RBC units have recoveries as high as 95% and as low as 65%.<sup>48</sup> These differences in viability correlate with differences in the red cell ATP concentrations, but poorly ( $r^2 = 0.4$ ).

There have been attempts to measure the functionality of red cells, as opposed to their survival. Presumably, the functionality of red cells is related to their ability to deliver oxygen to tissues and to flow in the microcirculation. However, none of the red cell rigidity or microcirculatory flow measures is widely available or validated. The level of 2,3-DPG is just a surrogate marker for red cell function and is limited by the difficulty of performing the test. In a recent shared sample exercise, 12 of the world's premier laboratories could not consistently measure 2,3-DPG.<sup>78</sup>

Finally, in countries that do not perform chromium-51 recovery measures, there has been a trend to use the ATP level as a red cell quality measure. While the ATP is a poor surrogate for recovery in small clinical trials, its central role in the inhibition of erythro-apoptosis probably gives it special importance. Unfortunately the measure is not very reproducible from laboratory to laboratory, so a wide margin of safety is required.<sup>78</sup>

## Summary

RBC storage systems work remarkably well, making red cells for transfusion available, safe, effective, and cheap for the populations who can organize effective national blood systems. They are a product of slow and empiric development, and our present systems do not reflect our current understanding. They can be expected to improve in the future.

## Red Cell Immunology and Compatibility Testing

**W. John Judd**

Emeritus Professor of Immunohematology, Department of Pathology, University Hospitals, University of Michigan, Ann Arbor, Michigan, USA

Immunohematology is the study of immune aspects of blood. This chapter begins with a review of the basic concepts of immunity as they apply to the formation of antibodies to foreign antigens, also called *allo*antibodies. Other areas of immunohematology such as autoantibodies and drug-induced antibodies are presented elsewhere.

The relevance of immunohematology in transfusion medicine is addressed through detailed discussion of the principles of serologic tests and their application to donor-recipient compatibility testing. Identification of the blood group specificity of alloantibodies (alloantibody identification) encountered during such testing is presented in a step-by-step manner such that a limited number of possible specificities remain. Additional testing may be required to obtain a definitive answer. The chapter concludes with discussion of computer-based programs to prevent release of ABO-incompatible units from the blood bank, as well as new technologies, including nanotechnology, that prevent transfusion errors caused by patient misidentification.

---

### Red Cell Immunology

#### The Immune Response

Immune responses can be divided into two categories: humoral immunity and cell-mediated events. Humoral immunity is B-cell mediated and entails the generation of antibodies. Cell-mediated immunity is a reflection of the action of T cells, which regulate the immune response through the production of cytokines and direct interactions with other elements/cells of the immune system.

An individual's genetic constitution determines the characteristics of that person's cells and fluid-phase molecules; this is

referred to as the "self" of the individual. All other ("non-self") molecules are considered foreign. During fetal development, and continuing through the neonatal period, B and T cells produce receptors that enable each lymphocyte to recognize a single specific antigen.<sup>1</sup>

#### Antigen Receptors of T Cells and B Cells

The antigen receptors of both T and B cells consist of two polypeptide chains synthesized under the direction of two different chromosomal loci. The loci for B-cell receptors are on chromosome 14 and either on chromosome 2 or 22; the loci for T-cell receptors are on chromosome 7 and 14 (but not the same locus as for B-cell receptors). In the early stages of lymphocyte development, the genetic material at each of these loci undergoes a process of rearrangement that is unique to each cell.<sup>2</sup>

Germline DNA at these loci contain numerous base-pair sequences, each capable of encoding different amino acid sequences. The gene rearrangement process entails selection of single base-pair sequences for each portion of the immunoglobulin molecule from the assortment (library) of base pairs available (Fig 5-1), and also involves elimination of unused genetic material.<sup>3</sup>

Each T-cell/B-cell receptor chain consists of a constant portion and a variable portion. Amino acid sequences of the variable portion determine the idiotypic specificity of the immunoglobulin molecule. For both receptors, one chain contains selections from three libraries (V, D, J), while the other chain contains selections from V and J libraries. Given that the heavy chain locus has as many as 400 exons in the V library, 20 in the J library, and six in the D library, the number of possible combinations for different protein configurations is astronomic. At the light chain loci there are some 300 possible selections in the V library, and four in the J library. Selection from each library is random, and further amino acid sequence variation is introduced by inaccurate splicing or when different exons are joined together. Consequently,  $10^9$  different receptor configurations can be generated.<sup>1</sup>

**Figure 5-1.** Diagram of the immunoglobulin heavy chain locus on chromosome 14. In the unrearranged locus (top) V, D, and J libraries are on the left; sequences for the constant regions are on the right. Gene rearrangement occurs by selection of one D and one J exon to form a D/J unit. This is then joined by one V exon. The V/D/J unit is adjacent to the exons for  $\mu$  and  $\delta$  constant regions. Through alternative splicing, the primary transcript generates either  $\mu$  or  $\delta$  heavy chains with the same variable region configuration (idiotypic). In later generations, clonal progeny can attach the V/D/J transcript to other sequences from the constant region (isotype switch).

### Exposure to Foreign Protein Antigens

If foreign protein antigens enter the host, antigen-presenting cells (APCs) isolate the antigen and display the molecular configurations as epitopes on their cell surfaces. T and B lymphocytes with the appropriate receptor for the unique molecular configuration can then establish intimate contact with the APC. This contact initiates cellular events that generate clones of activated lymphocytes specific for the foreign antigen. Cytokines produced by APCs and by activated T cells cause B cells to evolve into immunoglobulin-secreting plasma cells. In turn, B cells capture antigen and present it back to T cells in a manner that causes the T cells to secrete cytokines that promote more focused antibody production.

Most plasma cells have a short but active life of antibody production. Some, however, become memory cells that retain intracellular changes resulting from exposure to APCs; these persist in the circulation long after their initial activation.

### Primary Response

The first immunoglobulin class to appear in the bloodstream is always IgM; the lag phase (time between sensitizing event and appearance of antibody) can vary from days to months. Shortly after the appearance of IgM antibody, IgG antibody of the same specificity usually becomes detectable. The IgM component disappears over time, while the IgG component persists indefinitely. Cytokines from activated T cells are essential for this isotype switching and for generation of memory cells.

### T-Cell Independent Response

It is of note that antibodies to carbohydrate antigens are invariably IgM. This is because B-cell APCs can interact directly with complex polysaccharides such as those that carry blood group A or B activity. Structures that have multiple identical repeat carbohydrate chains can initiate B-cell proliferation and antibody secretion without the action of T cells. In the absence of the

immunomodulatory effects of T cells, isotype switching does not occur, and no memory cells develop.<sup>4</sup>

### Secondary (Anamnestic) Response

Within a few hours or days after subsequent exposure to T-dependent antigen, there is a sharp rise in the level of IgG antibody. Because there has been prior clonal expansion, the number of participating B cells will be high, resulting in production of significantly (eg, 100-fold) more IgG than was produced in the primary response. Cytokines secreted by T cells promote more focused antibody production.

### Affinity Maturation

The affinity of IgG antibody for specific antigen increases progressively during the secondary immune response, particularly after stimulation with low doses of antigen. This affinity maturation is most pronounced after secondary challenge with antigen.

One explanation for affinity maturation is clonal selection. A second explanation for affinity maturation is that, after a class switch has occurred in the immune response, somatic mutations occur that fine-tune the antibodies to be of higher affinity. There is experimental evidence for this mechanism, although it is not known how the somatic mutation mechanism is activated after exposure to antigen.

### Clonality

Only antigen-specific B cells proliferate and mature into antibody-secreting plasma cells. The number of progenitor B cells that are initially activated will determine the heterogeneity (clonality) of the immune response. The response will range from polyclonal (when many different B cells are activated simultaneously) to monoclonal (when the antibody-producing cells originate from a single ancestral B cell). Monoclonal antibodies for reagent use can also be produced in vitro using hybridoma technology.<sup>5</sup>

## Immunoglobulin Molecules

Figure 5-2 portrays the basic structure of an antibody molecule, which consists of four polypeptide chains: two identical light chains of 214 amino acids, and two identical heavy chains of 440 or more amino acids. Antigenic specificity is conferred by the 134 N-terminal amino acids of the light chains and the 144 N-terminal amino acids of the heavy chains; these are described as variable regions. The remaining portions of both chains are referred to as constant regions.<sup>6</sup>

### Light Chains

The constant region of the light chains can have one of two different amino acid sequences, designated kappa ( $\kappa$ ) and lambda ( $\lambda$ ).  $\kappa$  chains are encoded by a locus on chromosome 2,  $\lambda$  chains by a locus on chromosome 22. A single cell will synthesize an immunoglobulin molecule containing either  $\kappa$  or  $\lambda$  chains, but never both.

### Heavy Chains

The constant region of heavy chains can manifest one of five amino acid sequences, designated by the Greek letters  $\alpha$  (alpha),  $\delta$  (delta),  $\epsilon$  (epsilon),  $\gamma$  (gamma), and  $\mu$  (mu). These give rise to

**Figure 5-2.** Basic structure of an immunoglobulin molecule.

five types of immunoglobulin classes termed IgA, IgD, IgE, IgG, and IgM, respectively. The site on chromosome 14 that governs the manufacture of heavy chains contains DNA sequences for all five types of heavy chain.

### Antibody Diversity

Serologic studies have revealed a number of antigenic markers on the heavy and light chains of immunoglobulin molecules. The results of such studies are strongly supported by molecular analysis of the immunoglobulin genes.<sup>3,6</sup> Differences between these antigenic markers are illustrated in Fig 5-3.

### Isotypes

Isotypes result from structural changes to the constant region heavy and light chains. Genes encoding the various isotypes (IgA, IgD, IgE, IgG, IgM,  $\kappa$ , and  $\lambda$ ) are all present in the human genome. Antibodies for isotype determination can be prepared by heterologous immunization (eg, mouse immunization with human serum).

### Allotypes

Allotypic distinctions between antibodies are the result of genetic polymorphisms, and each marker is not present in every individual. This genetic variation results from different alleles at structural loci. Antibodies to allotypic variants can be raised by same-species (homologous, allogeneic) immunization, and are often found in the sera of women who have given birth to infants with different allotypic markers. These markers usually represent amino acid changes in the constant regions of antibody molecules.

### Idiotypes

Idiotypic variation is the result of differences in amino acid sequence of the variable regions of either light or heavy chains. Antibodies to idiotypes may recognize sequences either within or outside the antigen-combining site, and can be prepared by either homologous or heterologous immunization.

### Blood Group Antibodies

Blood group antibodies are immunoglobulins that react with antigens on the surface of red cells. They can either be acquired

**Figure 5-3.** Diversity of antibody molecules.

Table 5-1. Characteristics of Blood Group Active Immunoglobulins

| Immunoglobulin Characteristic | IgM             | IgG         | IgA                  |
|-------------------------------|-----------------|-------------|----------------------|
| H-chain isotype               | μ               | γ           | α                    |
| Subclasses                    | 2               | 4           | 1                    |
| L-chain types                 | κλ              | κλ          | κλ                   |
| Sedimentation constant        | 19 S            | 7 S         | 11 S                 |
| Molecular weight              | 900-1000 kD     | 150 kD      | 180-500 kD           |
| Electrophoretic mobility      | Between β and γ | γ           | γ                    |
| Serum concentration (mg/dL)   | 85-205          | 1000-1500   | 200-350              |
| Antigen binding sites         | 10 (5)          | 2           | 4                    |
| Fixes complement              | Often           | Some        | No                   |
| Placental transfer            | No              | Yes         | No                   |
| Direct agglutinin             | Yes             | Usually not | Usually not          |
| Hemolytic in vitro            | Often           | No          | No                   |
| Example                       | Anti-A, anti-B  | Anti-D      | Anti-Lu <sup>a</sup> |

naturally or through immunization with foreign red cells.<sup>7</sup> Most blood group antibodies are either IgG or IgM; occasionally they may be IgA. The IgD and IgE immunoglobulins have not been implicated as blood group antibodies,<sup>8</sup> and will not be discussed further.

Physical Properties

The physical properties and serologic characteristics of the three immunoglobulin classes involved with blood group specificity are summarized in Table 5-1. IgM antibodies have 10 available antigen binding sites, have a wide spanning distance, and often fix complement to red cells. Antibodies to A and B antigens are predominantly IgM; they are found normally in persons whose red cells lack the corresponding antigen. They are stimulated by antigens present in the environment. Bacteria constituting normal intestinal flora carry blood group A- and B-like polysaccharides. As these flora establish themselves in the gut, they provide the immune stimulus for anti-A and anti-B.<sup>7</sup> Anti-A and anti-B formed in this manner are often referred as “natural” antibodies. They are also called “expected” antibodies, because in adults with a normal immune system these antibodies are almost always present when the corresponding antigens are absent on the red cells.

In contrast to anti-A and anti-B, most other blood group antibodies are IgG, which are immune in origin and do not appear in plasma/serum unless the host is exposed directly to foreign red cell antigens. The stimulating event is usually blood transfusion or pregnancy. IgG antibodies are smaller than IgM, and have only two sites for antigen binding.

All antibodies to red cell antigens, other than naturally occurring anti-A and anti-B, are considered unexpected. They can be either alloantibodies, directed toward non-ABO-system antigens absent on the red cells of the antibody producer, or autoantibodies, directed toward self-antigens. The latter may cause autoimmune hemolytic anemia. Unexpected antibodies in donor plasma may destroy recipient red cells, while antibodies in the

recipient may cause accelerated destruction of transfused red cells. In pregnant women, such antibodies may cross the placenta and cause hemolytic disease of the fetus and newborn.<sup>8</sup>

Close to 300 different blood group alloantibodies have been described.<sup>9</sup> Each antibody reacts with its specific antigen on the surface of red cells. The immunoglobulin class and clinical relevance of some of the antibodies encountered during compatibility testing are shown in Table 5-2.

Red Cell Antigen-Antibody Interactions

Red cells normally repel one another. The force of repulsion (zeta potential) that exists at the red cell surface depends not only on the electronegative surface charge, but also on the ionic cloud that normally surrounds it.<sup>10,11</sup> The electronegative charge is imparted primarily by the carboxyl (COO<sup>-</sup>) group of N-acetyl-neuraminic acid,<sup>12</sup> which is a constituent of alkali-labile tetrasaccharides that are attached to MN and Ss sialoglycoproteins (glycophorins A and B, respectively).<sup>9</sup> At a minimum, there are 3.2 × 10<sup>7</sup> of these charged groups per red cell. The magnitude of this charge is modified by the formation of an ionic cloud of positively charged (+) sodium ions and negatively charged (−) chloride ions that align in alternating sequence extending from the red cell membrane surface (Fig 5-4). The net effect of this ionic cloud is to decrease the electrostatic repulsion between red cells.

In considering the interaction of red cell antigens with blood group antibodies, three variables must be considered: the surface charge of the red cells, the dielectric constant of the medium (a relative measure of its charge dissipation), and the mutual attraction between antigen and antibody. The latter involves electrostatic (coulombic) and hydrogen bonds, and van der Waals interactions, which hold antigen and antibody together.<sup>10</sup> Further, there must be structural complementarity between antigen and its binding site on antibody molecules.<sup>13</sup>

There are two phases of red cell antigen-antibody interactions; these often occur simultaneously. The first phase is one of association, involving binding of antibody to antigens on the red cell membrane. The second phase involves the formation of an agglutination lattice of antibody-coated cells. For the latter to occur, antibody molecules must be able to span the distance between adjacent red cells.

Interaction between red cells and blood group antibodies can be observed either directly by examination of red cell and antibody mixtures for agglutination (or clumping) and/or hemolysis, or indirectly by use of the antiglobulin test. These two serologic techniques are summarized in Table 5-3.

Direct Agglutination

IgM antibody molecules can span the distance that exists between red cells when suspended in saline, and cause direct agglutination of those cells if they carry the corresponding antigen. This direct agglutination can be observed when red cells are mixed with IgM antibody, briefly incubated at room temperature, and centrifuged. Examination for hemagglutination may be performed either macroscopically or microscopically, but the latter is not

**Table 5-2.** Characteristics of Blood Group Alloantibodies

\* Coating antibodies detected primarily through the use of the indirect antiglobulin test.  
† Predominant immunoglobulin class shown first.  
‡ HDFN = reported to cause hemolytic disease of the fetus and newborn.  
§ HTR = reported to cause hemolytic transfusion reactions.  
|| HLA = antibody to antigen present on white blood cells that is variably expressed on red cells.  
¶ HTLA = antibody, usually of high titer, to antigen of low site density on red cells. Incorrectly called high-titer, low avidity antibody.  
# C4d = antibody to epitopes found on the fourth component of human complement (C4).  
\*\* Rare in Whites and Blacks. Seen almost exclusively in individuals of Mongolian ancestry (South American Indians, Chippewa Indians, Chinese, Japanese).  
†† WAIHA = seen as an autoantibody in some cases of warm autoimmune hemolytic anemia.

**Figure 5-4.** (A) Red cells carry a strong negative electric charge, imparted primarily by the carboxyl (COO<sup>-</sup>) group of N-acetyl-neuraminic acid. (B) When suspended in a saline medium, red cells are kept apart by virtue of their negative surface charge. The magnitude of this charge is modified by the formation of an ionic cloud of positively charged (+) sodium ions and negatively charged (-) chloride ions that align in alternating sequence extending from red cell membrane surface. The force of repulsion that exists between red cells in suspension is referred as the zeta potential. (C) In order for antibody molecules to cause agglutination of adjacent red cells, the antigen binding sites must be able to span the intercellular distance. Pentameric IgM antibody molecules can readily bridge the distance between adjacent red cells. (D) IgG molecules (black) cannot readily effect direct agglutination. However, they are able to coat red cells. This antibody coating can be detected by a second IgG antibody (eg, rabbit antihuman IgG), depicted here in gray.

Table 5-3. Two Types of Red Cell Serologic Tests

| Direct Tests                             | Indirect Tests                                       |
|------------------------------------------|------------------------------------------------------|
| Mix serum and red cells                  | Mix serum and red cells*                             |
| Incubate (room temperature) <sup>†</sup> | Incubate (37°C)                                      |
| Centrifuge                               | Centrifuge                                           |
| Examine for agglutination and hemolysis  | Examine for agglutination and hemolysis <sup>‡</sup> |
|                                          | Wash, to remove unbound globulins                    |
|                                          | Add antihuman globulin reagent                       |
|                                          | Centrifuge                                           |
|                                          | Examine for agglutination <sup>‡</sup>               |

\* An enhancement reagent, to promote antibody uptake, may be incorporated here.  
† This step is optional.  
‡ Confirm negative test results with IgG-coated red cells.

encouraged because it leads to the detection of nonspecific reactivity. The strength of the observed reactions can be graded, and numerical values can be assigned based on a scoring system in common use.<sup>14</sup>

**Hemolysis**

IgM antibodies, in particular anti-A and anti-B, can also cause direct lysis of antigen-positive red cells, especially if tests are incubated at 37°C. This hemolysis results from the action of complement, a series of α and β globulins that act in sequence as enzymes (eg, esterases) to form a complex (membrane attack complex) that causes holes to be formed in the red cell membrane through which the intracellular hemoglobin can escape (see Fig 5-5). For initiation of the complement cascade, the “tails” (Fc portions) of two

**Figure 5-5.** Classical pathway for complement activation.

pairs of immunoglobulin heavy chains must be in close proximity to each other on the red cell surface. Initiation of the complement cascade readily occurs when a single pentameric IgM antibody molecule is bound; for it to occur with IgG antibodies there must be closely adjacent heavy chain regions of two IgG molecules at the cell surface. Further, not all IgM antibodies bind complement to red cells and complement binding does not always proceed to complete red cell lysis by membrane attack complex (intravascular hemolysis). Rather, activated C3b may be cleaved to C3d, which does not initiate the binding of C5; hence, no membrane attack complex is formed. However, C3d remains bound to red cells and can be detected by the antiglobulin test (see below).<sup>8,14</sup>

Red cells coated with C3b are also removed by cells of the reticuloendothelial system (extravascular hemolysis). However, there are no receptors on macrophages for C3d. Thus, inactivators of C3b serve to limit the degree of both intravascular and extravascular hemolysis.

### Antiglobulin Test

IgG antibodies do not readily cause direct agglutination of red cells, because intercellular distances are wider than the spanning distance of the antigen-binding sites of the IgG molecule. However, some IgG antibodies will cause direct agglutination if the red cell zeta potential is reduced. This can be accomplished by treating the cells with proteolytic enzymes such as papain or ficin, which remove the proteins that carry the negatively charged neuraminic acid residues. Alternatively, zeta potential can be decreased by raising the dielectric constant of the red cell suspending medium by the addition of colloids such as bovine serum albumin.<sup>8</sup>

IgG antibodies, as well as complement components bound to red cells by either IgM or IgG antibodies, are best detected by the antiglobulin test. This test, once called the Coombs' test, entails the use of antibodies raised in animals (usually rabbit or sheep), or prepared by hybridoma technology,<sup>5</sup> to detect human IgG and

complement bound to red cells. The principles of this test are as follows:

1. Antibody molecules and complement components are globulins.
2. The injection of human globulins, either purified or in whole serum, into an animal stimulates the animal to produce antibodies against the foreign globulins. These antibodies are referred to as antihuman globulins (AHGs). The antihuman globulins that are important for blood group serologic work are anti-IgG and anticomplement (anti-C3d).
3. Antihuman globulin will react with human globulins, either bound to red cells or free in serum. Thus, red cells must be washed free of unbound globulins before testing with AHG. This is crucial to the avoidance of false-negative tests caused by neutralization of AHG by unbound globulins.
4. Washed red cells coated with human globulin are agglutinated by AHG.

Antiglobulin tests can be performed either indirectly following in-vitro incubation of red cells with serum, or directly to demonstrate that red cells are coated with globulins in vivo. An indirect antiglobulin test (IAT) is used to detect and identify unexpected antibodies in the serum of blood donors, prospective transfusion recipients, and prenatal patients. The direct antiglobulin test (DAT) is used to detect antibodies bound to red cells in vivo; such antibodies may be seen in patients with hemolysis caused by autoantibodies or drugs, infants with hemolytic disease of the fetus and newborn, and patients manifesting an alloimmune response to a recent transfusion.<sup>14</sup>

### Compatibility Testing

Pretransfusion compatibility testing comprises a series of policies and procedures, including laboratory tests, the goals of which are to provide blood for transfusion that will have the

optimal clinical effect without causing undue harm to the recipient. These elements of pretransfusion testing can be placed into one of three categories: those related to donor unit testing and processing, those related to patient sample collection and testing, and those that serve as a final check between the donor unit and intended recipient (Table 5-4). Proper performance of each element will enable the right unit of blood to be transfused to the right patient.<sup>15</sup>

## Donor Testing

### Collection Facility

The initial ABO, Rh, and antibody detection tests on donor blood, tests for infectious diseases, the interpretation of these tests, and correct labeling of donor units are functions normally carried out by a regional donor center. However, some hospital-based transfusion services continue to procure a portion of their blood needs from the population at large (allogeneic donors), and some collect blood from patients for their own use in

elective surgical procedures (autologous donors). In addition, some patients request that they receive blood from relatives or friends (directed donations). Regardless of the type of donor, each unit of blood must be subjected to tests for ABO, Rh, and unexpected antibodies, as well as for markers of infectious disease (see Chapter 62).

The volume of testing that needs to be performed at donor centers often necessitates use of automated equipment. Instrumentation currently in use is often based on microplate technology, and test results may be interpreted electronically. ABO grouping entails testing both donor red cells and serum/plasma. Red cells are tested with anti-A and anti-B; and the serum/plasma is tested with A<sub>1</sub> and B red cells. Although not required, anti-A, B, and A<sub>2</sub> red cells may also be used, because results with these reagents serve to detect subgroups of A that may be nonreactive in direct tests with anti-A alone.

Rh typing is performed with anti-D. Because D is highly immunogenic,<sup>8</sup> it is presumed that even weak expression of the

antigen will evoke an immune response; consequently, donor red cells that initially type as Rh-negative in direct agglutination tests are tested further for weak D, usually by an IAT (see Table 5-3). Only those units that are negative with anti-D by this method or an equivalent procedure can be labeled Rh-negative.<sup>16(p37)</sup> All straightforward D-positive and weak D-positive blood is considered Rh-positive.

### Transfusing Facility

The ABO group of all units of Whole Blood or Red Blood Cells, and the Rh group of those labeled Rh-negative, must be confirmed by the transfusion facility before transfusion.<sup>16(p43)</sup> Only tests with reagent antisera and donor red cells need to be performed; units labeled group O can be tested with anti-A,B alone.<sup>17</sup> For D typing of units labeled Rh-negative, only direct tests with anti-D are necessary; testing for weak expression of D is not required, nor is repeat testing for unexpected antibodies or for markers of infectious diseases.<sup>16(p43)</sup> For transfusion facilities that also collect blood, confirmatory testing for first-time donors must be performed after the original ABO and Rh label has been affixed using a sample from a segment attached to the donor unit. For repeat donors, the ABO/Rh may be confirmed by an electronic record check of previous donations, provided that tests for ABO compatibility are to be performed serologically. However, if blood is to be released using an electronic cross-match process (see later), the ABO/Rh of the donor unit must be confirmed serologically by testing an attached segment, even for repeat donors.

### Patient Testing

#### Sample Collection

Because the major cause of fatal, hemolytic transfusion reactions is ABO-incompatible transfusion resulting from patient/sample misidentification, the importance of the following measures cannot be overemphasized.

1. *Requisition.* Forms requesting blood and blood components must contain the first and last names and a unique numerical identifier of the intended recipient, such as a hospital registration number.<sup>16(p41)</sup> The name of the requesting physician, gender and date of birth of the patient, clinical diagnosis, and previous transfusion or pregnancy history are additional useful pieces of information.

2. *Patient Identity.* The collection of a properly labeled blood sample for pretransfusion testing from the correct patient is critical to safe blood transfusion. The person collecting the sample must positively identify the patient.<sup>14</sup> This is facilitated through use of a wristband, containing the patient's full name and unique hospital registration number that remains attached to the patient throughout the hospitalization. The information on the requisition form should be compared with that on the wristband; blood samples should not be collected if there is a discrepancy.

In the absence of a wristband, the nursing staff should follow hospital procedure for identifying and attaching a wristband to the patient before any samples are drawn. In an emergency,

a temporary identification number should be used, and cross-referenced with the patient's name and hospital identification number once they are known.

3. *Labeling.* Blood samples must be drawn into correctly labeled tubes. The tubes must be clearly labeled at the bedside with the patient's first and last names, the patient's unique hospital identification number, and the date of collection.<sup>11</sup> There must be a means of identifying the person who collected the sample. Conventionally, the phlebotomist signs or initials the tube and signs or initials the requisition form so that there is a permanent record of the phlebotomist's name.<sup>14</sup>

4. *Confirmation of Sample Identity.* Upon receipt of blood samples for pretransfusion testing, the information on the label must be compared with that on the requisition. A new sample must be obtained whenever there are discrepancies or if there is any doubt about the identity of the sample. It is unacceptable to correct an incorrectly labeled sample.

5. *Type of Sample.* Either serum or plasma may be used for pretransfusion testing, but most workers performing tube testing use serum to avoid introducing small fibrin clots into serologic tests. Such clots may be mistaken for agglutination. Fibrin clots may also form when samples from heparinized patients are collected into non-anticoagulated tubes. These samples will clot properly following the addition of protamine sulfate.<sup>14</sup> However, anticoagulated (plasma) samples are required if testing is automated.

Few workers prefer to use serum rather than plasma for compatibility testing, to facilitate detection of antibodies that primarily coat red cells with the C3d component of complement. Bound C3d will not activate the lytic phase of the complement cascade but can be detected with AHG reagents containing anti-C3d.<sup>8,18</sup> EDTA, citrate and other commonly used anticoagulants chelate calcium ions that are essential for complement activation. However, as discussed later, the use of AHG reagents containing anti-C3d for compatibility testing is not mandatory.<sup>14</sup>

6. *Age of Specimen.* To ensure that the specimen used for compatibility testing is representative of a patient's current immune status, serologic studies must be performed using blood collected no more than 3 days in advance of the transfusion when the patient has been transfused or pregnant within the preceding 3 months, or when such information is uncertain or unavailable.<sup>16(p44)</sup> From a practical standpoint, it is simpler to stipulate that all pretransfusion samples must be collected within 3 days before red cell transfusions, rather than ascertain whether or not each patient has been recently transfused or pregnant.

7. *Storage.* Blood samples used for compatibility testing, including donor red cells, must be kept at 1-6°C for at least 1 week after each transfusion.<sup>16(p42)</sup> This ensures that appropriate samples are available for investigational purposes should adverse responses to transfusion occur.

### ABO Typing

Both reagent antisera and red cells for ABO typing are available commercially. Anti-A and anti-B are monoclonal antibodies prepared by hybridoma technology. Reagent red cells are

**Table 5-5.** The Expected Reactions of the Four Common ABO Phenotypes: Results of Blood Typing Tests

| Blood Type | Anti-A | Anti-B | A <sub>1</sub> Red Cells | B Red Cells |
|------------|--------|--------|--------------------------|-------------|
| O          | 0      | 0      | 4+                       | 4+          |
| A          | 4+     | 0      | 0                        | 4+          |
| B          | 0      | 4+     | 4+                       | 0           |
| AB         | 4+     | 4+     | 0                        | 0           |

O = no agglutination; 4+ = strong agglutination

usually suspended in a preservative medium containing EDTA, to prevent lysis of the red cells by complement-binding anti-A and anti-B.<sup>14</sup> ABO grouping is performed using a direct agglutination technique (Table 5-3).<sup>19</sup> Red cells are tested with anti-A and anti-B, and the serum or plasma with known A<sub>1</sub> and B red cells. Use of anti-A,B and A<sub>2</sub> red cells is optional, but generally considered unnecessary when ABO typing potential transfusion recipients.<sup>17</sup>

The expected findings for each of the four common ABO phenotype are shown in Table 5-5. When interpreting the results of ABO grouping tests, it is important to note the reciprocal relationship that exists between the absence of A and/or B antigens on red cells and the presence of the expected anti-A and/or anti-B in the serum. If there is conflict between cell and serum ABO tests, group O blood should be provided for transfusion until the discrepancy is resolved and reliable conclusions of the patient's ABO type can be made.<sup>14</sup>

**Rh Typing**

Only tests for D are performed routinely on the red cells of prospective transfusion candidates. There are two different types of reagent anti-D available for Rh typing. High-protein reagents are prepared with human IgG anti-D diluted in bovine albumin and other substances that potentiate agglutination. Their final protein concentration may be greater than 20 g/dL. Such a high protein level is needed to potentiate IgG antibody reactivity so that positive and negative tests can be recognized almost instantaneously using a direct agglutination technique. In the United States, low-protein reagents (protein content ≤ 7 g/dL) are a blend of monoclonal IgM and monoclonal/polyclonal human IgG anti-D. With blended anti-D reagent the IgM component causes direct agglutination of Rh-positive red cells and the IgG component permits detection of the weak expression of D by application of the antiglobulin test.<sup>14</sup>

Only direct tests with blended anti-D reagents are required on patient samples; the test for weak D is not necessary.<sup>16(p43)</sup> To avoid incorrect designation of an Rh-negative recipient as Rh-positive because of autoantibodies or abnormal serum proteins, a control system appropriate to the anti-D reagent in use is required.<sup>14</sup> For low-protein anti-D, a concurrent negative test with anti-A and/or anti-B is considered an appropriate control system. Apparent AB Rh-positive samples should be retested concurrently with anti-D and an inert Rh control reagent.<sup>19</sup>

**Table 5-6.** Acceptable Methods for Pretransfusion Antibody Detection

|                                      | Serum     | Red Cells    | Incubation      | AHG*   |
|--------------------------------------|-----------|--------------|-----------------|--------|
| Saline                               | 2-3 drops | 1 drop, 3-5% | 30-60 min; 37°C | IgG/PS |
| Albumin                              | 2-3 drops | 1 drop, 3-5% | 15-30 min; 37°C | IgG/PS |
| Low-ionic-strength saline (solution) | 2 drops*  | 2 drops, 2%* | 10-15 min; 37°  | IgG/PS |
| Gel                                  | 25 µL     | 50 µL, 0.8%  | 15 min; 37°C    | IgG    |

**Tests for Unexpected Antibodies**

Methods for detecting unexpected antibodies in the serum or plasma of prospective transfusion recipients must be those that detect clinically significant antibodies.<sup>16 (p44)</sup> An IAT after 37°C incubation of patient's serum or plasma with reagent red cells that are not pooled is usually required. Table 5-2 lists many of the blood group alloantibodies that can be detected during pretransfusion testing, and provides the approximate percentage of compatible units that are likely to be encountered in a predominantly Caucasian blood donor population, except as otherwise noted.

A number of options exist regarding the selection of methods for pretransfusion antibody detection (see Tables 5-6 and 5-7). Decisions relative to these options are within the purview of the blood bank medical director. They should be made based on the type of patients served, the causes and frequency of previous significant antibody-mediated transfusion reactions, the availability of resources, and with the realization that no one method will detect all clinically significant antibodies.

**Tube Test Methods**

A variety of red cell suspending media or additives are used either to enhance antibody uptake or to potentiate the agglutination phase of antibody-antigen interactions (Table 5-7). Low-ionic-strength saline (LISS) solution,<sup>20</sup> normal saline, or red cell preservatives (modified Alsever's solution) are used as red cell suspending media. Bovine serum albumin (22% or 30% w/v), LISS-additives, or polyethylene glycol (PEG) are commonly added directly to serum-red-cell mixtures.<sup>19,21</sup>

Antibody uptake (the first stage of an antigen-antibody interaction) is accelerated when red cells are suspended in LISS or PEG. The magnitude of the ionic cloud (see Fig 5-4) that forms around negatively charged red cells suspended in LISS (approximately 0.03 M) is lower than that surrounding red cells suspended in normal saline (0.15 M NaCl). This cloud not only decreases intercellular distances by reducing the zeta potential imparted by negatively charged carboxyl groups, but also hinders

**Table 5-7.** Changes in Pretransfusion Testing Practices, 2001-2004<sup>30,31</sup>

| Test            | Specific Methods      | Percentage of US Laboratories Performing Test |      |

|                 | Solid-phase adherence | 0.2                                           | 0.2  |
|                 | Liquid microplate     |                                               | 0.1  |

association between antibody and antigen; thus, reducing the magnitude of the ionic cloud promotes antibody association.<sup>10</sup> Weakening of the ionic cloud also causes an increase in attraction between the negatively charged red cell membrane and positive charges on the antigen-binding sites of antibody molecules. In addition, PEG competes for and removes water molecules at the red cell surface. Similar to the ionic cloud of  $\text{Na}^+$  and  $\text{Cl}^-$  ions that forms around red cells suspended in saline, these water molecules also sterically hinder antibody association. The net effect of these phenomena is that more antibody can be bound in a shorter period of time using LISS or PEG as opposed to saline. Consequently, incubation times can be reduced to 10 to 15 minutes for LISS, or 15 to 30 minutes for PEG, compared to 30 to 60 minutes for saline.<sup>22</sup>

In contrast, albumin promotes the second stage of antigen-antibody interactions, namely the agglutination of antibody-coated red cells. It does so by increasing the dielectric constant of the suspending medium, thereby reducing the zeta potential (force of repulsion) between red cells.<sup>11</sup> Because of this effect, albumin can promote the direct agglutination of IgG-coated red cells (see Judd<sup>19</sup> for a method). However, it should be noted that albumin is not used in the United States in a manner that promotes direct agglutination of antibody-coated red cells. Rather, the enhancing effect of albumin on red cell antigen interactions can be attributed to its formulation as a low-ionic solution.

In the low-ionic polycation technique, serum is incubated with red cells suspended in LISS to enhance antibody uptake.<sup>23</sup> The second phase of the reaction is facilitated by aggregating red

**Figure 5-6.** The gel test for detecting unexpected antibodies.

cells with the polycation, Polybrene. Aggregation is reversed with sodium citrate, but agglutinates formed by antigen-antibody interactions are not dispersed.

It is common practice to examine saline, albumin, and LISS tests for direct agglutination before subjecting them to an IAT. These examinations can be made immediately after mixing cells and serum together (immediate-spin tests) and again after incubation at 37°C. For antiglobulin testing, either anti-IgG or polyspecific AHG (containing anti-IgG and anti-C3) may be used.<sup>14</sup> However, use of polyspecific AHG leads to the detection of an inordinate number of unwanted positive tests,<sup>24</sup> and its use in routine antibody detection tests is not recommended.<sup>17</sup> Because of nonspecific aggregation and uptake of complement components that can occur in PEG tests, the tests should not be examined for direct agglutination and should not be tested with antiglobulin reagents containing anti-C3.<sup>21</sup>

### Column Technologies

A gel test for detecting red cell antigen-antibody interactions was first described in 1990 by Lapierre and colleagues.<sup>25</sup> Cards consisting of six microcolumns, each containing agarose gel suspended in anti-IgG, are commercially available. Atop each card is an incubation chamber in which reagent red cells and test plasma are dispensed. The cards are incubated at 37°C, then centrifuged. As the red cells pass through the gel, they are separated from the serum/plasma and come into contact with anti-IgG. If the red cells become coated with antibody during incubation, they will be agglutinated by anti-IgG. The agglutinated red cells become trapped in the gel; unagglutinated red cells pellet to the bottom of the microcolumn. A procedure for the gel test is depicted in Fig 5-6.

The gel test has proven to be equivalent to standard tube technologies (LISS; PEG) for the detection of unexpected antibodies. In one study,<sup>26</sup> the sensitivity and specificity of gel for potentially significant antibodies was 92% to 97%, respectively. This compares to 98% (sensitivity) and 90% (specificity) for a tube LISS procedure.

Column technologies offer several advantages over conventional test tube procedures:

1. Simplified testing, as follows:
  - a. Dispense measured volumes of test plasma/serum and red cells (in LISS) into gel card incubation chambers.
  - b. Transfer cards to an incubator (15 minutes) and then to a centrifuge (10 minutes).
  - c. Read and record results.
2. When compared to conventional tube tests, there is no centrifugation/reading for direct agglutination after incubation; no addition of antiglobulin reagent; no need to validate negative tests using IgG-coated red cells. Omission of these manipulations (especially the associated, repetitive transfer of test tubes between racks and centrifuges) provides significant “hands-on” time savings.
3. Increased time savings through batch testing; a technologist can perform 36 to 48 antibody screens in about the same amount of time it takes to process 12 samples by conventional tube techniques.<sup>26</sup>
4. Increased reproducibility of results, through use of measured volumes of reactants, elimination of the washing process, less subjective reading of tests.
5. Stability of reactions, facilitating validation of results by a second technologist. With conventional tube methods, there is only one opportunity to read reactions; with the gel test, reactions can be read as many times as needed up to 48 hours after centrifugation.
6. Reduction in the detection of cold agglutinins (anti-I/HI -M, -P<sub>1</sub>, -Le) of no or doubtful clinical significance with consequential reduction in the number of samples requiring antibody identification.
7. Can be automated, or semi-automated using liquid sample handling devices, thereby further reducing “hands-on” time.

#### Solid-Phase Adherence Methods

Two forms of solid-phase adherence assays are available for red cell serologic testing. For direct tests, antibody is fixed to wells of a microplate, and red cells are added (eg, anti-A and anti-B for direct testing of donor/recipient ABO typing). Following centrifugation, red cells expressing the corresponding antigen will efface across the well; red cells lacking the antigen will pellet to the bottom of the well.

For indirect tests, (eg, for detecting unexpected antibodies to red cell antigens) red cell membranes are affixed to microplate wells; test serum or plasma are added and the plates washed to remove unbound globulins. Indicator red cells, which are coated with anti-IgG, are then added and the plates are centrifuged. The indicator red cells efface across the well in a positive test, and pellet to the center of the well in a negative test.<sup>27</sup> An overview of a solid-phase adherence assay for antibody detection is depicted in Fig 5-7.

#### Quality Assurance for Antiglobulin Tests

All negative IATs must be validated using IgG-coated red cells.<sup>14,16(p44)</sup> The agglutination of these red cells confirms that

Figure 5-7. Solid-phase adherence assays.

negative tests for unexpected antibodies are not caused by either inadequate washing before the addition of antiglobulin reagent, or inactivation of the antiglobulin reagent by contamination with human serum. This testing is applicable to tube tests; for gel and solid-phase assays, the control system specified by the manufacturer should be used.

#### Automated Pretransfusion Testing

In recent years, several automated systems for pretransfusion testing have received US market approval from the Food and Drug Administration (FDA). They are particularly suited for large hospital-based transfusion services, and include:

1. Automated gel column technology (ProVue, Ortho Clinical Diagnostics, Raritan, NJ).
2. Automated liquid microplate and solid-phase adherence technologies (Galileo, Immucor, Norcross, GA).
3. Microplates containing dried antisera for ABO/Rh typing and a modified solid-phase method for antibody detection (Tango, Biotest Diagnostics, Denville, NJ).

These fully automated systems perform sample and reagent pipetting and subsequent analysis of agglutination reactions. Standard features include positive sample identification, process control through automated documentation of reagent lot numbers and expiration dates, batch and random access operating modes, STAT sample interrupt, and image analysis. The test results can be transmitted via an interface into the laboratory computer system.

The benefits of automation include technologist time savings, positive sample identification, standardized testing (compliance with current good manufacturing practice), increased accuracy, and increased workload capacity. These have to be weighed against the costs for the instrument, reagents, and maintenance, as well as the time required for validation and training.

#### Reagent Red Cells for Antibody Detection

The FDA<sup>28</sup> currently mandates that sets of reagent red cell samples licensed for use in pretransfusion antibody detection tests carry C, c, D, E, e, Fy<sup>a</sup>, Fy<sup>b</sup>, Jk<sup>a</sup>, Jk<sup>b</sup>, K, k, Le<sup>a</sup>, Le<sup>b</sup>, P<sub>1</sub> M, N, S, and s antigens. Such red cells must not be pooled.<sup>16(p43)</sup>

It is impossible to find a single donor with red cells that carry all of the above antigens because adults rarely, if ever, have strong expression of both  $\text{Le}^a$  and  $\text{Le}^b$  on their red cells. Thus, reagent red cells for antibody detection are available commercially as sets of either two or three samples. The Rh phenotypes of red cells used in two-sample sets are  $\text{R}_1\text{R}_1$  ( $\text{D}+\text{C}+\text{c}-\text{E}-\text{e}+$ ) and  $\text{R}_2\text{R}_2$  ( $\text{D}+\text{C}-\text{c}+\text{E}+\text{e}-$ ). In three-sample sets, an  $\text{rr}$  ( $\text{D}-\text{C}-\text{c}+\text{E}-\text{e}+$ ) sample is provided, in addition to  $\text{R}_1\text{R}_1$  and  $\text{R}_2\text{R}_2$  red cells. Use of three red cell samples facilitates the inclusion of red cells from individuals homozygous for particular blood group genes. Such red cells tend to have a stronger expression of an antigen when compared to red cells from individuals heterozygous for the same gene; this phenomenon is known as dosage. It is easier to find double-dose expression of blood group antigens among three reagent red cell samples than two samples; however, use of three samples increases the workload for antibody detection by 50% and rarely affords detection of significant alloantibodies that are not detected with two reagent red cell samples.<sup>29</sup>

### Further Options

Table 5-7 shows changes in pretransfusion testing practices within the United States from 2001 to 2004.<sup>30,31</sup> Of note is the increased use of gel technology for both ABO/Rh typing and antibody detection. Not shown (2004 survey did not include) are practices that are considered redundant, including the following:

1. Use of polyspecific AHG reagents. These contain anticomplement activity in addition to anti-IgG, and facilitate detection of some antibodies that coat red cells with complement components including, notably, anti-Jk<sup>a</sup> and anti-Jk<sup>b</sup>. Failure to detect such antibodies may lead to acute intravascular destruction of antigen-positive red cells.<sup>8</sup> However, use of polyspecific AHG also facilitates detection of IgM complement-binding autoantibodies that are of no clinical significance.<sup>24</sup> Many of these antibodies are autoantibodies directed toward the I antigen, and are found naturally in virtually all normal adult human sera.<sup>8</sup>

2. Room temperature incubation to detect agglutinating alloantibodies, as well as the detection of IgM autoantibodies. Antibodies that do not react at body temperatures rarely, if ever, cause significant destruction of transfused incompatible red cells.<sup>8</sup> While room temperature incubation of tests was widely used through the early 1980s, many laboratories have since abandoned the practice.<sup>30</sup>

3. The use of a microscope to examine serologic tests. Examination for agglutination may be macroscopic, performed using an illuminated concave mirror, or microscopic. The latter is rarely necessary in routine practice; indeed, such critical examination of serologic tests can result in incorrectly recording negative tests as positive.<sup>17,18</sup>

4. Inclusion of an autocontrol (AC) as part of pretransfusion testing. The AC consists of testing the patient's serum against his or her own red cells under the same conditions as those to which screening tests for unexpected antibodies are subjected. This test, or the DAT, is performed to detect globulins bound to

the patient's red cells in vivo. Such in-vivo coating of red cells occurs in patients with autoimmune hemolytic anemia or hemolytic disease of the fetus and newborn, and may also be seen following therapy with certain drugs or transfusion with incompatible blood.<sup>14</sup> Moreover, a positive DAT may be the earliest manifestation of an alloimmune response to a previous, recent transfusion.<sup>32</sup>

Inclusion of the DAT/AC as part of routine pretransfusion testing is no longer advocated; in the absence of detectable serum antibodies, the predictive value of a positive DAT is so low (0.29%) that routine testing is not cost effective.<sup>32</sup> However, the DAT/AC is a good predictive test for immune-mediated hemolysis when performed on samples from patients with clinical manifestations of hemolytic anemia.<sup>33</sup>

### The Principles of Antibody Identification

When unexpected antibodies are present, as indicated by positive screening tests, they must be identified. At a minimum, this involves testing the patient's serum against a panel of fully phenotyped reagent red cell samples as well as the patient's own cells. A typical panel is shown in Table 5-8, which also includes the results of antibody identification tests with a serum containing a mixture of anti-M and anti-K. It should be noted that the tests performed in this example do include a reading for direct agglutination after room temperature incubation and after incubation at 37°C. The results of tests with ficin-treated red cells are also displayed. This example will be used to illustrate a process by which the antibody specificities can be ascertained whenever there are reactive and nonreactive red cell samples. A typical approach follows:

1. The reactions of the AC are examined. Alloantibodies, by definition, should not react with the red cells of the antibody producer. When the AC is reactive, autoantibodies may be present or the AC may react because alloantibodies have formed to recently transfused red cells that are still circulating in the recipient. In other cases, both auto- and alloantibodies may be present. Therapy with certain drugs such as intravenous penicillin or a cephalosporin can also cause the DAT/AC to be positive.<sup>14</sup> The AC is negative in the case shown in Table 5-8, so autoantibodies likely are not present.

2. The graded reaction strengths are examined. If all positive tests are equally reactive, then only a single antibody may be present. If there are no negative tests with reagent red cells but the AC is nonreactive, the presence of antibody to a high-prevalence antigen should be considered. Variability in reaction strength may be an indication of dosage; ie, the antibody reacts stronger with red cells from homozygotes (double-dose) than with red cells from heterozygotes (single-dose). Except for antibodies to D,  $\text{P}_1$ , and  $\text{Xg}^a$  antigens, most blood group antibodies manifest dosage. There is variable expression of  $\text{P}_1$  and  $\text{Xg}^a$  antigen on red cells from different donors, but this is unrelated to their zygosity. Given the varying degrees of reactivity of positive red cell samples in Table 5-8, more than one antibody appears to be present and  $\text{M}+\text{N}-$  red cells react significantly stronger than  $\text{M}+\text{N}+$  red cells.

3. A process of crossing out is undertaken. This process involves evaluating the antigens present on nonreactive red cells. Only

|         |                               |   |   |                |   |   |   |     |   |   |   |                |                 |                 |     |   |                 |                 |                 |                 |                 |                 |                 |  |      |    |     |       |     |    |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
|         |                               |   |   |                |   |   |   |     |   |   |   |                |                 |                 |     |   |                 |                 |                 |                 |                 |                 |                 |  |      |    |     |       |     |    |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
|         |                               |   |   |                |   |   |   |     |   |   |   |                |                 |                 |     |   |                 |                 |                 |                 |                 |                 |                 |  |      |    |     |       |     |    |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
|         |                               |   |   |                |   |   |   |     |   |   |   |                |                 |                 |     |   |                 |                 |                 |                 |                 |                 |                 |  |      |    |     |       |     |    |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
|         |                               |   |   |                |   |   |   |     |   |   |   |                |                 |                 |     |   |                 |                 |                 |                 |                 |                 |                 |  |      |    |     |       |     |    |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
|         |                               |   |   |                |   |   |   |     |   |   |   |                |                 |                 |     |   |                 |                 |                 |                 |                 |                 |                 |  |      |    |     |       |     |    |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
|         |                               |   |   |                |   |   |   |     |   |   |   |                |                 |                 |     |   |                 |                 |                 |                 |                 |                 |                 |  |      |    |     |       |     |    |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
|         |                               |   |   |                |   |   |   |     |   |   |   |                |                 |                 |     |   |                 |                 |                 |                 |                 |                 |                 |  |      |    |     |       |     |    |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
|         |                               |   |   |                |   |   |   |     |   |   |   |                |                 |                 |     |   |                 |                 |                 |                 |                 |                 |                 |  |      |    |     |       |     |    |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
|         |                               |   |   |                |   |   |   |     |   |   |   |                |                 |                 |     |   |                 |                 |                 |                 |                 |                 |                 |  |      |    |     |       |     |    |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
|         |                               |   |   |                |   |   |   |     |   |   |   |                |                 |                 |     |   |                 |                 |                 |                 |                 |                 |                 |  |      |    |     |       |     |    |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
|         |                               |   |   |                |   |   |   |     |   |   |   |                |                 |                 |     |   |                 |                 |                 |                 |                 |                 |                 |  |      |    |     |       |     |    |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |
|         |                               |   |   |                |   |   |   |     |   |   |   |                |                 |                 |     |   |                 |                 |                 |                 |                 |                 |                 |  |      |    |     |       |     |    |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |

reagent red cell samples 2 and 4 of Table 5-8 are nonreactive. Antibodies to any of the antigens (D, C, c, E, e, N, S, s, P<sub>1</sub>, Le<sup>a</sup>, Le<sup>b</sup>, Jk<sup>a</sup>, Jk<sup>b</sup>, Fy<sup>a</sup>, Fy<sup>b</sup>, and Xg<sup>a</sup>) present on these two cell samples can be eliminated from initial consideration. This leaves only antibodies to M, K, C<sup>w</sup>, f, Kp<sup>a</sup>, and Js<sup>a</sup>. However, C<sup>w</sup>, Kp<sup>a</sup>, and Js<sup>a</sup> are low-prevalence antigens and are not likely to have been present on the reagent red cells used for antibody detection. Similarly, f antigen will not be present on a two-sample screening set of R<sub>1</sub>R<sub>1</sub> and R<sub>2</sub>R<sub>2</sub> cells. Thus, a provisional specificity of anti-M and anti-K can be assigned to this serum.

4. The test phase at which reactivity is observed is evaluated. Antibodies that are usually IgM (see Table 5-2), such as anti-M, -N, -Le<sup>a</sup>, and -P<sub>1</sub>, react as direct agglutinins at room temperature. They do not react solely by an IAT, although there may be carry-over of direct agglutination that can be observed in antiglobulin tests. Similarly, those antibodies that are usually IgG (eg, anti-Rh, -K, -Fy, -Jk, -S) react preferentially by an IAT. However, IgM antibodies of these specificities can be encountered, especially during the early stages of the immune response.

If hemolysis of reagent red cells has been observed, a complement binding antibody such as anti-Le<sup>a</sup> or anti-Jk<sup>a</sup> may be present. This complement-binding activity is often enhanced in tests with ficin-treated red cells, and in the absence of direct lysis of test red cells can best be observed through the use of polyspecific AHG.

With the case under discussion, the anti-M appears to react best at room temperature and the anti-K reacts best by IAT. This is consistent with the anti-M being IgM, although many examples of anti-M do have an IgG component,<sup>9</sup> while the anti-K is most likely IgG (see Table 5-2). The anti-f does not appear to be present because f-positive cell samples 1, 6, 8, and 11 are nonreactive by IAT.

5. The results of tests with enzyme-treated red cells, if performed, are evaluated. Knowledge of the anticipated behavior of certain antibodies with enzyme-treated red cells can be very helpful when identifying antibodies—especially when dealing with

sera containing mixtures of alloantibodies. Antigens of the MNS, FY, and XG systems are cleaved by treatment of red cells with proteolytic enzymes such as papain or ficin. The high-prevalence antigens Ch, En<sup>a</sup>, JMH, In<sup>b</sup>, Rg, Yt<sup>a</sup>, and some Ge antigens are also cleaved by proteolytic enzymes.<sup>9</sup> Negative or weak reactions are observed when antibodies to these antigens are tested with ficin or papain treated red cells. In contrast, treatment of red cells with proteolytic enzymes enhances their reactivity with Rh antibodies, as well as complement-binding antibodies such as anti-Le<sup>a</sup>, -P<sub>1</sub>, and -Jk<sup>a</sup>.

With the case under discussion, the double-dose M-positive red cell samples (3, 5, 9) react in LISS tests at 37°C and by IAT. These cells are nonreactive when pretreated with ficin, which of course is expected for anti-M. In contrast, K antigen is not affected by ficin treatment, so there is no difference in the IAT reactions of ficin and LISS tests with cell samples 3, 7, and 10. Anti-f can now be completely eliminated from consideration because if present, it should have reacted with all the K-negative ficin-treated cells from donors with *r* (*ce*) haplotype.

6. The data are reviewed to ensure that all other antibodies that must be excluded (by virtue of the FDA's requirements for reagent red cells) are not present in the serum. In this case, this was accomplished in Step #3. The fact that antibodies to C<sup>w</sup>, Js<sup>a</sup>, and Kp<sup>a</sup> could be present should not be of concern; they are no more likely to be present in this case than they are in patients with negative screening tests for unexpected antibodies.

Some workers believe that exclusion tests should be performed with double-dose red cells. Their rationale appears to be based on the notion that if a patient has made one alloantibody they are likely to make another—more so than a nonalloimmunized patient is likely to make their first antibody following transfusion. To detect newly forming antibodies, they advocate the use of red cells from apparent homozygotes. However, there are no data to support this notion.

Use of double-dose red cells for pretransfusion antibody detection is not required by either the FDA<sup>28</sup> nor recommended by the AABB<sup>14</sup> (see requirements for reagent red cells). Reagent manufacturers do provide red cells with double-dose expression of Rh antigens, and some workers have established institutional policies regarding the required expression of other antigens on these cells. It would seem appropriate to use the same policies for exclusion purposes whenever practical; ie, ensure absence of anti-Jk<sup>a</sup> with Jk(a+b-) cells if such apparent double-dose expression is required for antibody detection. It would not, however, be practical to exclude anti-E in a patient found to have anti-D using D-negative cells carrying double-dose expression of E, because this would require use of rare r"r" cells.

7. The data are subjected to statistical analysis. Before final conclusions can be made regarding antibody specificity, there must be sufficient negative test results with red cells that lack the corresponding antigen and sufficient positive test results with red cells that carry that antigen. To obtain a confidence level of >95% ( $p = 0.05$ ), there should be at least three nonreactive antigen-negative red cell samples and at least three reactive antigen-positive red cells. This requirement has been met for both the anti-M and the anti-K of Table 5-8.

8. The patient's red cells lack the corresponding antigen. As discussed earlier, this is fundamental to the formation of alloantibodies following transfusion or pregnancy. The red cells from the patient of Table 5-8 should be tested with anti-M and anti-K. They should lack both M and K antigens. There are, however, exceptional cases of alloantibody formation when the corresponding antigen appears to be present on the autologous red cells. Most notably, this is seen with Rh-positive individuals of the partial-D phenotype who make antibody to the portions of D antigen that are absent from their red cells.

The above illustration represents but a basic approach to antibody identification. More complex cases involving autoantibodies, multiple alloantibodies, mixtures of both auto- and alloantibodies and antibodies to high-prevalence antigens will require the resources of an immunohematology reference laboratory. The interested reader is referred elsewhere<sup>14,19</sup> for information regarding the investigation of complex antibody problems.

## Donor-Recipient Testing

### Selection of Blood for Transfusion

#### ABO and Rh

Red Blood Cells (RBCs) and Whole Blood selected for transfusion must be compatible with the serum of the intended recipient. To avoid the hemolytic and often fatal consequences of an ABO-mismatched transfusion, red cells carrying A and/or B antigens should not be transfused to a patient unless the patient's red cells also carry those antigens. Group O individuals should receive group O red cells, but AB individuals can receive red cells of any ABO type. Rh-negative individuals, particularly females of childbearing potential, should receive Rh-negative blood. Rh-positive individuals may receive blood of either Rh type.<sup>14</sup>

### Unexpected Antibodies

When the identified antibodies are known to cause accelerated destruction of transfused incompatible red cells, blood selected for transfusion should be shown to lack the corresponding antigen or antigens.<sup>14,16(p45)</sup> This entails testing donor units with reagent antisera that are available commercially or prepared in-house from previously investigated samples. Examples of potentially significant antibodies include those directed toward antigens of the RH, JK, KEL, and FY systems, and the S and s antigens of the MNS system, as well as most other antibodies active at 37°C and/or by an IAT (see Table 5-2). When antibodies with specificities directed toward M, N, P<sub>1</sub>, and LE antigens are present, particularly when the antibodies react best at or below room temperature, blood selected for transfusion need only be shown to be compatible by IAT following 37°C incubation; demonstrating that compatible units lack the relevant antigen(s) is not required.<sup>34,35</sup> In instances when autoantibodies are present, least incompatible units should be selected for transfusion once it has been established that the autoantibody is not masking a concomitant, clinically significant alloantibody.<sup>33</sup>

### Serologic Crossmatch

Before whole blood or red cells are administered, except in an emergency, a major crossmatch must be performed. This usually entails tests between donor red cells selected for transfusion and the prospective recipient's serum or plasma sample that was used for ABO, Rh, and antibody detection tests. The methods used should be capable of detecting ABO incompatibility and include an IAT. However, in the absence of unexpected antibodies (and absence of records of prior detection of such antibodies) in the intended recipient's serum, only testing to detect ABO incompatibility is required.<sup>16(p46)</sup>

### Antiglobulin Crossmatch

When clinically significant unexpected antibodies are present, or a patient's records indicate that such antibodies have been detected previously, blood selected for transfusion must be tested with the patient's serum or plasma by an IAT. Any of the methods described earlier for antibody detection can be used. An antiglobulin crossmatch can also be performed routinely on patients with nonreactive screening tests for unexpected antibodies. This will detect ABO incompatibility and may detect unexpected antibodies that were missed in pretransfusion screening tests. Unexpected antibodies to low-incidence antigens and antibodies manifesting dosage may be detected in this manner, as may antibodies missed in screening tests because of technical error. However, the predictive value of a positive IAT crossmatch following nonreactive screening tests for unexpected antibodies is sufficiently low that many large hospital transfusion services do not perform an IAT crossmatch except as required when unexpected antibodies are present or there are records of such antibodies.<sup>30,31</sup>

### Detection of ABO Incompatibility

Only a procedure for detecting ABO incompatibility is required when screening tests for unexpected antibodies are negative and there is no record of the patient having had such antibodies in

the past.<sup>16(p46)</sup> Detection of ABO incompatibility can be done serologically or, in certain situations, electronically through the use of computers. An immediate-spin crossmatch between the prospective recipient's serum or plasma and donor red cells suspended in EDTA-saline (to prevent false-negative results from prozone by complement-fixing high-titer anti-A and -B) is an acceptable serologic method for the detection of ABO incompatibility.<sup>36</sup> Alternatively, the ABO groups of both the donor units and a blood sample from the intended recipient can be confirmed immediately before the units are released for transfusion.

### **Electronic Crossmatch**

With the emergence of blood bank information systems, laboratories are beginning to use the integrity of computer software to detect ABO incompatibility between the sample submitted for pretransfusion testing and the donor unit selected for transfusion.<sup>37</sup> This computer or electronic crossmatch (EXM) replaces the immediate-spin test for detecting ABO incompatibility. Currently, an EXM is performed in some 2% of North American facilities,<sup>30,31</sup> and in other countries (Canada, Sweden, Australia, United Kingdom, Hong Kong).<sup>38-42</sup>

An EXM may be used instead of an immediate-spin crossmatch provided that:

1. The computer system has been validated on-site to ensure that only ABO-compatible red-cell-containing components have been selected for transfusion.
2. No clinically significant antibodies are detected in the recipient's serum/plasma and there is no record of previous detection of such antibodies.
3. There are concordant results of at least two determinations of the recipient's ABO type on record, one of which is from a current sample.
4. The system contains the donor unit number, the component name, its ABO/Rh type and the interpretation of confirmatory tests; and recipient information and ABO/Rh.
5. A method exists to verify the correct entry of data before release of blood or components.
6. The computer contains logic to alert the user to discrepancies between donor unit labeling and confirmatory test interpretation, and to ABO incompatibilities between the recipient and the donor unit.
7. The donor unit blood type has been confirmed serologically using red cells from an attached segment.

These requirements are promulgated in *AABB Standards*,<sup>16</sup> which should be consulted for the precise wording. Table 5-9 summarizes the FDA requirements for facilities wishing to implement an electronic crossmatch.<sup>43</sup> Flow diagrams for EXM processes are depicted in Fig 5-8. Information on implementing an EXM is available elsewhere.<sup>44-46</sup>

### **Advantages of the EXM**

The advantages of implementing an EXM are as follows:

1. Technologist time savings. This is the major advantage, and equates to approximately 2.5 minutes per unit crossmatched.<sup>37</sup>

2. Reduced sample volume requirements. A 5- to 7-mL sample is more than adequate, and can be used for EXM for at least 30 days after collection provided other pretransfusion tests are performed soon after collection. The latter greatly facilitates same-day admission programs.

3. Reduced sample handling. Significant reduction in exposure to biohazardous materials results from elimination of the need to prepare donor red cell suspensions from attached segments and the need to use the patient's sample for the immediate-spin crossmatch.

4. No unwanted "false"-positive test results. Cold agglutinins, rouleaux, etc, are a frequent cause of a positive immediate-spin crossmatch following a negative antibody screen. These unwanted positive results are avoided with use of an EXM.

5. Improved accuracy (no unwanted "false"-negative test results), unlike the immediate-spin crossmatch, which is prone to yield false-negative results between some 50% of group B sera and eclectic A<sub>2</sub>B red cells.<sup>47,48</sup> The EXM will detect such incompatibilities provided, of course, the patient and donor ABO types are accurately entered into the computer, and the EXM system has been properly designed, validated, and implemented. Moreover, unwanted negative test results associated with potent, prozoning anti-A and anti-B<sup>36</sup> are avoided.

6. Decreased turnaround time, which can lead to a decrease in the crossmatch-to-transfusion ratio.

### **Disadvantages of the EXM**

The disadvantages of implementing an EXM are few. Barriers to implementation include availability of a laboratory information system with software for blood bank applications, the effort required to develop a system that conforms to AABB and FDA requirements, and the on-site validation process that must be undertaken to obtain FDA approval. Consideration should also be given to the fact one cannot bill for performing EXM, but given current health-care reimbursement practices and policies (managed care, diagnosis-related groups), this may not be a real issue. One can, and should, bill for the second ABO and Rh, if required. A current procedural terminology code of 909090 has been assigned to the EXM. This code can be used to track activity, but does not generate a charge.<sup>49</sup>

### **Prior Records Check**

As part of ongoing quality assurance, and for compliance with the *Standards for Blood Banks and Transfusion Services* of the AABB,<sup>16</sup> the results of current ABO, Rh, antibody detection, and compatibility tests must be checked against records of previous tests, if performed. This must be accomplished before blood is released for transfusion, preferably at the time pretransfusion tests are completed. The specific records that must be checked are those for ABO and Rh typing performed within the previous 12 months, and any difficulties in typing, unexpected

**Table 5-9.** FDA Expectations of Facilities Performing an Electronic Crossmatch<sup>43</sup>**STANDARD OPERATING PROCEDURE (SOP)**

Standard operating procedures shall include:

1. Identification of the source(s) of the application software (name of software vendor or developer, the name and version of the software package).
2. A note to the effect that the computer crossmatch function was designed by a commercial vendor or a modification or extended usage under the control of the blood bank or transfusion service.
3. The location(s) where the system will be used.
4. Institution-specific, detailed instructions that address all facets of the procedure; including all circumstances for which the SOP will be used.

**SOFTWARE REQUIREMENTS**

The software will not permit electronic release of blood products unless there are:

1. Records of two determinations of the recipient's ABO group, one of which is from a current sample.
2. A record of a negative test for clinically significant antibodies from a current specimen and no record of previous detection of such antibodies.

**INFORMATION**

The software contains:

1. Donor unit information:
  - a. Unit number.
  - b. Component name.
  - c. ABO and Rh type.
  - d. The interpretation of the ABO confirmatory test (for units collected, processed and labeled by a separate facility).
2. ABO and Rh type of the recipient.
3. Detection of ABO incompatibility:
  - a. The complete decision table is defined in the software; eg, expected response for each possible combination of recipient/donor ABO combinations.
  - b. Appropriate restrictions based on component type are defined in the software; eg, most facilities will use decision tables to approve/reject release of a number of different red cell products (decision tables must be validated for each product code).
4. Logic to alert the user to:
  - a. Missing required information.
  - b. Donor unit labeling and confirmatory test interruption do not match.
  - c. ABO incompatibilities between the recipient and the donor unit.
  - d. Any other user-defined criteria.

**VALIDATION**

1. The validation design must cover both "automated" software decision-making and decisions made "manually" by users following the SOP.
2. The validation must be performed on site using the same hardware and software that will be employed in routine use.
3. Validation documentation includes:
  - a. Testing strategies.
  - b. Test acceptance and completion criteria.
  - c. Copies of the documentation and testing results.
4. There is a method to review and validate entry of data before it can be used in the decision process. For manual entry this may be double entry of data or an affirmation response after reviewing on-screen display in addition to initial entry.
5. Validation testing must include:
  - a. At least one case of each possible combination of decision variables.
  - b. A reasonable number of cases where one or more required data elements are missing.
  - c. A reasonable number of challenges for the selection of blood and/or components that do not meet specified criteria.
6. If the decision tables govern issues other than ABO (eg, donor/recipient Rh match), they must be adequately tested in the validation protocol.

antibodies, severe adverse reactions to transfusion, and any special transfusion requirements. Any discrepancies between past and present ABO and Rh typing results must be thoroughly investigated; the most likely explanation is that the present sample is not from the same individual whose blood was tested previously. Further, even in the absence of detectable unexpected antibodies in the current sample, a record of such unexpected antibodies in previous samples must be taken into consideration when selecting and crossmatching blood for present and future transfusions.

**Labeling**

Before blood is released for transfusion the container shall have an affixed label or tie tag indicating the recipient's first and last names, unique identification number, the donor unit number, and the interpretation of compatibility tests, if performed.<sup>16(p50)</sup> The unit must be inspected visually before release; if any abnormality in color or appearance is noted, the unit should not be issued. A record should be made of this inspection. The expiration date should also be checked to avoid issuing an out-dated unit.<sup>14</sup>

**Figure 5-8.** Flow diagrams for the electronic crossmatch. From the top left: process for donor unit entry and confirmatory ABO/Rh typing; process for initial patient ABO/Rh typing and detecting unexpected antibodies; electronic crossmatch process; dispense (release) process.

### Issue

At the time blood and blood components are issued, there must be a final check of records maintained in the transfusion service.<sup>16(p50-51)</sup> These records shall include:

1. The recipient's name and unique identification number; the ABO group and Rh type of the recipient, if required.
2. The donor unit number, or pool identification number (for platelets and cryoprecipitate); and the ABO group and Rh type of the donor.
3. The interpretation of compatibility tests, if performed.
4. The date and time of issue.

Documentation that this process occurred can be facilitated by use of a log book or the information system, in which the name of the person performing the release check can be recorded.<sup>14</sup>

### Emergency Release

When a patient's ABO group is not known, only group O Red Blood Cells can be issued.<sup>16(p52)</sup> For female patients of childbearing potential, these should also be Rh-negative. If the ABO group and Rh type have been determined on a current sample, type-specific Whole Blood or ABO-compatible RBCs may be issued. The container label or tie tag should indicate that compatibility testing was not completed at the time the unit was released. Testing should be completed expeditiously, and the records should contain a statement, signed by the requesting physician,

indicating the need for transfusion before completion of compatibility testing.

### Bedside Check

Before administering blood, the physician's written order should be reviewed to verify the request for transfusion.<sup>14</sup> The transfusionist who administers the blood is responsible for this and for performing a final errors check. Verification of the following information must occur<sup>16(p53-54)</sup>:

1. *Recipient Identification:* The name and identification number on the patient's wristband must be identical to the name and number on the form attached to the unit.
2. *Unit Identification:* The unit number on the blood container must match the unit number on the transfusion form.
3. *ABO/Rh:* The ABO and Rh type on the donor unit primary label must agree with that recorded on the transfusion form.
4. *Expiration Date:* The expiration date of the unit should be checked and the unit verified as acceptable for transfusion.

### Hemovigilance and Pretransfusion Testing

Blood transfusion subjects a patient to significant risks, ranging in severity from febrile nonhemolytic reactions and red cell alloimmunization to disease transmission and death from bacterial contamination or transfusion of grossly incompatible blood. The latter can prove fatal, and while considerable resources have been spent

in recent decades to reduce infectious disease transmission, only recently has the issue of “errors in transfusion” been addressed. These errors in transfusion care stem from the following causes:

1. Wrong blood in tube, or WBIT, resulting from misidentification of the patient at time of pretransfusion sample collection or mislabeling of the collection tube.
2. Inappropriate transfusion; ie, exposing patients to the hazards of transfusions that they did not need.
3. Mistransfusion; ie, transfusion of the wrong unit or transfusion to the wrong patient.

Adherence to standard operating procedures mandated at an institutional level and use of dedicated phlebotomy service personnel to collect pretransfusion samples can decrease the incidence of WBIT (Friedman BA, personal communication). To eliminate errors caused by WBIT, some facilities require concordant results on two independently collected samples before release of non-group-O red cell products. Yet others have implemented locking devices (eg, Bloodloc, Novatec Medical, Effingham, IL) that require assignment of a three-letter code to any potential transfusion candidate. This code is printed on the patient’s identification bracelet and transcribed on the sample tube and requisition at time of sample collection. After completion of pretransfusion testing, units of blood are placed into plastic bags, each of which is closed with a combination lock set to the patient’s assigned three-letter code. At the bedside, the transfusion nurse can open the lock only by using the patient’s code. If there is any discrepancy, the blood is returned to the blood bank.

More recently, transfusion services have begun to apply new technologies widely available in commerce to prevent these errors in transfusion.<sup>50</sup> Such technologies include:

1. Barcodes and radio-frequency identification (RFID) technologies, both of which serve to improve the accuracy of sample labeling and the bedside checking process. RFIDs are also capable of constant monitoring of blood product location and storage temperature, thereby improving compliance with good manufacturing practice regulations.
2. Computerized order entry and support systems to improve the decision-making process, including use of nanotechnology sensors that act as barriers to inappropriate transfusions.

Technologies now being implemented in Europe place the entire transfusion process under computerized control.<sup>51</sup> Features of such a process include:

1. Direct order entry, requiring documentation of the reason to transfuse and notification of the ordering physician if the request does not meet established guidelines.
2. Barcode scanning of both phlebotomist and patient identification bracelets at time of sample collection, using a personal digital assistant (PDA) device to produce accurate sample labels.
3. Following processing and compatibility testing, scanning and placement of blood into a computer controlled blood issue refrigerator.
4. Tracking of all movements in and out of the refrigerator. Access to patient-assigned products requires entry of operator and patient identification information.

Following FDA approval and successful validation, it is anticipated that such systems will gain acceptance within the United States.

## Conclusion

Compatibility testing constitutes a quality assurance program designed to detect serologic incompatibility between donor unit and the intended recipient and to prevent both clerical and technical errors that may have serious if not fatal consequences. Assurance of quality requires proper performance of each individual task. There can be no substitute for proper patient identification, proper sample labeling, and proper performance of serologic tests.

## Carbohydrate Blood Groups

**Eldad A. Hod,<sup>1</sup> Patrice F. Spitalnik,<sup>2</sup> & Steven L. Spitalnik<sup>3</sup>**

<sup>1</sup> Transfusion Medicine Fellow, Department of Pathology and Cell Biology, Columbia University Medical Center, New York, New York, USA

<sup>2</sup> Assistant Professor of Clinical Pathology, Department of Pathology and Cell Biology, Columbia University Medical Center, New York, New York, USA

<sup>3</sup> Professor of Pathology and Vice Chairman of Laboratory Medicine, Department of Pathology and Cell Biology, Columbia University Medical Center, New York, New York, USA

Many important human blood group antigens are glycoconjugates. These antigens are grouped together in this chapter because there are similarities in their biosynthesis, in the human immune response to these antigens, and in the outcome in vivo after transfusion of incompatible blood.

The antigens in the ABH, Lewis, P, and I blood group systems are synthesized by interrelated pathways. These oligosaccharide antigens may exist free in solution. In addition, they may be covalently attached to lipids (ie, ceramides) to form glycosphingolipids, or to polypeptides to form mucins, integral membrane glycoproteins, or soluble glycoproteins. Specific glycosyltransferase enzymes catalyze formation of the relevant glycosidic linkages (ie, the bonds between monosaccharides). Some glycosyltransferases, found in all individuals, form framework structures. The genes encoding other glycosyltransferases are allelically inherited and the resulting enzymes specify the synthesis of variable structures. Because of their variable inheritance and expression, the latter may form immunologically recognized blood group antigens. The absence of particular blood group antigens in certain individuals may result in specific antibody production after stimulation by the foreign antigen. As described below, antigens in the ABH, Lewis, P, and I blood group systems are synthesized on common precursor framework molecules. Competition between genetically inherited blood-group-specific glycosyltransferases results in a rich mixture of antigenic molecules. In addition, a single oligosaccharide may encode several different blood-group antigens.

The immune response to carbohydrate antigens, particularly when presented as repetitive epitopes, is typically thymus independent (for review, see Mond et al<sup>1</sup>). That is, the repetitive, multivalent antigens can directly stimulate B cells to synthesize antibodies without the aid of helper T cells. Thymus-independent immune responses classically produce IgM antibodies, and most antibodies to carbohydrate blood group antigens are of the IgM

class. Individuals lacking a particular carbohydrate blood group antigen on their red cells often have “naturally occurring” IgM antibodies to that antigen in their sera, even if they were not previously exposed to human blood components. Most evidence suggests that these antibodies did not arise spontaneously without prior antigenic stimulation, but rather that cross-reacting antigens in the environment, such as on gut bacteria, stimulate specific IgM production.<sup>2</sup> For example, a particular serotype of *Escherichia coli* synthesizes the blood group B antigen as part of its lipopolysaccharide.<sup>3</sup> In contrast, high-titered IgG antibodies to carbohydrate antigens are found in certain individuals. These IgG antibodies may be induced by a thymus-dependent form of these oligosaccharides, perhaps as individual epitopes on glycoproteins, in which T-cell help leads to an isotype switch from IgM to IgG.

Because antibodies to carbohydrate blood group antigens are predominantly IgM, these decavalent molecules directly agglutinate antigen-positive human red cells without the aid of an antiglobulin reagent. Agglutination by these antibodies in vitro typically improves at temperatures <37°C. Because most IgM molecules directly fix complement, these antibodies can cause immediate intravascular hemolysis after transfusion of incompatible, antigen-positive red cells. In unusual cases, carbohydrate-specific IgG antibodies coat red cells in vivo, leading to extravascular hemolysis after incompatible transfusion. In addition, the latter may cross the placenta, resulting in hemolytic disease of the fetus and newborn.<sup>4,5</sup>

### ABH, Secretor, and Lewis Systems

#### ABH Antigens: Introduction

The ABO blood group system is the most important one with respect to blood transfusion, hematopoietic stem cell transplantation, and solid organ transplantation. Karl Landsteiner was the first to discover human alloantigens by using a conceptually simple experiment (Table 6-1). The red cells of each individual were found either to lack or to have one or both of two antigens, A and B. In addition, the serum of each subject contained “naturally

Table 6-1. ABO Blood Group Antigens and Antibodies

| Blood Group | Red Cell Antigens |   | Serum Antibodies |        |
|-------------|-------------------|---|------------------|--------|
|             | A                 | B | Anti-A           | Anti-B |
| A           | +                 | − | −                | +      |
| B           | −                 | + | +                | −      |
| AB          | +                 | + | −                | −      |
| O           | −                 | − | +                | +      |

occurring” directly agglutinating antibodies that recognized the antigens absent from their own red cells. The modern explanation of this experiment is that cross-reacting carbohydrate structures on environmental agents stimulate thymus-independent production of IgM anti-A and/or anti-B in individuals not tolerant of these antigens. The IgM antibodies then directly agglutinate the corresponding antigen-positive red cells.

Although the ABH antigens (the H antigen is the relevant carbohydrate structure present on group O red cells) are typically described as “blood group antigens” because of their presence on red cells, they are also found on other tissues, and are more appropriately termed “histo-blood group antigens.”<sup>6</sup> In blood they are both membrane bound (eg, on platelets<sup>7</sup>) and soluble (eg, as blood-group-active glycosphingolipids inserted in plasma lipoprotein particles). They also are membrane antigens on such diverse cells as vascular endothelial cells and intestinal, cervical, urothelial, and mammary epithelial cells. Soluble forms are found in various secretions and excretions, such as saliva, milk, urine, meconium, and feces. Their expression in some tissues is developmentally regulated.<sup>8</sup> Despite their wide distribution, genetic inheritance, developmental regulation, and importance in transfusion and transplantation, their normal physiologic function, if any, remains a mystery.

ABH Antigens: Biochemistry

To appreciate the structure and antigenicity of ABH antigens, and their relationship to other blood group systems, it is necessary to understand the underlying biochemistry. Early studies indicated that anti-A, anti-B, and anti-H specifically recognize epitopes composed of the terminal trisaccharides or disaccharides illustrated in Figure 6-1. From these results it was possible to conclude that the A, B, and H antigens are not directly encoded by the corresponding genes; rather, the genes encode glycosyltransferases, commonly called the A, B, and H transferases, or equivalently, the A, B, and H enzymes. The H enzyme is a fucosyltransferase that specifically adds fucose in an α1-2 linkage to a terminal galactose. The A and B enzymes then add N-acetylgalactosamine or galactose, respectively, in an α1-3 linkage to the same terminal galactose. In addition, the substrate for the A and B enzymes is the H antigen sequence; these enzymes do not transfer the relevant sugar to galactose in the absence of (α1-2)-linked fucose. Similarly, the H enzyme does not function if this galactose is

Figure 6-1. Biochemical structures of the immunodominant oligosaccharides of the A, B, and H antigens. Gal = D-galactose; GalNAc = D-N-acetylgalactosamine; Fuc = L-fucose.

already substituted with a different sugar. Thus, the biosynthetic pathway is as follows:

where reaction 1 is catalyzed by the H enzyme and reaction 2 by the A or B enzyme.

The finding that the A and B genes encode glycosyltransferases explains some classical results from the analysis of family pedigrees. In particular, the A and B genes are inherited in a strict mendelian fashion and are dominant compared to O, but A and B are codominant with each other. That is, an individual with the genotype AO (or BO) is phenotypically A (or B), an individual of genotype AB is phenotypically AB, and an individual of genotype OO is phenotypically O. Because the A and B enzymes both use the H antigen as substrate, even the presence of only approximately 50% of these enzyme proteins in an AO (or BO) heterozygote is sufficient to convert the red cells to the corresponding A (or B) phenotype. Similarly, if both the A and B enzymes are present, they each convert approximately 50% of the available H antigen substrate, yielding red cells expressing both the A and B antigens.

Most of the molecular biology of the ABH system has been elucidated over the last 15 years. The allelic A and B genes are located on chromosome 9<sup>9,10</sup> (see Table 6-2). They encode membrane-bound glycosyltransferases containing 354 amino acids (Fig 6-2) and are members of the Glycosyltransferase 6 family cataloged in the CAZY database (<http://www.cazy.org>). Homologues of the A and B genes can be identified throughout evolution, beginning with amphibians.<sup>21</sup> In addition, the A and B enzymes exhibit a great degree of homology and differ at only four amino acid residues, at positions 176, 235, 266, and 268.<sup>15,22</sup> The two adjacent residues near the C-terminus of the protein are critically important in determining their substrate specificity: amino acids 266

and 268<sup>23,24</sup> (Fig 6-2, Table 6-3). A valuable Web site, maintained by the National Center for Biotechnology Information, contains a current catalog of the sequences of the known human blood group antigens, including the glycosyltransferases encoding the ABH system (Blood Group Antigen Gene Mutation Database; <http://www.ncbi.nlm.nih.gov/projects/mhc/xslcgi.fcgi?cmd=bgmute/home>; Blumenfeld and Patraik<sup>25</sup>). The current chapter uses the nomenclature defined in that database.

The explosion of readily available sequence data led to the identification of many variant alleles in the ABH system. For example, to date, more than 100 alleles of the *A* and *B* genes have been identified. Several illustrative variants are described below

**Table 6-2.** Chromosomal Assignment of Cloned Genes in the ABH, Se, Le, I, and P Blood Group Systems

| Gene                      | Gene Product                                                          | Location      | Ref.  |
|---------------------------|-----------------------------------------------------------------------|---------------|-------|
| <i>H</i> ( <i>FUT1</i> )  | ( $\alpha$ 1-2) fucosyltransferase (Fuc-TI)                           | 19q13.3       | 11    |
| <i>Se</i> ( <i>FUT2</i> ) | ( $\alpha$ 1-2) fucosyltransferase (Fuc-TII)                          | 19q13.3       | 11    |
| <i>Sec1</i>               | Pseudogene (nonfunctional; homologue of <i>FUT1</i> and <i>FUT2</i> ) | 19q13.3       | 12,13 |
| <i>Le</i> ( <i>FUT3</i> ) | ( $\alpha$ 1-3/4) fucosyltransferase (Fuc-TIII)                       | 19p13.3       | 11,14 |
| <i>A</i>                  | ( $\alpha$ 1-3) N-acetylgalactosaminyl transferase                    | 9q34.1-q34.2  | 9, 15 |
| <i>B</i>                  | ( $\alpha$ 1-3) galactosyltransferase                                 | 9q34.1-q34.2  | 9, 15 |
| <i>I</i>                  | ( $\beta$ 1-6) N-acetylglucosaminyl transferase                       | 9q21          | 16    |
| <i>P<sup>k</sup></i>      | ( $\alpha$ 1-4) galactosyltransferase                                 | 22q13.2       | 17    |
| <i>P<sup>I</sup></i>      | ( $\alpha$ 1-4) galactosyltransferase                                 | 22q12.3-q13.1 | 18,19 |
| <i>P</i>                  | ( $\beta$ 1-3) N-acetylgalactosaminyl transferase                     | 3q25          | 20    |

The *A* and *B* genes are allelic. The *H*, *Se*, and *Sec1* genes are encoded at distinct, but closely linked, loci and are not alleles of each other. Although the *H*, *Se*, *Sec1*, *Le*, *A*, *B*, *P*, *P<sup>k</sup>*, and *I* cDNA sequences and some genomic sequences have been determined, neither the *P<sup>I</sup>* gene nor its cDNA have yet been cloned.

and in Tables 6-3 through 6-5. For example, in addition to identifying the original (ie, wild type) *A* and *B* genes (herein denoted *A101* and *B101*; see Table 6-3), molecular methods also identified several fully functional variants of each (ie, *A102*, *A103*, *A104*, *B102*, and *B103*) (Tables 6-4 and 6-5). These variants contain silent nucleotide polymorphisms that do not affect the function of these enzymes.<sup>15,26-30</sup>

A common allele corresponding to blood group O, *O01*, is highly homologous to the *A* and *B* alleles, but contains a single nucleotide deletion near the N-terminus of the protein. This leads to a shift in reading frame and a prematurely terminated translation product that lacks enzymatic activity (Table 6-3).<sup>15</sup> More than 50 other *O* alleles have been identified that do not encode functional glycosyltransferases,<sup>27,28,31-38</sup> including some with missense mutations that abolish enzymatic activity.<sup>31,32,36</sup>

**Figure 6-2.** Structure of a generic blood group-active glycosyltransferase. The enzymes involved in the synthesis of blood-group-active carbohydrate antigens all share a similar overall structure. That is, they are Type II membrane glycoproteins that contain a single N-terminal cytoplasmic domain, a single transmembrane domain, a single large catalytic domain, a variable number of N-glycans, and a variable number of structurally important motifs. In particular, they all share a "DXD" motif involved in binding to a catalytically critical divalent cation (eg, a  $Mn^{+2}$  atom).

**Table 6-3.** Nucleotide and Amino Acid Sequences of the cDNA Derived from the *A*, *B*, and *O* Genes

|                 | Nucleotide Residues |        |       |            |        |        |        |        |        |        |        |        |        |        |        |

| <i>O02</i>      | A                   | t      | T     |            | g      |        | A      |        | a      |        | t      |        |        | A      |        |
| <b>Mutation</b> | 63R→F               | silent | 74P→S | frameshift | silent | 176R→G | 216F→I | silent | silent | 235G→S | silent | 266L→M | 268G→A | 277V→M | silent |

The *A<sub>1</sub>* and *B* transferases are 354 amino acid, Type II, membrane glycoproteins. All sequences in this figure are compared with the *A<sub>1</sub>* sequence encoded by the *A101* allele; blank boxes represent nucleotides identical to the *A101* allele. An uppercase nucleotide indicates that there is an amino acid change induced by the mutation, whereas a lowercase letter indicates that the nucleotide polymorphism is silent at the amino acid level. The frameshift mutation induced by the deletion at nucleotide 261 in *O01* allows for the translation of a significant length of amino acid sequence that differs from the *A101* sequence before an early termination signal at a new stop codon.

**Table 6-4.** Weak Subgroups of A: cDNA Sequences

| <i>Ael01</i>    |                     |        |        |        |        |        |        |        |        |        | ins G  |        |        |        |        |        |            |
| <i>Ael02</i>    |                     | T      |        |        | A      |        | a      |        |        |        |        |        |        |        |        |        |            |
| <i>B101</i>     | g                   |        | G      |        |        | t      |        | A      |        | A      | C      |        |        | a      |        |        |            |
| <b>Mutation</b> | silent              | 156P→L | 176R→G | silent | 216F→I | silent | silent | 235G→S | silent | 266L→M | 268G→A | 277V→M | 291D→N | silent | 337R→G | 352R→W | frameshift |

All sequences in this table are compared with the *A101* allele. The *B101* allele is included for comparison. The frameshift mutation induced by the deletion at nucleotide 1059 in alleles *A201*, *A206*, and *A302* allows for the translation of several additional amino acids beyond the original stop codon, until the translation process encounters a new stop codon. The insertion at nucleotide 803 in the *Ael01* allele induces a frameshift that allows for the translation of a significant length of amino acid sequence that differs from the *A101* sequence before a termination signal at a new stop codon.

All sequences in this table are compared with the *A101* allele. The *B101* allele is included for comparison. The critical amino acids that distinguish the A and B enzymes are at positions 176, 235, 266, and 268.

These findings using molecular biology not only confirm and extend the results obtained from carbohydrate biochemistry and enzymology, but they also suggest new ways of blood typing.<sup>38-41</sup>

### Antigenic Variants in the ABH System

Some relatively common variations in the ABH system relate to the “strength” of the A antigen on group A red cells. Multiple subgroups of A that have weak expression of the A antigen are known. The red cells of most group A individuals (eg, 80% of Whites) type as  $A_1$  due to their inheritance of one of the  $A^1$  alleles. Most of the remaining group A individuals have weaker expression of this antigen and are denoted  $A_2$ . Other less common subgroups of A (eg,  $A_3$ ,  $A_x$ ,  $A_m$ ,  $A_{el}$ ) have progressively weaker A antigen expression. Many individuals with weak A expression produce an antibody, anti- $A_1$ , which does not agglutinate their own red cells but does agglutinate  $A_1$  red cells. This phenomenon is explained by quantitative and qualitative differences in antigen expression. For example, the number of A antigen sites per red cell varies from approximately 800,000 sites for  $A_1$  cells to 250,000 sites for  $A_2$  cells to 700 sites for  $A_m$  cells.<sup>42</sup> The finding that  $A_2$  individuals can produce  $A_1$ -specific antibodies also implies the existence of qualitative differences. Indeed, biochemical investigations demonstrate that A antigens on  $A_1$  red cells differ from those on cells of the various subgroups of A.<sup>43,44</sup> Many different classes of ABH-active glycosphingolipids have been isolated from human red cells (for example, see Clausen et al<sup>43</sup>) and novel structures continue to be discovered. Examples of relevant structures, provided in Fig 6-3, illustrate that complex oligosaccharides (ie, on Type 3 chains) can contain the A epitope not only as a terminal trisaccharide, but also as an “internal” structure. Thus, one hypothesis is that individuals whose red cells type as  $A_1$  can express all of these classes of structures, whereas those whose red cells type as  $A_2$  lack the

structures built on Type 3 and Type 4 chains; this implies that  $A_1$  antibodies specifically recognize these structures.

The presence of Type 3 chains on  $A_1$  human red cells has another practical implication related to the goal of producing “universal donor” red cells by enzymatically removing the immunodominant GalNAc residues from A-active oligosaccharides.<sup>45</sup> Thus, although many  $\alpha$ -N-acetylgalactosaminidases can remove terminal GalNAc residues, all  $\alpha$ -N-acetylgalactosaminidases identified to date are unable to remove the internal GalNAc residues found on Type 3 chains.<sup>46</sup> Therefore, although it is now possible to perform the enzymatic  $A_2 \rightarrow O$  conversion, the goal of performing the  $A_1 \rightarrow O$  conversion to prepare large numbers of universal donor units currently remains elusive.<sup>46</sup>

More recently, the molecular biological approach has identified mutations in the cDNA and genomic DNA sequences of the A alleles of individuals with red cells expressing weak A activity (Table 6-4).<sup>28,29,47-53</sup> For example, the A transferase in  $A_2$  individuals encoded by the *A201* allele has a 156 P→L missense mutation and a frame shift mutation near the 3'-end of the coding sequence.<sup>49</sup> In addition, some  $A_3$  individuals have an allele, *A301*, containing a 291 D→N mutation in the coding sequence.<sup>48</sup> These types of findings are summarized in Table 6-4. In some cases, transfection studies prove that these mutations result in weakened or variant enzyme activity of the encoded glycosyltransferase (for example, see Yamamoto et al<sup>49</sup>). When the coding sequence is evaluated alone, there is not always a one-to-one correspondence between genotype and phenotype. For example, even within a given family, the red cells of individuals inheriting the *A206* allele can have either the  $A_2$  or  $A_3$  phenotype.<sup>53</sup> In another family, the red cells of individuals inheriting the *A201* allele typed as either  $A_2$  or  $A_x$ .<sup>50</sup> A complete understanding of these results is not yet available, but it may be important to investigate the regulation of expression of

**Figure 6-3.** Biochemical structures of the A antigen-active terminal trisaccharide carried on various types of backbone structures (ie, Types 1-4) attached to a glycosphingolipid. Glc = D-glucose; GlcNAc = D-N-acetylglucosamine; cer = ceramide; Gal = D-galactose; GalNAc = D-N-acetylglactosamine; Fuc = fucose.

these genes in greater detail, particularly by focusing on the promoter and enhancer regulatory regions.<sup>54-57</sup> Finally, the identification of individuals with weak subgroups of A allowed the first successful attempts to transplant “incompatible” A<sub>2</sub> renal allografts into group O recipients.<sup>58</sup>

By analogy with the subgroups of A, “weak” subgroups of B also exist (eg, B<sub>3</sub>, B<sub>x</sub>, B<sub>el</sub>). For example, the gene encoding the B301 allele responsible for the B<sub>3</sub> subgroup has a 352 R → W mutation in the coding sequence that is not found in the wild type B101 allele (Table 6-5).<sup>48</sup>

The B(A) and *cis* AB phenotypes are interesting and unusual variations in the ABH system.<sup>59</sup> In each case, one chromosome in the affected individual apparently encodes for a gene (or genes) that leads to the synthesis of both the A and B antigens. In the B(A) phenotype, the red cells predominantly have B antigens with a small amount of A antigens.<sup>47</sup> In the *cis* AB phenotype, the red cells have equivalent amounts of A and B antigens.<sup>60</sup> Molecular studies demonstrated that the coding sequence of one B(A) transferase, B(A)01, is virtually identical to the wild type B101 allele, except that it lacks the 235 G → S mutation.<sup>47</sup> Thus, at three of the relevant amino acid positions the B(A)01 allele is identical to B101 and at one position it is identical to A101; this allows the resulting glycosyltransferase to create small amounts of A antigen in addition to large amounts of B antigen.<sup>47</sup> In contrast, the sequence of the B(A)02 allele is identical to B101 except for the addition of a 234 P → A mutation (Table 6-5); this mutation is immediately adjacent to one of the four key amino acid residues that confer A or B transferase activity,<sup>61</sup> thereby presumably modifying their function. In one case of *cis* AB, the AB01cs allele has mutations resulting in two amino acid substitutions (Table 6-5).<sup>62</sup> The 156 P → L mutation is identical to that found

in the weak A allele, A201; the 268 G → A mutation is a change that is important for conferring B transferase activity to the resulting enzyme.<sup>23,24</sup> Thus, these changes result in an enzyme that functions as an AB transferase chimera. No evidence for an alternative model, in which crossing-over results in one chromosome that contains *both* an intact A gene and a separate, intact B gene, has been found.

A major recent advance in our understanding of the structure and function of the wild type and variant A and B transferases resulted from the determination of the x-ray crystal structure of the blood group B transferase.<sup>63</sup> This initial structure provided great insight to the mechanism of binding of the nucleotide sugar donor (ie, UDP-Gal) and the oligosaccharide acceptor substrate (ie, the blood group H-active disaccharide). In addition, the availability of this structure allowed for models to be constructed of the A transferase.<sup>64</sup> More recently, mechanistic insight has been gained regarding why the 214 M → R mutation encoded by the *Bel01* gene (Table 6-5) leads to markedly weakened B transferase activity.<sup>65</sup> In particular, the amino acid at position 214 is immediately adjacent to the “DXD” motif at D211-V212-D213 that is critically involved in coordinating the Mn<sup>2+</sup> atom required for enzyme activity. Therefore, this single mutation prevents binding of Mn<sup>2+</sup> and, thereby, markedly diminishes transferase function, an instructive and remarkably beautiful result. Similar types of studies will no doubt yield increasingly important and useful information.<sup>66</sup>

### Secretion of ABH Antigens

The ABH antigens are found not only on red cells, but also in secretions, particularly saliva and plasma. The ability to secrete ABH antigens is genetically inherited: approximately 80% of Whites are

**Table 6-6.** Biochemical Structures of ABH Antigens

| Blood Group | Secretions (Type 1 Chain)                                                                                                                                                       | Red Cells (Type 2 Chain)                                                                                                                                                        |

secretors and 20% are non-secretors. This trait is inherited as a single locus gene in simple mendelian fashion. The secretor gene (*Se*) is dominant; non-secretor (*se*) is recessive. The terminal carbohydrate sequences of the ABH antigens in saliva and plasma are identical to those on red cells. However, the backbone or framework carbohydrate structures are different. ABH antigens on glycosphingolipids and glycoproteins synthesized by red cell precursors are primarily coupled to framework Type 2 chains (ie, Gal(β1-4)GlcNAc-R); the same antigens on plasma glycosphingolipids and salivary mucins are coupled to framework Type 1 chains (ie, Gal(β1-3)GlcNAc-R) (Table 6-6). Because ABH blood-group-active glycosphingolipids on plasma lipoproteins are also passively transferred onto red cells, red cells of secretors have ABH antigens not only on Type 2 precursor chains, but also on small numbers of Type 1 chains. In contrast, red cells of non-secretors have ABH antigens only on Type 2 chains.

Initially, it was thought that the *H* gene was a structural gene coding for the H enzyme and the secretor locus encoded a regulatory gene that permitted expression of the *H* gene in the relevant tissues. This hypothesis suggested that a single H enzyme transferred fucose in an α1-2 linkage to the terminal galactose residue on either Type 1 or Type 2 chains. In this model, the H enzyme is always expressed in red cell precursors, but expression in “secretory” tissues (eg, salivary epithelium) is controlled by the *Se* gene. However, this model did not explain all the available data, and multiple biochemical, immunologic, and genetic studies supported an alternative model.<sup>67,68</sup> The latter postulated two different H transferases: one adding fucose to Type 1 chains (an H Type 1 enzyme) and one acting on Type 2 chains (an H Type 2 enzyme). In this model, the H Type 1 enzyme is the structural protein encoded by the secretor gene (*Se*) and is expressed only in secretory tissues.

### Se and H Genes

The cloning of genes and cDNAs encoding multiple mammalian fucosyltransferases (for review, see Oriol et al<sup>69</sup>) show that *Se* is

the *FUT2* gene and that the product of the *Se* gene, the H Type 1 enzyme, is the *Se* (or Fuc-TII) enzyme.<sup>12,70</sup> At least one copy of the *Se* gene is found in approximately 80% of individuals and leads to ABH antigen expression in secretions. Indeed, *FUT2* mRNA expression is found in both normal epithelial cells<sup>12</sup> and cell lines derived from carcinomas,<sup>71</sup> but not in cell lines derived from hematopoietic neoplasia.<sup>71</sup> By contrast, the traditional *H* locus encodes the H Type 2 enzyme; the latter is equivalent to the H (or Fuc-TI) fucosyltransferase.<sup>72</sup> This gene (*H* or *FUT1*) is active in virtually all individuals (for exceptions, see below) and leads to ABH antigen expression on red cells and other tissues. The *FUT1* (or *H*) and *FUT2* (or *Se*) genes are closely linked on chromosome 19 (Table 6-2).<sup>11</sup> In addition, a third gene in this region, *Sec1*, has been cloned.<sup>12</sup> *Sec1* is a pseudogene of *FUT2*<sup>12</sup> and, although actively transcribed in human cell lines,<sup>71</sup> but perhaps not in normal human tissues,<sup>12</sup> it has no intrinsic enzymatic activity. These genes are arranged on chromosome 19 in the following sequence: Centromere → *Sec1* → *FUT2* → *FUT1* → Telomere. In addition, the high homology of these three genes, and the proximity of many *Alu* sequences, make this region a hot spot for mutation and genetic recombination<sup>71</sup> (see below).

### The Se (Fuc-TII) Glycosyltransferase

The *Se* enzyme is a Type II membrane glycoprotein containing 332 amino acids, a short cytosolic domain, and a large luminal domain (see Figure 6-2).<sup>70</sup> There are three potential N-glycosylation sites in the luminal domain at N177, N271, and N297. Its overall structure is similar to that of other mammalian glycosyltransferases, including the A and B enzymes. By analyzing the sequences of many eukaryotic and prokaryotic (α1-2)fucosyltransferases, three highly conserved sequence motifs were identified.<sup>69</sup> Motifs I, II, and III encompass amino acid residues 184-204, 226-239, and 278-288, respectively; Motif I may be responsible for binding the nucleotide sugar substrate, GDP-fucose, required for the catalytic action of this enzyme.

**Table 6-7.** Functional Alleles of the *Secretor* (*Se* or *FUT2*) Gene: cDNA Sequences

The H type 1 transferase (FUT2) is a 365 amino acid, Type II membrane glycoprotein. All sequences in this table are compared with a “parental” *Se* sequence. There is no generally agreed upon nomenclature for naming variant alleles of the *Se* gene; the system chosen here is based on the literature, but is otherwise arbitrary.

Following cloning of *Se*,<sup>12,70</sup> multiple functional and non-functional variants were described. For example, many individuals have a normally functioning variant, *Se*<sup>1</sup>, which contains a silent mutation: 357 c → t (Table 6-7).<sup>73-77</sup> In other individuals, normally functioning genes are found that contain only missense mutations (eg, *Se*<sup>2</sup>, *Se*<sup>3</sup>, *Se*<sup>4</sup>) or combinations of silent and missense mutations (eg, *Se*<sup>6</sup> and *Se*<sup>7</sup>).<sup>76,77</sup> In addition, the *Se*<sup>w</sup> mutant encodes a functional, but significantly less active, enzyme.<sup>74,78,79</sup> This allele contains a missense mutation that leads to partial expression of the secretor phenotype; individuals with this allele can have red cells with the unusual Le(a+b+) Lewis blood group phenotype (see below). None of the mutations found in functional *Se* variants occur in any of the three highly conserved (α1-2)fucosyltransferase motifs (Table 6-7).

In contrast, at least 10 nonenzymatically active variants of the *Se* gene have been described (Table 6-8). Most of these are caused by nonsense (ie, *se*<sup>1</sup>, *se*<sup>2</sup>, *se*<sup>3</sup>, *se*<sup>4</sup>, *se*<sup>5</sup>, *se*<sup>8</sup>) or small deletion (ie, *se*<sup>9</sup>) mutations that yield premature stop codons, resulting in the expression of truncated, nonfunctional enzyme proteins.<sup>70,73,75-77,80-82</sup> However, the *se*<sup>7</sup> allele contains one missense mutation at amino acid 101 that presumably encodes a full-length nonfunctional enzyme; nonetheless the effect of this mutation on enzyme function was not directly tested with recombinant protein.<sup>83</sup> Similarly, the *se*<sup>10</sup> allele contains a three base-pair deletion resulting in the deletion of a single amino acid, V230; although the encoded protein is presumably nonfunctional, this was not verified by transfection studies.<sup>84,85</sup> The mutation in the *se*<sup>10</sup> allele occurs in the highly conserved (α1-2)fucosyltransferase Motif II (Fig 6-5 and 6-7). One nonfunctional allele, *se*<sup>6</sup>, is the result of a fusion gene between *FUT2* (ie, *Se*) and the adjacent upstream *Sec1* pseudogene.<sup>75,80</sup> Although the recombinant *se*<sup>6</sup> protein has low, but measurable, enzymatic

activity using model substrates in vitro, it did not produce H antigen when expressed in transfected cells. Finally, the complete deletion of the entire *FUT2* gene is seen in individuals with the classical Bombay phenotype (see below); this allele is denoted as *se*<sup>del</sup>.<sup>86,87</sup> This large deletion is mediated by the presence of *Alu* sequences,<sup>88</sup> many of which are present in this chromosomal region.<sup>71</sup>

Given the abundance of sequencing data, it is possible to speculate on the temporal sequence during which the various mutations in the *Se* gene developed. One possible sequence is provided below:

This model supports the “out of Africa” hypothesis for the evolution of human populations. The *Se* and *Se*<sup>1</sup> genes are commonly found in Black, White, and Asian populations. In contrast, *se*<sup>10</sup> and *Se*<sup>w</sup> have been found only in Asian populations.<sup>74,78,79,84</sup> In addition, *Se*<sup>6</sup> has been found in Black and White, but not Asian, populations.<sup>76</sup> Finally, *se*<sup>8</sup> and *Se*<sup>7</sup> have been found only in Black and White populations, respectively.<sup>76</sup>

**The H (Fuc-TI) Glycosyltransferase**

The H enzyme contains 365 amino acids and is highly homologous to the *Se* enzyme (Fig 6-2).<sup>70</sup> In particular, it also contains the three highly conserved (α1-2)fucosyltransferase sequence motifs: Motifs I, II, and III comprise amino acids 214-224, 256-269, and 308-318,

**Table 6-8.** Nonfunctional Alleles of the *Secretor* (*Se* or *FUT2*) Gene: cDNA Sequences

All sequences in this table are compared with a “parental” *Se* sequence. There is no generally agreed upon nomenclature for naming variant alleles of the *Se* gene; the system chosen here is based on the literature, but is otherwise arbitrary. In the *se*<sup>1</sup> allele, the amino acid change at position 247 is downstream of the stop codon at position 143. The *se*<sup>6</sup> allele is a fusion gene that encodes an unusual chimeric protein where the N-terminus is encoded by the *Sec1* pseudogene, which is homologous to *Se*, and the C-terminus is encoded by the *Se* gene.<sup>75</sup>

In the *se*<sup>8</sup> allele, the frameshift mutation induced by the deletion at nucleotide 778 allows for the translation of a length of amino acid sequence that differs from the *Se* sequence before an early termination signal at a new stop codon. In the *se*<sup>10</sup> allele, the three nucleotide deletion (ie, GTG) at position 685 does not lead to a shift in the reading frame, but just leads to a deletion of a single amino acid (V230).

The *se*<sup>del</sup> allele, which is not included in this table, represents a complete deletion of the *Se* gene and is found in individuals with the Bombay phenotype.

respectively.<sup>69</sup> Based on the premise that the *H* gene codes for the H Type 2 glycosyltransferase (FUT1), then the allelic *h* gene codes for a nonfunctional enzyme. Since the cloning and sequencing of the *H* gene,<sup>72</sup> various groups have investigated the molecular nature of the defective *h* alleles.<sup>86,89-95</sup> More than 25 different *h* alleles have been identified, variously containing missense, nonsense, and frameshift mutations (Table 6-9). It is noteworthy that most families examined in these studies each had a different mutation leading to inactivation of Fuc-TI activity. In addition, several missense mutations occurred in the (α1-2)fucosyltransferase motifs; for example, the amino acid substitution 220 R → C occurs in Motif I, 259 V → E and 262 S → K occur in Motif II, and 315 A → V occurs in Motif III. The mutation at position 220 is particularly interesting in that the arginine at this position, in the putative nucleotide sugar binding domain, is absolutely conserved in (α1-2) and (α1-6)fucosyltransferases throughout evolution from bacteria to mammals.<sup>97</sup> Although the 327 N → T mutation does not occur in an (α1-2)fucosyltransferase motif, it does destroy a potential N-glycosylation site, suggesting that this posttranslational modification is important in the activity of this enzyme. In addition to the variants described above, one individual had a completely normal coding sequence, but no enzyme activity,<sup>92</sup> suggesting a defect in transcriptional regulation rather than in protein structure. This latter result shows that caution is required when molecular approaches for blood typing based on genotype are used, rather than classical methods, which directly determine blood group phenotype.

### H-Deficient Phenotypes and Genotypes

Based on the information described above, it should be clear that there are multiple molecular mechanisms by which an individual could express low amounts of H antigens on their red cells and/or in their secretions.

The most common example of an H-deficient individual is a “classical non-secretor,” that is, an individual with the general genotype *Hh sese* or *HH sese* (see Table 6-10). This individual has normal amounts of H Type 2 antigens on red cells, but does not express H Type 1 antigens in secretions. In this case, the individual would carry two *se* alleles, which could theoretically be combinations of any of the following: *se*<sup>1</sup>, *se*<sup>2</sup>, *se*<sup>3</sup>, *se*<sup>4</sup>, *se*<sup>5</sup>, *se*<sup>6</sup>, *se*<sup>7</sup>, *se*<sup>8</sup>, *se*<sup>9</sup>, *se*<sup>10</sup>, or *se*<sup>del</sup>.

“Classical weak secretors” are those individuals who are either homozygous or heterozygous for wild-type *H* and are either *Se<sup>w</sup>Se<sup>w</sup>* or *Se<sup>w</sup>se* at the secretor locus. *Se<sup>w</sup>* is a weak secretor allele (see above) that can synthesize small amounts of H Type 1 antigens and allows expression of the unusual Le(a+b+) phenotype (see below).

The most striking example of an H-deficient phenotype is the “classical Bombay phenotype,” often denoted as O<sub>h</sub>.<sup>98</sup> These individuals were originally identified in Bombay, India, their red cells type as group O, and they are non-secretors of ABH antigens. In addition, they do not express any H antigens on their red cells and their sera contain high-titered, IgM, hemolytic H antibodies that induce complement-mediated lysis of red cells of individuals

Table 6-9. *h* Alleles: Weak or Inactive Alleles of *FUT1*

| Nucleotide Change         | Amino Acid Change  | Enzymatic Activity | Ref.       |
|---------------------------|--------------------|--------------------|------------|
| <b>Missense Mutations</b> |                    |                    |            |

| 969 ΔCT                   | 323 V → frameshift | None               | 92         |
| 990 ΔG                    | 330 L → frameshift | Weak               | 90         |

This table summarizes results published in peer-reviewed papers; several additional mutations have been reported in abstract form. The activity of each *h* allele was determined by transfection and expression of the recombinant protein and/or inferred on the basis of serologic studies of the red cells of the corresponding propositus. The *h* allele containing the 327 (N → T) amino acid mutation also contains an amino acid mutation at position 12 (A → V). However, because the latter is a conservative change in the putative transmembrane domain, it probably is not involved in the function of this enzyme.

The *h* allele containing the 180 (Q → stop) mutation in the amino acid sequence also contains a silent nucleotide change (1089 t → g), which does not change the amino acid code, and is downstream of the stop codon.

One *h* allele has been identified in which there are no mutations in the coding sequence; the lack of enzymatic activity is presumably due to a mutation(s) in a regulatory sequence.<sup>92</sup>

of any ABO group, except those from another individual with a similar type of global deficiency of H antigens. Individuals with the classical Bombay phenotype are homozygous for an *h* allele with the amino acid substitution 242 L → R; they are also homozygous for a deletion of the entire *FUT2* gene, that is, the *se<sup>del</sup>* allele of *Se*.<sup>86-88</sup> In this way, they are incapable of synthesizing either H Type 1 or H Type 2 structures. Although some of these individuals do express

active A and/or B enzymes, the A (or B) antigen is not detected because the appropriate substrate for these enzymes (ie, H Type 1 or H Type 2 chains) is not synthesized (Table 6-6). Nonetheless, the functional A (or B) genes can be transmitted to the next generation, yielding the apparently paradoxical pedigree O × O → A (or B).

On rare occasions, individuals are identified with ABH-deficient red cells but with ABH antigens in their secretions; this is often referred to as the “para-Bombay phenotype.”<sup>89-91,93,99</sup> However, the literature can be confusing on this point and this broad phenotypic description can, at least theoretically, encompass individuals with functional *Se* alleles and nonfunctional *H* alleles, or with weakly functioning *H* alleles and nonfunctional *Se* alleles (see Table 6-10). Thus, individuals with the “RBC H-deficient, secretor,” “RBC H-deficient, weak secretor,” and “RBC weak H, non-secretor” phenotypes could all be described as having the para-Bombay phenotype. Therefore, confusion can be avoided by using more specific terms that describe the types of alleles an individual has at the *Se* and *H* loci (Table 6-10).

Medical Implications of the ABH and Secretor Systems

In transfusion medicine, the major implications of these systems relate to the occurrence of serious, acute hemolytic transfusion reactions in patients receiving incompatible red cells (eg, red cells from a group A donor transfused to a group O recipient, or red cells from a regular donor transfused to a Bombay O recipient). The incidence, pathophysiology, prevention, and treatment of such reactions are discussed elsewhere in this book. However, these blood group systems are also relevant in several other situations, examples of which are described below.

Biological Relevance of the ABH Antigens in Coagulation

The normal physiologic functions of the ABO histo-blood group system are still unknown. However, the level of expression of the A/B antigens on the N-glycans of the von Willebrand factor (vWF) procoagulant glycoprotein affects circulating plasma levels of both vWF and Factor VIII, the latter of which is protected from degradation by its association with vWF.<sup>100</sup> Thus, group AB individuals have the highest levels of vWF followed by those of group B, A, and then O, who have the lowest. This finding correlates well with the increased incidence of thrombotic diseases in non-group-O individuals as opposed to the increased bleeding tendency in group O individuals. Nonetheless, the precise mechanisms underlying how the presence of terminal ABH structures on vWF N-glycans may affect overall thrombotic risk are still unclear,<sup>101</sup> although their contribution to the resistance of vWF to degradation by ADAMTS13 may be critically important.<sup>102</sup>

The Role of the ABH Antigens in Malaria: A New Hypothesis

A fascinating new hypothesis may provide a comprehensive explanation of the distribution of the ABO blood groups in various human populations.<sup>103</sup> This unifying hypothesis may also explain variations in the Secretor system and the Lewis blood group system (see below). In brief, this hypothesis addresses the pathophysiology of adherence of red cells infected with

**Table 6-10.** Phenotypes and Genotypes Involving *FUT1* and *FUT2*

| Phenotype                   | RBC ABH<br>Antigen Level | Salivary ABH<br>Antigen Level | <i>H (FUT1)</i> Gene      | <i>Se (FUT2)</i> Gene                                          |

Where the type of *Se*, *se*, or *h* allele is not specified, various alleles described in Tables 6-7 through 6-9 could theoretically be used. Most, if not all, of the phenotypes in this table have been described in the literature using serologic and/or genetic methods. The "RBC H-deficient, weak secretor" and the "RBC H-deficient, secretor" phenotypes are often described as para-Bombay phenotypes; however, on occasion, the "RBC weak H, non-secretor" phenotype can also be described as a "para-Bombay" phenotype, which can lead to confusion.

*Plasmodium falciparum* to capillary endothelium, which is particularly relevant for the severe, and often fatal, complication of cerebral malaria. Thus, the surface of infected red cells expresses the malarial PfEMP-1 protein, which has lectin-like properties with specificity for the A (and B) oligosaccharide structures. In this way, infected red cells could adhere directly to endothelial cells bearing A (or B) antigens. Alternatively, infected red cells could indirectly adhere to endothelial cells by first binding to either platelets or vWF expressing A (or B) structures. If correct, this hypothesis would predict that individuals who did not express A or B antigens (ie, group O individuals) would be at least partially protected from the severe consequences of *P. falciparum* malaria. Similarly, the presence of the Secretor phenotype would be somewhat protective in group A or B individuals, because the A/B antigens on plasma lipoproteins would block endothelial adherence of infected red cells. This protection would be enhanced if these particular individuals also lacked Lewis antigens (see below); that is, if they had the Le(a-b-) phenotype. In summary, this hypothesis would explain the relative abundance of the group O and Le(a-b-) phenotypes in populations that have a long history of exposure to *P. falciparum* malaria. It will be of great interest to see whether future studies confirm this novel hypothesis.

### ABO-Incompatible Solid Organ Transplantation

The increasing number of patients needing organ transplantation and the shortage of available organs led to studies of the feasibility of ABO-incompatible (ABOI) transplantation. Because of naturally occurring IgM and IgG anti-A/B found in "unimmunized" naïve individuals, early attempts at ABOI transplantation resulted in hyperacute or acute rejection.<sup>104,105</sup> However, protocols allowing for successful ABOI transplantation were subsequently developed. These typically involve removal of anti-donor,

anti-A/B by plasmapheresis before transplantation along with pharmacologic immunosuppressive agents, often combined with splenectomy.<sup>106,107</sup> Using these approaches, the overall 1-year graft survival is approximately 50% to 60% following ABOI kidney, liver, or heart transplantation, compared with 70% to 80% for ABO-compatible transplantation.<sup>108</sup>

ABOI kidney transplants in adults have been performed in significant numbers and with quite good success, especially in Japan where religious beliefs preclude the use of cadaveric organs.<sup>109</sup> In particular, the reduced antigen expression in blood group A<sub>2</sub> donors results in protection from antibody-mediated injury; thus, group A<sub>2</sub> kidneys can be transplanted into group B or O individuals without prior depletion of anti-A.<sup>110</sup>

ABOI liver transplants in adults tend to have a poor outcome because of major complications associated with high preoperative IgM and IgG anti-A/B titers.<sup>111</sup> Graft survival of ABOI liver transplants is still substantially lower than for ABO-matched transplants; therefore, ABOI liver transplants are reserved for emergent situations when a compatible donor cannot be found.<sup>112</sup> In addition, in ABO-compatible but nonidentical transplants (ie, "minor" mismatch), graft-derived anti-A/B can be produced by passenger lymphocytes, leading to often mild, but occasionally serious, hemolysis of the recipient's red cells.<sup>113</sup>

ABOI heart transplants in adults are associated with high mortality.<sup>114</sup> In contrast, following preoperative antibody reduction, ABOI heart transplants in newborns and infants have been relatively successful, especially considering the high mortality associated with extended stays on the transplant waiting list.<sup>115</sup>

### ABOI Hematopoietic Stem Cell Transplantation

Because of the distribution of ABO blood types in human populations, many allogeneic hematopoietic stem cell transplants are ABO incompatible.<sup>108</sup> These may result from a major incompatibility

**Figure 6-4.** Biochemical structures of the Lewis-active glycosphingolipids. Glc = D-glucose; GlcNAc = D-N-acetylglucosamine; cer = ceramide; Gal = D-galactose; Fuc = fucose.

(eg, group A or B donor cells transplanted into a group O recipient),<sup>116</sup> where the primary immediate risk from the procedure is the transfusion of ABO-incompatible red cells present in the hematopoietic stem cell product. This type of risk can be ameliorated by removing red cells in the donor product and/or removing anti-A/B in the recipient by plasmapheresis. In contrast, transplants involving a minor ABO mismatch (eg, group O donor cells transplanted into a group A or B recipient) may produce severe delayed hemolysis resulting from anti-A/B production by passenger lymphocytes in the graft;<sup>117</sup> various methods can be employed to address this issue (for example, see Worel et al<sup>118</sup>).

The Lewis System

The two Lewis blood group antigens Le<sup>a</sup> (Lewis a) and Le<sup>b</sup> (Lewis b) were discovered in the 1940s (for review, see Henry et al<sup>119</sup>). Virtually all individuals fall into one of three different Lewis types: Le(a+b−), Le(a−b+), and Le(a−b−) (Table 6-11). These molecules are not intrinsic red cell antigens; they are synthesized in another tissue (probably intestinal epithelium), circulate in plasma attached to lipoproteins, and then passively transfer onto red cells.<sup>120</sup> Biochemically these are carbohydrate antigens on glycosphingolipids (Fig 6-4). They are structurally similar to the Type 1 ABH antigens found on plasma glycosphingolipids, which can also transfer onto red cells.

The Lewis gene (*Le*) is on chromosome 19<sup>11,14</sup> and is distantly linked to the *H* and *Se* loci (Table 6-2). The gene encodes an (α1-4)fucosyltransferase, denoted Fuc-TIII, and thus behaves in a dominant fashion. A human cDNA derived from the *Le* gene (equivalently, the *FUT3* gene) was cloned and encodes a 361 amino acid Type II membrane-bound glycoprotein (Fig 6-2).<sup>121</sup> In addition to adding fucose in an α1-4 linkage to the GlcNAc residue on a Type 1 chain, it can also add fucose in an α1-3 linkage to the GlcNAc on a Type 2 chain (Table 6-6). Although the latter reaction is relatively inefficient, it forms the Lewis x antigen, Le<sup>x</sup>, an important tumor-associated antigen. Thus, Fuc-TIII is a very unusual glycosyltransferase in that it can transfer a monosaccharide to two very different substrates using different glycosidic linkages; therefore, it is technically an (α1-3/4)fucosyltransferase.<sup>121</sup> The sequence near its NH2-terminus is important

**Table 6-11.** The Lewis Blood Group System

| Blood Group | Red Cell Antigens |                 | Serum Antibodies     |                      |
|-------------|-------------------|-----------------|----------------------|----------------------|
|             | Le <sup>a</sup>   | Le <sup>b</sup> | Anti-Le <sup>a</sup> | Anti-Le <sup>b</sup> |
| Le(a+b−)    | +                 | −               | —                    | Very Rarely          |
| Le(a−b+)    | −                 | +               | Very Rarely          | —                    |
| Le(a−b−)    | −                 | −               | Occasionally         | Occasionally         |

for determining its acceptor specificity.<sup>122-126</sup> Thus, mutating the sequence of Fuc-TIII at residues 111 and 112 to that which is found in the (α1-3)fucosyltransferase Fuc-TVI (ie, from WD in Fuc-TIII to RE in Fuc-TVI), significantly improves its ability to use Type 2 chains as substrates.<sup>122</sup> By sequence analysis, Fuc-TIII is a member of a family of (α1-3)fucosyltransferases that is conserved from bacteria to mammals.<sup>69,97</sup> As such, there are two highly conserved sequence motifs: Motif I comprising amino acids 152-171 and Motif II comprising amino acids 239-272. Fuc-TIII also contains two potential N-glycosylation sites; the site at N154 is in sequence Motif I. Although FUT-TIII has not yet been crystallized, molecular modeling has provided some insight into its three-dimensional structure.<sup>127</sup>

The transfer of fucose to a Type 1 chain by Fuc-TIII results in formation of the Le<sup>a</sup> antigen; the addition of α1-4 linked fucose to the H Type 1 structure leads to formation of Le<sup>b</sup>. Thus, the latter is formed by the cooperation of two glycosyltransferases encoded by two genes, one from the Lewis system (*Le* on chromosome 19) and one from the ABH system (*Se* at a different locus on chromosome 19). The biosynthetic pathways connecting the ABH, Secretor, and Lewis systems (encoded by genes at three distinct loci on chromosomes 9 and 19) are shown in Fig 6-5. Cooperation of the *Le*, *Se*, and *A* (or *B*) genes leads to the formation of a minor antigen, AL<sup>b</sup> (or BL<sup>b</sup>), recognized by both anti-A (or anti-B) and anti-Le<sup>b</sup>. Because the *Se* enzyme (ie, Fuc-TII) converts virtually all Type 1 chains into H Type 1, whether or not Fuc-TIII is present, Lewis-positive secretors have virtually no Le<sup>a</sup> antigen and their red cells type as Le(a−b+). By contrast, Lewis-positive non-secretors have Le(a+b−) red cells. This is summarized in Table 6-11.

Individuals whose red cells type as Le(a+b+) are very unusual among Whites, but are relatively common in Asian populations. In these individuals the *Le* gene is normal but the *Se* (Fuc-TII) enzyme is partially defective due to a variant allele (*Se<sup>w</sup>*) containing the 129 I → F mutation<sup>74,77-79</sup> (Table 6-7). Because the *Se<sup>w</sup>* enzyme has partial activity, some Type 1 chains are converted to H Type 1, which are then converted to Le<sup>b</sup> by the normal Lewis enzyme, Fuc-TIII (Fig 6-5). In addition, some Type 1 chains avoid α1-2 fucosylation by the partially defective *Se<sup>w</sup>* enzyme and are converted into Le<sup>a</sup> by the normal Lewis Fuc-TIII enzyme (Fig 6-5). Thus, the red cells of these individuals contain both the Le<sup>a</sup> and Le<sup>b</sup> antigens and type as Le(a+b+).

**Figure 6-5.** Biosynthesis of blood group antigens with Type 1 chains. The genes encoding the relevant glycosyltransferases are denoted in italics and the reactions catalyzed are indicated by arrows. The names of the individual blood group antigens are shown in boxes next to the relevant structures. GlcNAc = D-N-acetylglucosamine; Gal = D-galactose; GalNAc = D-N-acetylgalactosamine; Fuc = fucose.

The presence of defective *Le* alleles is relatively common and approximately 5% of Whites and 25% of Blacks type as *Le(a-b-)*. The increased prevalence of the *Le(a-b-)* phenotype in Blacks may have evolved from selective pressure due to infection with *P. falciparum* malaria (see above).<sup>103</sup> To date, at least 10 different defective *Le* alleles (*le<sup>1</sup>* through *le<sup>10</sup>*) have been identified (Table 6-12).<sup>128-135</sup> Based both on family studies and expression of transfected chimeric cDNAs in vitro, the mutations at amino acids 68,<sup>134</sup> 170,<sup>129,130,132</sup> 223,<sup>136</sup> 270,<sup>136</sup> and 356<sup>129-131</sup> severely inhibit or abolish enzyme activity. One of these mutations occurs in ( $\alpha 1-3$ )fucosyltransferase Motif I and one in Motif II. The mutation at amino acid 20, which is in the transmembrane domain, affects Golgi localization of this enzyme and its activity with glycosphingolipid and glycoprotein substrates, thus yielding a paradoxical “nongenuine” Lewis-negative phenotype.<sup>129-132</sup> That is, although red cells of individuals homozygous for *le<sup>3</sup>* lack Lewis-active glycosphingolipids and type as *Le(a-b-)*, their salivary mucins do contain Lewis antigens.<sup>131,137</sup>

Although hemolytic transfusion reactions and hemolytic disease of the fetus and newborn are rarely caused by antibodies to the Lewis blood group antigens, this blood group system may be important in renal transplantation,<sup>138</sup> coronary heart

disease,<sup>139,140</sup> gastrointestinal cancer,<sup>141</sup> infection by *Helicobacter pylori*,<sup>142,143</sup> and *P. falciparum* malaria (see above).<sup>103</sup>

## Ii Blood Group System

The Ii antigens are oligosaccharides that form the Type 2 chain precursors for the ABH antigens (Fig 6-6; see also Table 6-6). The best available evidence indicates that the difference between the I and i antigens relates to branching of the oligosaccharide chain; i antibodies recognize an unbranched oligosaccharide chain, and I antibodies recognize a similar chain that is also branched. Fetal and cord red cells contain mostly i antigen with small amounts of I; adult red cells demonstrate the opposite pattern. This suggests that the glycosyltransferase necessary for synthesis of the branched structure, a ( $\beta 1-6$ )N-acetylglucosaminyltransferase, is developmentally regulated. The availability of the cloned cDNA encoding both this enzyme<sup>16</sup> and the “i-extension” enzyme<sup>144</sup> (Table 6-2) allowed this hypothesis to be tested. Rare adults have red cells that type as i; these individuals have mutations in a particular isoform of ( $\beta 1-6$ )N-acetylglucosaminyltransferase and their red cell precursors lack the relevant branching glycosyltransferase activity.<sup>145-147</sup>

The Lewis transferase (FUT3) is a 361 amino acid, Type II membrane glycoprotein. All sequences in this table are compared with a “parental” *Le* sequence. There is no generally agreed upon nomenclature for naming variant alleles of the *Le* gene; the system chosen here is based on the literature, but is otherwise arbitrary.

Figure 6-6. Ii blood group antigens. GlcNAc = D-N-acetylglucosamine; Gal = D-galactose; GalNAc = D-N-acetylgalactosamine.

Antibodies specific for the Ii antigens are clinically relevant in the setting of cold type autoimmune hemolytic anemia. The sera of these patients typically contain high titers of a monoclonal antibody, usually with anti-I specificity. In patients demonstrating hemolysis in vivo, the antibodies bind to red cells at or near 37°C in vitro and have the ability to fix complement. Surprisingly, almost all normal individuals have low titers of anti-I; these autoantibodies agglutinate red cells only at room temperature or below and do not cause accelerated red cell destruction in vivo. Patients with particular infectious diseases such as infectious mononucleosis and mycoplasmal pneumonia often develop cold agglutinins, typically with anti-i and anti-I specificity, respectively.<sup>148</sup> In unusual cases, this may result in immune-mediated hemolytic anemia. At present, there is not a complete understanding of the mechanisms

underlying the differences between cold agglutinins that cause hemolysis in vivo and those that do not.<sup>149-152</sup>

P Blood Group System

The P blood group system consists of at least three well-defined glycosphingolipid antigens (P<sup>k</sup>, P, and P<sub>1</sub>) and associated structures such as LKE, Globo-H, and Globo-A (Table 6-13) (for review, see Spitalnik<sup>133</sup>). These carbohydrate chains are related structurally and biosynthetically.<sup>154</sup> Each has a common precursor, Gal(β1-4)Glc-ceramide (also called lactosylceramide). The P<sup>k</sup> antigen is the biosynthetic precursor of the P antigen and both P<sup>k</sup> and P<sub>1</sub> share a common disaccharide structure, Gal(α1-4)Gal(β1-4)-R, at the nonreducing end of the glycosphingolipid. These antigenic structures are not found on red cell membrane glycoproteins.<sup>155</sup> The glycosyltransferase that converts lactosylceramide to the P<sup>k</sup> antigen is denoted as P<sup>k</sup> synthase, that which converts P<sup>k</sup> to P is denoted as P synthase, and that which converts paragloboside to P<sub>1</sub> is denoted as P<sub>1</sub> synthase (Tables 6-13 and 6-14, Fig 6-7). Although the human P<sup>k</sup> synthase was cloned,<sup>17,20</sup> the gene encoding the P<sub>1</sub> synthase has been localized to chromosome 22, but has not yet been cloned (Table 6-2).<sup>18,19</sup> Indeed, identifying the P<sub>1</sub> synthase gene has been quite controversial.<sup>156</sup>

Five different red cell phenotypes have been described in which various combinations of these three antigens are expressed (Table 6-14). The P<sub>1</sub> and P<sub>2</sub> phenotypes are common and account for almost the entire population. The serum of some P<sub>2</sub> individuals contains anti-P<sub>1</sub>. These antibodies are usually low-titered IgM cold

agglutinins and are rarely of clinical significance; however, rare acute hemolytic transfusion reactions have been described.<sup>157</sup> In contrast, the unusual individuals with the P<sub>1</sub><sup>k</sup>, P<sub>2</sub><sup>k</sup>, and p phenotypes<sup>158</sup> have naturally occurring high-titered IgM antibodies with specificity either for the P antigen (ie, anti-P) or for all the antigens in the P blood group system (ie, anti-P<sub>1</sub>PP<sup>k</sup>, or, equivalently, anti-Tj<sup>a</sup>). These antibodies are clinically relevant in that they can cause severe hemolytic transfusion reactions. An unusual syndrome of recurrent spontaneous abortions has also been associated with these antibodies,<sup>159</sup> presumably caused by the presence of P<sup>k</sup>- and P-active glycosphingolipids on trophoblastic tissue.<sup>160</sup> In addition, the syndrome

of paroxysmal cold hemoglobinuria, originally associated with syphilis, is caused by Donath-Landsteiner antibodies. The latter are cold-reacting, complement-fixing IgG antibodies with anti-P specificity that cause immune-mediated hemolysis in vivo.<sup>161</sup>

The P blood group antigens are present on multiple cell types in addition to red cells and have various functions. For example, the P antigen is the receptor for parvovirus B19 on erythropoietic precursors.<sup>162,163</sup> This virus causes both transient aplastic crises in patients with underlying hemolysis (eg, in sickle cell disease) and anemia in immunocompromised patients.<sup>164</sup> In addition, the P<sup>k</sup> antigen, also denoted as CD77, is the receptor on endothelial cells for *E. coli* verotoxins, which are important in the pathogenesis of the hemolytic uremic syndrome.<sup>165</sup> The LKE antigen also functions as a receptor for uropathogenic *E. coli*.<sup>166</sup> Finally, the P<sup>k</sup> antigen appears to be important in signal transduction following binding of α-interferon and also in apoptosis.<sup>167,168</sup>

## Summary

The carbohydrate blood group antigens that are most relevant for the practice of transfusion medicine are found in the ABH, Secretor,

Lewis, Ii, and P human blood group systems. These may be more appropriately regarded as “histo-blood group antigens” in that their expression is not restricted to red cells. The oligosaccharide structures in these systems are related to each other biochemically and immunologically. Great progress has been made in understanding the enzymatic pathways involved in synthesizing these antigens and in the molecular biology of the genes encoding these glycosyltransferases. Although the normal biological functions of these structures are not yet fully understood, many of them play important roles in human infectious diseases.

# Rh and LW Blood Group Antigens

**Connie M. Westhoff<sup>1</sup> & Don L. Siegel<sup>2</sup>**

<sup>1</sup> Scientific Director, Molecular Blood Group and Platelet Testing Laboratory, American Red Cross, and Adjunct Assistant Professor, Division of Transfusion Medicine, Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, USA

<sup>2</sup> Vice-Chair and Professor, Pathology and Laboratory Medicine, and Chief, Division of Transfusion Medicine, Department of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, USA

Although it is now clear that the Rh and LW antigens are carried on entirely different proteins, they are incorporated together in this chapter on the basis of a historic serologic connection (and confusion) and, more recently, evidence that they are physically associated within the red cell membrane.

## Rh Blood Group System

### History and Nomenclature

The Rh system is second only to the ABO system in importance in transfusion medicine because Rh antigens, especially D, are highly immunogenic and cause hemolytic disease of the fetus and newborn (HDFN) and hemolytic transfusion reactions (HTRs). HDFN was first described by a French midwife in 1609 in a set of twins, one of whom was hydropic and stillborn, while the other was jaundiced and died of kernicterus.<sup>1</sup> That a wide range of observed clinical scenarios involving red cell hemolysis were related—from severely hydropic stillborn fetuses to infants with mild or significant levels of jaundice and kernicterus—was not realized until 1932.<sup>2</sup> The cause of red cell hemolysis remained elusive until 1939, when Levine and Stetson described a woman who delivered a stillborn fetus and also suffered a severe hemolytic reaction when transfused with blood from her husband. Levine and Stetson correctly surmised that the mother had been immunized by a fetal red cell antigen inherited from the father and suggested that the cause of the erythroblastosis fetalis was maternal antibody in the fetal circulation.<sup>3</sup> They did not give the target blood group antigen a name. Meanwhile Landsteiner and Wiener, in an effort to discover new blood groups, injected rabbits and guinea pigs with rhesus monkey red cells. The antiserum they obtained agglutinated not only rhesus monkey red cells, but also the red cells of 85% of White subjects, whom they called “Rh positive”; the remaining 15% of individuals studied were termed “Rh negative.”<sup>4(p195)</sup> The “anti-Rhesus” serum seemed to be

reacting similarly to the maternal antibody in serologic testing, hence the blood group system responsible for HDFN came to be known as “Rh.” It is now clear that the anti-Rhesus serum was detecting the LW antigen (subsequently named for Landsteiner and Wiener), which is present in greater amounts on D-positive than on D-negative red cells.<sup>4(p407)</sup> Years of debate followed concerning whether the human antibodies and the Rhesus antibodies were detecting the same antigen and extended long after serologic profiles suggested they were reacting with different structures. Landsteiner and Wiener never accepted the LW terminology, because doing so would imply that they had not discovered the cause of HDFN.<sup>5</sup>

It was soon obvious that Rh was not a simple, single-antigen system. In 1941, Fisher named the C and c antigens (A and B had been used for ABO), and used the next letters of the alphabet, D and E, to define antigens recognized by additional antibodies. In 1945, the e antigen was identified.<sup>4(p195)</sup>

It is important for transfusion medicine specialists to appreciate that the often confusing nomenclature used to describe Rh antigens results from the difference in opinion that existed concerning the number of genes that were involved in their expression. The Fisher-Race nomenclature suggested that three closely linked genes (C/c, E/e, and D) were responsible, while the Wiener nomenclature (Rh-Hr) was based on his belief that a single gene encoded one “agglutinin” that carried several blood group factors. Even though neither theory was correct (there are two genes—*RHD* and *RHCE*—correctly proposed by Tippett<sup>6</sup>), for written communication the Fisher-Race designation (CDE) for haplotypes is preferred, and for spoken communication a modified version of Wiener’s nomenclature is preferred (Table 7-1). The “R” indicates that D is present and use of a lowercase “r” (or “little r”) indicates that it is not. The C or c and E or e Rh antigens carried with D are represented by subscripts: 1 for Ce (R<sub>1</sub>), 2 for cE (R<sub>2</sub>), 0 for ce (R<sub>0</sub>), and Z for CE (R<sub>Z</sub>). The CcEe antigens present without D are represented by superscript symbols: “prime” for Ce (r’), “double-prime” for cE (r’'), and “y” for CE (r<sup>y</sup>). The “R” versus “r” terminology allows one to convey the common Rh antigens present on one chromosomal haplotype in a single term (a phenotype).

Table 7-1. Nomenclature and Prevalence of Rh Haplotypes

| Haplotype-Based Antigens (Fisher/Race) | Shorthand for Haplotype (Modified Wiener) | Occurrence (%) |        |        |
|----------------------------------------|-------------------------------------------|----------------|--------|--------|
|                                        |                                           | Whites         | Blacks | Asians |
| D <sub>Ce</sub>                        | R <sub>1</sub>                            | 42             | 17     | 70     |
| D <sub>cE</sub>                        | R <sub>2</sub>                            | 14             | 11     | 21     |
| D <sub>ce</sub>                        | R <sub>0</sub>                            | 4              | 44     | 3      |
| D <sub>CE</sub>                        | R <sub>Z</sub>                            | <0.01          | <0.01  | 1      |
| ce                                     | r                                         | 37             | 26     | 3      |
| Ce                                     | r'                                        | 2              | 2      | 2      |
| cE                                     | r''                                       | 1              | <0.01  | <0.01  |
| CE                                     | r <sup>y</sup>                            | <0.01          | <0.01  | <0.01  |

Table 7-2. Rosenfeld Numerical Terminology for Rh Antigens

| Numeric | Symbol                       | Numeric | Symbol            | Numeric | Symbol |
|---------|------------------------------|---------|-------------------|---------|--------|
| Rh1     | D                            | Rh27    | cE                | Rh48    | JAL    |
| Rh2     | C                            | Rh28    | hr <sup>H</sup>   | Rh49    | STEM   |
| Rh3     | E                            | Rh29    | "total"           | Rh50    | FPTT   |
| Rh4     | c                            | Rh30    | Go <sup>a</sup>   | Rh51    | MAR    |

Note: Rh13 through 16, 24, and 25 are obsolete.  
\*High-frequency antigen. The antibody is made by D—/D— and similar phenotypes.  
†Low-incidence antigen expressed by R<sup>N</sup> and DBT phenotypes.  
‡Original described on R<sub>0</sub>Har phenotype but also found on R<sup>N</sup>, D<sup>Via</sup>(C)—, R<sub>0</sub><sup>JoH</sup>, R<sub>1</sub><sup>Lisa</sup>.  
§Low-frequency antigen on D(C)(E) cell.

The major Rh antigens are D, C, c, E, and e, but the Rh blood group system is one of the most complex because of the number of additional antigens that have been reported (Table 7-2). These additional antigens include compound antigens in *cis* [eg, f (ce), Ce, CE], low-incidence antigens arising from partial-D hybrid proteins (eg, D<sup>w</sup>, Go<sup>a</sup>, Evans), and antigens arising from various point mutations in the RhCE protein (eg, C<sup>w</sup>, C<sup>x</sup>, VS). Table 7-2 also includes the numeric designations for Rh antigens that Rosenfeld introduced in 1962 in anticipation

of the computer era.<sup>7</sup> With a few exceptions (Rh17, Rh29), the numeric designations are not widely used in the clinical laboratory.

Genes and Their Expressed Proteins

Two genes designated *RHD* and *RHCE* encode the Rh proteins.<sup>8</sup> They are 97% identical, each has 10 exons, and they are the result of a gene duplication on chromosome 1p34-36.<sup>9</sup> Rh-positive individuals have both genes, while most Rh-negative individuals have only the *RHCE* gene (see below).

RhD and RhCE are 417-amino acid, nonglycosylated proteins. One protein carries the D antigen, and the other carries various combinations of the CE antigens (ce, cE, Ce, or CE). RhD differs from RhCE by 32 to 35 amino acids, depending on which form of RhCE is present (Fig 7-1).<sup>10-13</sup> This degree of difference explains why D is the most immunogenic of all the blood group proteins, because most other blood group antigen polymorphisms result from single amino acid changes in the respective protein. The Rh proteins migrate in sodium dodecyl sulphate polyacrylamide gels with an approximate *M<sub>r</sub>* of 30 to 32kD and hence are sometimes referred to as the Rh30 proteins. They are predicted to span the membrane 12 times and are covalently linked to fatty acids (palmitate) in the lipid bilayer (Fig 7-1).<sup>14</sup>

Molecular Basis for Antigen Expression  
D Antigen

“Rh positive” and “Rh negative” refer to the presence or absence of the D antigen, respectively. The Rh-negative phenotype occurs in 15% to 17% of Whites, but is not as common in other ethnic populations.<sup>4(p195)</sup> The absence of D in people of European ancestry was caused by a complete deletion of the *RHD* gene<sup>15</sup> and probably occurred on a D<sub>ce</sub> (R<sub>0</sub>) haplotype because the allele most often carried with the deletion is *ce*. In contrast, inactive or silent *RHD* rather than a complete gene deletion causes D-negative phenotypes in Asians or Africans. D-negative phenotypes in Asians occur with a frequency of <1%,<sup>4(p195)</sup> and most carry mutant *RHD* genes associated with *Ce*, indicating that they probably originated on a D<sub>Ce</sub> (R<sub>1</sub>) haplotype. Only 3% to 7% of South African Blacks are D-negative, but 66% have *RHD* genes that contain a 37-bp internal duplication, which results in a premature stop codon. The 37-bp insert *RHD*-pseudogene was also found in 24% of D-negative African-Americans. Additionally, 15% of D-negative phenotypes in Africans result from a hybrid *RHD-CE-D* gene that does not encode D epitopes. In total, only 18% of D-negative Africans and 54% of D-negative African-Americans completely lack *RHD*.<sup>16</sup> This is important when designing polymerase chain reaction (PCR)-based methods to predict the D status of the fetus and the possibility of HDFN. The population being tested and the different molecular events responsible for D-negative phenotypes must be considered. Even among D-negative Whites, rare cases of an *RHD* gene that is not expressed because of mutation or bp-insertions have been reported.<sup>17</sup>

**Figure 7-1.** Predicted membrane topology of RhD and the major RhCE proteins. The amino and carboxy termini are cytoplasmic and the proteins are predicted to transverse the membrane 12 times. The location of the amino acid residues that differ between D and CE are represented by open circles, only nine of which are predicted to be extracellular. The C/c (Ser103Pro) polymorphism located on the second extracellular loop and the e/E (Ala226Pro) polymorphism on the fourth extracellular loop are shown. The shared region of RhD and RhCe responsible for expression of the G antigen is shown in black. Amino acid changes responsible for C<sup>x</sup> and C<sup>w</sup> are located on the first extracellular loop and the VS antigen, common in Blacks, is located in the eighth transmembrane domain of Rhce. The zigzag lines represent covalent linkage to fatty acid in the lipid bilayer.

### Weak D

An estimated 0.2% to 1% of Whites (and a greater number of Blacks) have reduced expression of the D antigen,<sup>4(p407)</sup> which is characterized serologically as failure of such red cells to agglutinate directly with anti-D typing reagents, requiring the use of an indirect antiglobulin test for detection. The molecular basis

of weak-D expression is heterogeneous and is associated with the presence of point mutations in *RHD*. The mutations cause amino acid changes predicted to be intracellular or in the transmembrane regions of RhD rather than on the outer surface of the red cell (Fig 7-2).<sup>18</sup> This suggests that these mutations affect the efficiency of insertion and, therefore, the quantity of protein in the membrane, and may not affect the expression of D epitopes. This explains why most individuals with a weak-D phenotype can safely receive D-positive blood and do not make anti-D. Exceptions occur, however, and include individuals who make D antibodies that cross-react with their own red cells and appear to be autoantibodies, others that make alloanti-D, or both. There are over 50 different mutations known to cause weak-D expression (Type 1 through Type 54). The long history of transfusing patients who have weak-D red cells with D-positive blood suggests that weak-D Types 1, 2, and 3 (which represent the majority of Whites with weak D) are unlikely to make anti-D. Nevertheless, some have made anti-D, suggesting they have altered D epitopes. Predicting which mutations alter D epitopes is an active area of investigation.<sup>19,20</sup>

It is important that donor center typing procedures detect and label weak-D Red Blood Cell (RBC) units as D-positive, because they can stimulate D-negative recipients. However, weak-D typing is not required for transfusion recipients, who would then receive D-negative units without untoward effects.

A very weak form of D expression (D<sub>el</sub>), which cannot be detected by routine serology methods but can be demonstrated by adsorbing and eluting anti-D, is not uncommon in Asians (10-30% of apparent D-negative). Red cells with very low levels of D are primarily of concern for donor testing, because they have stimulated anti-D in D-negative recipients.<sup>21</sup>

### Partial D

The D antigen has long been described as a “mosaic” because of the observation that some Rh-positive individuals produce anti-D when exposed to D antigen. It was hypothesized that the red cells of these individuals lack some part of D and that they can produce antibodies to the missing portion. Molecular analysis has shown that this is correct, but what was not predicted is that the missing portions of *RHD* are replaced by corresponding portions of *RHCE* in the great majority of cases (Fig 7-3).<sup>17,20</sup> The novel sequences of amino acids and the conformational changes that result from segments of RhD joined to segments of RhCE can generate new antigens (eg, BARC, D<sup>w</sup>, FPTT, DAK, Go<sup>a</sup>, Evans, Rh32) (Fig 7-3 and Table 7-2). The replacements are the result of gene conversion, the hallmark being that the donor gene is unchanged. Replacements involve single or multiple exons, while others involve short stretches of amino acids (Fig 7-3). Some also result from only single amino acid changes (eg, DMH, DFW, D<sup>II</sup>) (Fig 7-2). In contrast to the single amino acid changes that cause weak D (above), which are predicted to be cytoplasmic or transmembrane in location, those that cause partial-D phenotypes are predicted to be located on the extracellular loops of the protein (Fig 7-2). The extracellular location

**Figure 7-2.** Predicted location of point mutations that cause weak D and partial-D phenotypes. Weak D phenotypes carry mutations in *RHD* that primarily cause amino acid changes predicted to be intracellular or in the transmembrane regions of D (upper panel). The specific amino acid mutation and the location in the protein are indicated. The partial D phenotypes that carry mutations in *RHD* are predicted to be located on extracellular loops of RhD (lower panel). The specific amino acid mutation and location in the protein, as well as the common name for each are indicated.

of the changes explains why these individuals recognize conventional D as foreign. From a clinical standpoint, individuals with partial-D antigens ideally should receive D-negative blood, especially females of childbearing potential, but in practice most will type as D-positive (especially if a weak-D test is performed) and will be recognized only after they have made anti-D following a transfusion with D-positive cells.

### Elevated D

Several phenotypes, including D<sup>-</sup>, D<sup>c</sup>-, and DC<sup>w</sup>-, have enhanced expression of D antigen and no, weak, or variant CE antigens, respectively.<sup>4(p407)</sup> These phenotypes are analogous to the partial-D rearrangements described above, only they involve the opposite situation—that is, replacement of portions of *RHCE* by *RHD* (Fig 7-3). The additional *RHD* sequences in *RHCE* along with a normal *RHD* explain the enhanced D and account for the reduced or missing CE antigens. Although these represent altered *RHCE* genes (see below), they are included here because of their elevated D phenotype. Individuals with such altered CE phenotypes can make anti-Rh17 when immunized.

### C/c and E/e Antigens

The four major forms of the *RHCE* gene encode four different proteins: RhCe, -ce, -cE and -CE (Fig 7-1).<sup>12</sup> C and c differ by four amino acids: Cys16Trp encoded by exon 1, and Ile60Leu, Ser68Asn, and Ser103Pro encoded by exon 2 (Fig 7-1, open circles

on RhCe). Of those four amino acids, only the residue at 103 is predicted to be extracellular and is located on the second loop. All the amino acids encoded by exon 2 of *RHCE* are identical to those encoded by exon 2 of *RHD* (Fig 7-1, black on RhCe). This suggests that *RHCE* arose from the transfer of exon 2 from an *RHD* into an *RHCE* gene, respectively. The sharing of exon 2 encoded amino acids by *RHD*, *RHCE*, and *RHCE* accounts for the expression of the G antigen on red cells that are D or C positive. E and e differ by one amino acid, Pro226Ala, predicted to reside on the fourth extracellular loop of the protein (Fig 7-1, solid circle). The E antigen arose from a single point mutation that occurred in exon 5 of a *RHCE* gene, giving rise to *RHCE*.

### Altered CE

C<sup>w</sup> and C<sup>x</sup> are low-incidence antigens that result from single amino acid changes (Gln41Arg and Ala36Thr, respectively) predicted to be located on the first extracellular loop of RhCE (Fig 7-1, gray circles).<sup>22</sup> These antigens are more common in Finns (4%), and are most often present on RhCe. C<sup>w</sup> is also associated with the deletion phenotype DC<sup>w</sup>- (Fig 7-3).

V and VS antigens, which are expressed on red cells of more than 30% of Blacks, result from a Leu245Val substitution located in the predicted eighth transmembrane segment of Rhce (Fig 7-1).<sup>23</sup> The V–VS+ phenotype results from a Gly336Cys change on the 245Val background.<sup>24</sup> V+ and VS+ are associated with weak and altered expression of e, indicating that Leu245Val probably

**Figure 7-3.** Gene conversion events between *RHCE* and *RHD* produce chimeric Rh proteins. Gray (*RHCE*) and black boxes (*RHD*) represent the 10 exons that encode Rh polypeptides. Gene conversion events involve amino acids (vertical bars) or whole exons (filled boxes). Replacement of portions of *RHD* by *RHCE* (upper set of panels) causes many of the partial-D phenotypes, some of which are shown here. Replacement of portions of *RHCE* by *RHD* cause elevated D phenotypes with concurrent loss of expression of CE antigens (middle panel) or altered CE expression (lower set of panels).

causes a local conformation change on the fourth extracellular loop where the e-specific amino acid resides.

Most individuals have e-positive red cells, but the e antigen is considered to be second in complexity to D because variant expression has frequently been observed.<sup>25</sup> The e antigen is altered on red cells with the following alleles—DHar, ceSL, R<sup>N</sup>, ceAR, ceEK (hr<sup>S</sup>-), ce<sup>S</sup> (hr<sup>B</sup>-), and ceMO (hr<sup>S</sup>-, hr<sup>B</sup>-) (Fig 7-3). Extensive discussion is beyond the scope of this chapter, but the majority are found in African ethnic groups, and consequently, are prevalent in patients with sickle cell disease (SCD).<sup>20,22,26</sup> These patients not infrequently produce anti-e following transfusion, despite having an e-positive red cell phenotype. Altered expression of e also results from loss of the codon for Arg229,<sup>17</sup> and is also associated with the presence of a 16Cys residue in Rhce, which occurs frequently on the R<sub>0</sub> haplotype common in African-Americans.<sup>27</sup>

E variants are not common and include EI, EII, and EIII, which result from a point mutation (EI) or gene conversion replacement

of RhcE amino acids with RhD residues (EII and EIII) with concurrent loss of some E epitope expression. Category EIV red cells, which have an amino acid substitution in an intracellular domain, do not lack E epitopes but have reduced E expression.<sup>28</sup>

Variants of c are infrequent. The very rare RH:-26 results from a Gly96Ser transmembrane amino acid change that abolishes Rh26 and weakens c expression.<sup>29</sup> The lack of c antigen variants in humans compared to the other Rh antigens, and the preservation of expression of c on the red cells of nonhuman primates suggest that the two proline residues involved form a stable structure that is resistant to perturbations and changes in Rhce.<sup>30</sup>

In summary, point mutations and genetic exchange, mainly involving gene conversion events between *RHD* and *RHCE*, are primarily responsible for the large number of Rh antigens. Additional complexity results because many of the Rh epitopes are highly conformational and single amino acid changes in one part of the protein, including changes within the transmembrane

regions, can affect the expression of cell-surface-exposed antigen epitopes.

### RH Genotyping

DNA-based molecular testing methods were introduced to the blood bank and transfusion medicine community approximately a decade ago, and much progress has been made in designing reproducible assays and validating gene targets. Assays for blood group antigens encoded by single nucleotide polymorphisms (SNPs) are highly reproducible and correlate with red cell phenotype. Genotyping for the two most important blood group systems, ABO and Rh, are more challenging because of the many different mutations that cause weak expression of A and B, and inactive O, and because of the numerous variant and hybrid *RH* alleles. Multiple regions of the genes must be sampled and hybrid genes are problematic for analysis. Genotyping for blood group antigens is performed principally in a reference laboratory setting, although testing platforms that used bead or microarray technology hold promise for implementation of high-throughput *RH* genotyping for donors and patients.<sup>31</sup>

### RHD Zygosity Testing

Serologic testing for red cell expression of D, C/c, and E/e can only predict the likelihood that a sample is homozygous (D/D) or heterozygous (D/–) for *RHD*. Genotyping enables zygosity to be determined by assaying for the presence of a recessive D-negative allele. In prenatal practice, paternal *RHD* zygosity testing is important to predict the fetal D status when the mother has anti-D. Several different genetic events cause a D-negative phenotype, and multiple assays must be performed to accurately determine zygosity. These include detection of the region generated by deletion of *RHD*, and the 37-bp insert *RHD* pseudogene or the D-negative *RHD-CE-D* hybrid gene common in African Black ethnic groups. If the father is *RHD* homozygous, the fetus will be D-positive, and monitoring of the pregnancy will be required. If the father is heterozygous, the D type of the fetus should be determined to prevent invasive and unnecessary testing.

### Fetal Typing

Genotyping is important in the prenatal setting to determine whether the fetus has inherited the paternal antigen to which the mother has a clinically significant antibody. Fetal DNA can be isolated from cells obtained by amniocentesis or chorionic villus sampling. Alternatively, the discovery that cell-free, fetal-derived DNA is present in maternal plasma or serum by approximately 5 weeks' gestation allows maternal plasma to be used as a source of fetal DNA.<sup>32</sup> Fetal DNA in maternal plasma is derived from apoptotic syncytiotrophoblasts, increases in concentration with gestational age, and is rapidly cleared following delivery.<sup>33</sup> The small quantity of cell-free fetal DNA present relative to maternal DNA poses a challenge, and positive controls for isolation of sufficient fetal DNA are critical to validate negative results. When combined with sensitive real-time PCR methodology, isolation of fetal DNA from maternal plasma has been successfully applied

to determine fetal D status.<sup>34</sup> This has been more successful for D typing because the D-negative phenotype in the majority of samples is caused by the lack of *RHD*. Testing for the presence or absence of a gene is less demanding than testing for a single gene polymorphism or SNP. Theoretically, testing the maternal plasma for the presence of a fetal *RHD* could be used to eliminate the unnecessary administration of antepartum Rh Immune Globulin (RhIG) to the approximately 40% of D-negative women who are carrying a D-negative fetus. RhIG is not entirely risk free, and this approach would be cost-effective for some health-care systems.<sup>34</sup>

### Distinction between Weak D and Partial D

As indicated above, altered expression of D antigen is not uncommon. Weak D phenotypes have single amino acid changes that primarily affect the quantity of RhD in the membrane. Partial D phenotypes have amino acid changes that alter D epitopes, or often are hybrid proteins with portions of RhD joined to portions of RhCE. The distinction between weak D and partial D phenotypes is of clinical importance because the latter make anti-D. Routine serologic typing reagents cannot distinguish between these red cells; however, genotyping strategies that sample multiple regions of *RHD* can discriminate between weak D and partial D.

### Detecting Patients at Risk for Production of Antibodies to High-Incidence Antigens

Alloimmunization is a serious complication of chronic transfusion, particularly in patients with SCD requiring long-term transfusion support. Many transfusion programs attempt to prevent or reduce the risk and incidence of alloantibody production in SCD patients by transfusing RBC units that are antigen-matched for D, C, E, and Kell. Although this approach reduces the incidence of alloimmunization, variant *RHD* and *RHce* genes are common in African Blacks and individuals of mixed ethnic backgrounds. The prevalence of *RH* alleles that encode altered D, C, and e antigens in this patient group explains why some SCD patients become immunized to Rh, despite Rh antigen-matching for D, C, and E.<sup>20,35</sup> These antibodies often have complex, high-incidence Rh specificities, and it can be difficult or impossible to find compatible units. Genotyping can identify those patients who are homozygous for variant *RH* alleles and at risk for production of alloantibodies to high-incidence Rh antigens and can identify compatible donors for transfusion.

### Rh<sub>null</sub> Phenotype

Rh<sub>null</sub> individuals lack expression of all Rh antigens. They suffer from a compensated hemolytic anemia, have variable degrees of spherocytosis, stomatocytosis, and increased red cell osmotic fragility.<sup>36</sup> The phenotype is rare and occurs on two different genetic backgrounds: the “regulator” type, caused by a gene at an unlinked locus, and the “amorph” type, which maps to the *RH* locus.<sup>5</sup> It is now clear that in the more common, regulator type of Rh<sub>null</sub>, the suppression of Rh is caused by a lack of, or a

mutant, Rh-associated glycoprotein (RhAG), also called Rh50 protein.<sup>37</sup> RhAG is a 409-amino acid glycosylated protein that coprecipitates with RhD and RhCE.<sup>38</sup> It shares 37% amino acid identity with the RhD/RhCE proteins and has the same predicted membrane topology. RhAG is not polymorphic and does not carry Rh antigens; however, it is important for targeting the Rh proteins to the membrane during erythroid development. RhAG has one N-glycan chain that carries ABO and Ii specificities.<sup>39</sup> It is encoded by a single gene, *RHAG*, located at chromosome 6p11-21.1.<sup>38</sup>

The amorph type of Rh<sub>null</sub> results from mutations in *RHCE* on a D-negative background.<sup>40</sup> Amorph-type red cells express no Rh protein and have reduced amounts (~20%) of RhAG.

### Rh-Membrane Complex

Additional complication in Rh protein structures arises because they exist in the red cell membrane as complexes with several other proteins. Rh and RhAG are associated in the membrane as a core complex.<sup>41</sup> The fact that several other proteins interact with the Rh-core complex is based on observations of Rh<sub>null</sub> cells. These red cells have reduced expression of CD47, an integrin-associated protein (IAP) that has wide tissue distribution, binds  $\beta_3$  integrins, and is required for integrin-regulated  $\text{Ca}^{2+}$  entry into endothelial cells. Its function on the red cells is unknown; however, a role in red cell senescence has been suggested.<sup>42</sup> Rh<sub>null</sub> cells also have reduced glyophorin B (GPB), a sialoglycoprotein that carries S or s and U antigens. GPB appears to aid RhAG trafficking to the membrane, because the RhAG protein in GPB-deficient cells has increased glycosylation, reflecting longer dwell time in the endoplasmic reticulum. Rh<sub>null</sub> cells also lack LW, a glycoprotein of unknown function that belongs to the family of intercellular adhesion molecules (ICAM-4, see below). Band 3 (the anion exchanger) enhances the expression of the Rh antigens in transfected cells, suggesting that band 3 may also be associated with the Rh-core complex.<sup>43</sup> Recent studies reveal that the Rh-core complex is linked to the membrane skeleton through interactions between CD47 and protein 4.2<sup>44</sup> and through a novel Rh/RhAG-ankyrin cytoskeleton connection.<sup>45</sup> Red cell membrane protein-cytoskeleton and protein-protein interactions are an active area of investigation.

### Rh Function

#### Rh Glycoproteins (RhAG, RhBG, RhCG)

The Rh blood group proteins are well known because of their importance in blood transfusion. However, the mammalian family of Rh proteins has been expanded with the discovery of RhAG in erythrocytes, and the related proteins, RhBG and RhCG, in other tissues.

Protein sequences with similarities to the mammalian Rh proteins were first found in *Caenorhabditis elegans*, and these homologues, in turn, showed similarity to the ammonia transporters from bacteria, yeast (MEP), and plants (AMT).<sup>46</sup> The relationship of the Rh glycoproteins to the AMT/MEP ammonia transporters from these other organisms has been substantiated

by functional transport data<sup>47-49</sup> and structural modeling.<sup>50,51</sup> The Rh proteins reveal the power of comparative genomics and proteomics, in which sequence analysis and homology modeling can give important insight into mammalian protein function.

The nonerythroid Rh glycoproteins, RhBG and RhCG, are present in the kidney, liver, brain, and skin where ammonia production and elimination occur. In the kidney collecting segment and collecting duct, RhBG and RhCG are found on the basolateral and apical membranes, respectively, of the intercalated cells where they mediate transepithelial movement of ammonia from the interstitium to the lumen.<sup>52</sup> In the liver, RhBG is found on the basolateral membrane of perivenous hepatocytes, where it may function in ammonia uptake. RhCG is also present in bile duct epithelial cells, where it is positioned to contribute to ammonia secretion into the bile fluid.<sup>53</sup>

The mechanism of ammonia transport by Rh glycoproteins is an active area of investigation. Expression of Rh glycoproteins in heterologous systems indicates that mammalian transport is an electroneutral process that is driven by the  $\text{NH}_4^+$  concentration and the transmembrane  $\text{H}^+$  gradient.<sup>54,55</sup> Functional studies of the kidney, liver, and brain Rh homologues, along with the erythrocyte RhAG/Rh proteins, promise to lead to development of a unifying hypothesis of ammonia transport in mammals by the Rh family of proteins.

### RhCE and RhD

The function of the more recently evolved erythrocyte blood group proteins, RhCE and RhD, has not yet been determined. When expressed in heterologous systems, they do not directly transport ammonia.<sup>56</sup> RhCE and RhD lack the highly conserved histidine residues located in the membrane pore that are critical for ammonia transport. RhCE and RhD may be evolving a new function in the red cell membrane as phylogenetic analysis indicates the RhCE/D proteins are rapidly evolving, suggesting their function may be changing.

### Immune Response to Rh

#### Medical Aspects

Human red cells can express more than 400 different blood group antigens. Typing patient and donor cells for every known antigen with the intention of providing perfectly matched blood would be a practical and fiscal impossibility. Fortunately, such extensive testing is not required for a number of reasons, the most important of which is that exposure to the majority of foreign red cell antigens through transfusion does not lead to the production of clinically significant alloantibodies. D is one notable exception. As many as 80% of D-negative patients exposed to D-positive red cells may develop high-titer, high-affinity, D IgG antibodies that may persist for the rest of their lives even if they are never exposed to the antigen again. The antibodies can cause HTRs and can cross the placenta causing HDFN when present in a D-negative female carrying a D-positive fetus. Therefore, because of its extraordinary immunogenicity and clinical significance, the D antigen is the only blood group antigen for which

it is routine to prophylactically match blood before transfusion so as to avoid immunization. Although antibodies to C, c, E, and e can cause HTRs and HDFN, they are much less immunogenic than D (~1% rate of sensitization) and the use of RBCs lacking one or more of those antigens are indicated for patients only after sensitization has occurred (management of sickle cell patients may differ as described in preceding section).

In practice, D-positive patients can be transfused with either D-positive or D-negative RBCs—the absence of D will cause no harm—but it is deemed prudent to reserve the rarer units of D-negative blood (~15% of donor units) for D-negative individuals who must receive them. In cases of trauma and/or massive transfusion in which the patient's D status is unknown, efforts are made to provide D-negative blood, especially for females of childbearing potential, until the appropriate testing can be completed. When D-negative blood is in short or critical supply, it may be necessary to transfuse D-negative patients with D-positive units. In such scenarios, D-negative units are reserved for females of childbearing potential and for patients whose serum contains anti-D from a previous sensitization.

Unlike ABO blood group antigens, which are expressed by all transfused blood cells including platelets, the D antigen is present only on red cells. Theoretically, the selection of platelet units for transfusion should be independent of the D status of the donor. However, a transfusion of pooled platelet concentrates may introduce as much as 5 mL of donor red cells, which may be sufficient to alloimmunize a D-negative patient. Therefore, the standard of care is to avoid transfusing D-negative patients, particularly females of childbearing potential, with platelet units derived from D-positive donors. If such units are unavailable and platelet transfusion must be undertaken, the administration of RhIG can be considered. A standard 300- $\mu$ g dose of RhIG, which may inhibit the immunizing potential of up to 15 mL of D-positive red cells, would neutralize the effects of D-positive red cells from several mismatched platelet transfusions. With respect to the transfusion of plasma products, the D status of the donor is not an issue because plasma products do not contain cellular or soluble material capable of inducing anti-D immune responses.

### Serologic Aspects

The immune response to Rh, like that to other peptide antigens, is typically thymus-dependent, requiring T-cell help. Upon exposure to a foreign Rh antigen, an IgM response may develop, but this is quickly followed by the production of IgG antibodies. Consequently, nearly all examples of Rh antibodies are IgG molecules (mostly IgG1 and IgG3), which bind optimally to red cells at 37°C and require the addition of an antiglobulin reagent to produce hemagglutination. Although IgG1 and IgG3 subclasses classically initiate complement activation, the vast majority of anti-Rh-containing sera do not do so. The usual explanation for this cites the relatively low copy number of Rh antigens per red cell, which results in Rh molecules situated too far apart on the cell surface to permit the simultaneous binding of C1q by multiple Rh IgG antibodies. Therefore, hemolysis from the transfusion

of Rh-incompatible RBCs is generally extravascular because of the phagocytosis of IgG-coated erythrocytes by cells of the reticuloendothelial system.

After anti-D, the Rh antibodies most commonly found in the sera of alloimmunized individuals are anti-E > anti-c > anti-e > anti-C. In approximately 50% of cases of warm-type autoimmune hemolytic anemia (WAIHA), autoantibodies are believed to be directed to Rh antigens by virtue of their “panreactivity” with all red cell phenotypes except Rh<sub>null</sub> cells. However, direct binding of autoantibodies to putative epitopes common to D and C/E polypeptides or to other components of the Rh-membrane complex (RhAG, CD47, etc) has yet to be demonstrated in WAIHA. The difficulties in approaching this problem are largely technical in nature and relate to both the inability to produce workable quantities of pure patient autoantibody *in vitro* (ie, clone the autoantibody-producing B lymphocytes) and the inability to purify Rh proteins in a way that retains their native conformationally dependent epitopes.

### Molecular Aspects

The characterization of Rh antibodies on a molecular level, particularly that of anti-D, has been the focus of much study not only because of their clinical significance, but also because of the need to develop suitable *in-vitro* methods for their production.<sup>57</sup> Ironically, because of better transfusion practice and the use of RhIG, alloimmunization of antigen-negative individuals is significantly less common (as are sera donors willing to be purposely hyperimmunized), so that supplies of Rh antibodies for use as typing reagents and for the preparation of RhIG are dwindling. To better understand the molecular make-up of Rh antibodies, investigations have focused on analyzing their variable regions in order to determine whether there are commonly shared genetic and/or structural features among Rh antibodies made by different individuals.

Early work using rabbit antisera specific for different human heavy-chain variable region gene products suggested a restriction in the use of certain heavy-chain gene families by the anti-D contained in polyclonal sera from several dozen anti-D donors.<sup>58</sup> Subsequent studies with rodent idiotypic antibodies demonstrated cross-reactive idiotypes among polyclonal anti-D preparations<sup>59,60</sup> and among different examples of human monoclonal anti-C, -c, -D, -E, -e, and -G produced by transformed B cells.<sup>61</sup> A more direct approach using nucleotide sequencing to examine immunoglobulin gene diversity examined a cohort of four IgM and 10 IgG monoclonal anti-D variable regions.<sup>62</sup> A restricted use of the human heavy-chain variable region genes *V<sub>H</sub>3-33* and *V<sub>H</sub>4-34* was found with a shift in repertoire usage toward *V<sub>H</sub>3-33* for anti-D that had isotype switched to the more clinically relevant IgG. The restriction of anti-D heavy chains to the use of these and other highly related *V<sub>H</sub>* genes has been confirmed and extended through the analysis of many additional examples of anti-D produced through both tissue culture and recombinant means.<sup>63-68</sup> The use of molecular approaches such as site-directed mutagenesis,<sup>69</sup> complementarity-determining region (CDR) sequence

randomization,<sup>70</sup> and heavy-chain/light-chain “shuffling”<sup>71</sup> has demonstrated the genetic relatedness among anti-D molecules directed against different D epitopes as well as among antibodies with D and E specificity. These studies and others<sup>72,73</sup> have supported the hypothesis that a restricted “Rh footprint” for D alloantibodies and a process termed “epitope migration”<sup>63</sup> play a role in the molding of the anti-Rh immune repertoire.<sup>74</sup>

Although the precise significance of immunoglobulin germline gene restriction by Rh antibodies is not fully understood, it may have practical significance for the preparation of anti-D for both therapeutic and diagnostic use. For example, the  $V_H$  genes used to encode anti-D are among the most cationic of the human germline  $V_H$  genes<sup>75</sup> and may account for the relatively high pI of polyclonal anti-D-containing antisera originally noted over 40 years ago.<sup>76</sup> Although the cationic nature of the antibodies may be important for binding to D, it has also been suggested that a constitutive net-positive charge may be necessary to permeate the highly negative red cell zeta potential, thus permitting antibody to contact antigen.<sup>77</sup> Second, while IgM D monoclonal antibodies are well-suited for antigen typing because they may serve as direct agglutinins, the fact that they are most often encoded by  $V_H4-34$  (the germline gene to which cold agglutinins are also restricted),<sup>78,79</sup> may explain why many IgM monoclonal anti-D typing reagents falsely agglutinate D-negative cells when used at cooler-than-recommended temperatures. This phenomenon may also explain the body of literature claiming that the D antigen was present on numerous nonerythroid cells. Using IgM anti-D, these investigators may have been detecting antigens of the I/i blood group system.

## LW Blood Group System

### History and Nomenclature

The LW antigens are the “true” Rhesus antigens shared by humans and the rhesus monkey. As discussed earlier, the confusion occurred because LW antigens are more abundant on D-positive than on D-negative red cells. When the situation was clarified, the term “Rh” remained associated with the human antigen, so the real Rhesus antigen was renamed LW in honor of Landsteiner and Wiener.<sup>5</sup> The confusion can be understood today in the transfusion service when a weak example of anti-LW<sup>a</sup> often appears initially to be anti-D. The LW system has undergone additional terminology revisions. The historical terminology of LW<sub>1</sub>, LW<sub>2</sub>, LW<sub>3</sub>, LW<sub>4</sub>, and LW<sub>0</sub> to describe phenotypes was based on both the LW and the D status of the red cells but is now obsolete.<sup>5</sup> The phenotypes are LW(a+b−), LW(a−b+), LW(a+b+), and the rare LW(a−b−); the antigens are designated LW<sup>a</sup>, LW<sup>b</sup>, and LW<sup>ab</sup>.

### Genes and Their Expressed Proteins

LW is encoded by a single gene located on chromosome 19. The 42-kD LW glycoprotein is a member of the family of ICAMs and has been renamed ICAM-4 (CD242). LW passes through

the red cell membrane once, and the N-terminal extracellular region is organized into two immunoglobulin superfamily (IgSF) domains.<sup>80</sup>

### Molecular Basis for Antigen Expression

LW<sup>a</sup> is the common antigen, whereas LW<sup>b</sup> has an incidence of less than 1% in most Europeans.<sup>4(p407)</sup> The LW<sup>a</sup>/LW<sup>b</sup> polymorphism is caused by a single amino acid substitution, Gln70Arg, on the LW glycoprotein.<sup>81</sup> An increased frequency of the uncommon LW<sup>b</sup> antigen in Latvians and Lithuanians (6%), Estonians (4%), Finns (3%), and Poles (2%) suggests that the LW<sup>b</sup> mutation originated in the people of the Baltic region. The LW<sup>ab</sup> antigen was originally defined by an alloantibody made by the only known (genetically verified) LW(a−b−) person, who lacks expression of all LW antigens.<sup>5</sup> The LW gene in this rare LW(a−b−) individual has a 10-bp deletion and a premature stop codon in the first exon.<sup>82</sup> Rh<sub>null</sub> red cells also lack LW antigens but do not have defective LW genes. Rh proteins appear to be required for LW to traffic to the membrane, and association with the D antigen is preferred.

LW antigens require divalent cations (eg, Mg<sup>2+</sup>) for expression and have intramolecular disulfide bonds that are sensitive to dithiothreitol (DTT) treatment.<sup>5</sup> This is helpful to differentiate anti-LW from anti-D, because the D antigen is resistant to DTT. Also helpful in identifying anti-LW is the fact that LW antigens are expressed equally well on D-positive and D-negative cord blood red cells.<sup>4(p407)</sup>

Transient loss of LW antigens has been described in pregnancy and patients with diseases, particularly Hodgkin disease, lymphoma, leukemia, sarcoma, and other forms of malignancy. Transient loss of LW antigens is associated with the production of autoanti-LW that can appear to be alloantibody.<sup>4(p407)</sup>

### LW Function

LW glycoprotein, ICAM-4, is a ligand with broad specificity for a number of  $\beta_1$ ,  $\beta_2$ ,  $\beta_3$ , and  $\beta_5$  integrins including  $\alpha_L\beta_2$  (LFA-1),  $\alpha_M\beta_2$  (Mac-1),  $\alpha_4\beta_1$  (VLA-4),  $\alpha_V\beta_1$ ,  $\alpha_V\beta_5$ , as well as platelet integrin  $\alpha_{2b}\beta_3$ .<sup>80,83-87</sup> In addition, LW binds to the I domains of CD11a/CD18 and CD11b/CD18 on leukocytes.<sup>84,88</sup> The function of LW glycoprotein on mature red cells is currently an area of active investigation. Evidence is emerging for both a normal homeostatic role in erythroblastic island formation through LW interaction with macrophage integrins<sup>89,90</sup> as well as pathophysiologic roles in the development of vaso-occlusion in SCD mediated by endothelial cell integrins<sup>91,92</sup> and of thrombosis mediated by activated integrins on platelets.<sup>87</sup>

## Summary

The molecular basis for the Rh antigens has now been elucidated. A gene deletion or silent *RHD* gene explains the absence of the D antigen in many Rh-negative individuals. The large number of amino acid differences between the RhD and RhCE proteins

explains why exposure in an individual lacking D often results in a vigorous immune response characterized by a very heterogeneous population of antibodies. The proximity of *RHD* and *RHCE*, duplicated genes on the same chromosome, has resulted in numerous exchanges by gene conversion between them. This has generated new polymorphisms and explains the many antigens observed in this blood group system. Molecular analysis has also revealed that Rh antigen expression is affected not only by changes in extracellular amino acids, but also by intracellular changes, highlighting the conformational nature of these blood group antigens and complicating attempts to map the epitopes to specific amino acid residues.

*RH* genotyping can be used to determine paternal *RHD* zygosity to predict HDFN and the fetus can be typed from amniocytes or from the maternal plasma. *RH* genotyping can also identify patients facing long-term transfusion therapy who are homozygous for variant *RH* alleles and at risk for production of alloantibodies to high-incidence Rh antigens. When partnered with *RH* genotyping of donors, this approach promises to have a positive impact on transfusion therapy outcomes by reducing alloimmunization, especially in patients with SCD.

Rh antibodies show restriction in their use of particular variable region immunoglobulin germline genes. Antibodies to serologically distinct epitopes may be genetically related, and epitope migration may be an important process that helps shape the composition of the anti-Rh immune repertoire. Questions remain concerning the function of the Rh proteins. The discovery that Rh protein homologues also exist in the liver and kidney indicates that the Rh blood group antigens belong to a larger, conserved family of proteins and will contribute to the elucidation of their function. Similarly, the function of LW on the mature red cell is not entirely clear but its ability to interact as an adhesion molecule with a broad range of integrin-binding specificity suggests an important role in both normal red cell development as well as disease-associated processes such as vaso-occlusion and unwanted thrombosis.

## Other Protein Blood Groups

### Petr Jarolim

Director, Clinical Chemistry, Brigham and Women's Hospital and the Dana Farber Cancer Institute, and  
Associate Professor of Pathology, Harvard Medical School, Boston, Massachusetts, USA

Of the 29 currently known blood group systems, only seven have antigens formed by carbohydrates. Antigens of the remaining 22 blood group systems are carried by proteins. Two of these 22 systems—Rh (ISBT 004) and the closely associated LW (ISBT 016)—were discussed in detail in the previous chapter. The remaining blood group systems are summarized in Table 8-1.

Many of the proteins carrying blood group antigens are functionally important; however, antibodies in only a few blood group systems represent a problem for the transfusion service. This chapter addresses only those antigens that elicit formation of clinically significant antibodies and briefly comments on the other blood group systems. Further details may be found in review articles<sup>2,3</sup> and comprehensive textbooks.<sup>4-6</sup>

### Kell and Kx Blood Group Systems (ISBT 006 and 019)

#### Structure, Function, and Interaction of the Kell and XK Proteins

Antigens of the Kell blood group system are carried by a 93-kD red cell membrane glycoprotein.<sup>7</sup> The glycoprotein contains a short cytoplasmic N-terminal portion, a single membrane-spanning  $\alpha$ -helical segment, and a large, 665 amino acid extracellular C-terminal portion held in a globular conformation by multiple disulfide bonds (Fig 8-1). Kell antigens are inactivated by reducing agents such as dithiothreitol, suggesting that disulfide bonds are important in maintaining its antigenic conformation.<sup>8</sup> Proteolytic cleavage with chymotrypsin or trypsin also destroys Kell antigens.

The Kell protein is a member of the neprilysin (M13) family of zinc metalloproteases. This family consists of Kell, neutral endopeptidase 24.11, two different endothelin-converting

enzymes, the product of the *PEX* gene, and XCE.<sup>9,10</sup> Members of the M13 subfamily of membrane zinc endopeptidases have widely different roles, including processing of opioid peptides, Met- and Leu-enkephalin, oxytocin, bradykinin, angiotensin, endothelins, and parathyroid hormone. Kell protein has been shown to preferentially activate endothelin-3<sup>11</sup>; however, the in-vivo physiologic role of Kell protein is probably complex, because K<sub>0</sub> (null) persons are healthy.

The Kell protein interacts in the membrane with the 37-kD protein XK, which plays an important role in the expression of Kell system antigens. In contrast to the Kell protein, XK spans the membrane 10 times and both of its N- and C-termini are located intracellularly (Fig 8-1). The function of XK is not known. Structurally, XK resembles the glutamate transporters but it has very little amino acid sequence homology with this group of transport proteins. The Kell and XK proteins are covalently associated in the membrane by a disulfide link between cysteine 72 of Kell and cysteine 347 of XK<sup>12-14</sup> (Fig 8-1). The gene encoding the Kx antigen is located on the short arm of the X chromosome near the loci for X-linked chronic granulomatous disease (CGD) and Duchenne muscular dystrophy (DMD).

#### Kell in Transfusion Medicine

The Kell blood group system is the second most important protein blood group system in transfusion medicine after Rh, because the antibodies can cause hemolytic transfusion reactions (HTRs) and hemolytic disease of the fetus and newborn (HDFN). The most important antigens in this system are KEL1, or K, and the antithetical KEL2, or k. K and k are codominant autosomal alleles; approximately 9% of Whites and 2% of Blacks are K positive (ie, KK or Kk); the remainder are K negative (ie, kk). Antigens of the Kell blood group system are highly immunogenic and, excluding ABO, K are second only to RhD in its potential to elicit production of alloantibodies.

K antibodies are commonly found. Fortunately, because more than 90% of donor units are K negative, it is easy to obtain blood for transfusion to individuals with anti-K. In contrast, although anti-k is relatively rare, it is also of clinical significance, and only

**Table 8-1.** Overview of the Protein Blood Group Systems Other than Rh and LW

\*Based on the ISBT Cape Town report.<sup>1</sup>

ISBT = International Society of Blood Transfusion; ISGN = International Society for Gene Nomenclature.

1 in 500 random-donor units is antigen negative. The other two sets of well-defined antithetical antigens are Kp<sup>a</sup>/Kp<sup>b</sup> and Js<sup>a</sup>/Js<sup>b</sup> (Fig 8-1).

Mothers with anti-K are relatively rare, but since the introduction of Rh prophylaxis, anti-K accounts for nearly 10% of cases of severe HDFN. In contrast to RhD, anti-K titers are not good predictors of fetal anemia. In addition, affected Kell-alloimmunized infants have lower reticulocyte counts and amniotic fluid bilirubin concentrations than RhD-sensitized infants. Anti-K has been hypothesized to suppress erythropoiesis at the progenitor cell level. It is important to determine if a fetus is at risk when the mother has anti-K. The prospective father should be typed and if he carries the K antigen, genotyping from amniocentesis can be performed using molecular techniques.

### Kell Variants

There are two rare but clinically interesting variants in the Kell blood group system. Rare individuals have red cells that completely lack the common Kell antigens. Although these cells exhibit the null phenotype (K<sub>0</sub>), they are morphologically normal and survive normally in vivo. In contrast, individuals lacking

the Kx antigen exhibit depressed levels of the Kell protein.<sup>7,8</sup> This phenotype, known as the McLeod syndrome, is associated with acanthocytic red cells and a mild chronic hemolytic anemia. The frequently reported neuromuscular symptoms in persons with McLeod phenotype may be caused by lack of Kx expression. Association of the McLeod phenotype with other rare syndromes, most frequently with CGD and DMD or Becker muscular dystrophy (BMD) is caused by large gene deletions encompassing *XK* together with adjacent genes *CYBB* that encodes a large subunit of cytochrome b<sub>558</sub> and is associated with X-linked CGD, and *DMD* that encodes dystrophin.<sup>15,16</sup>

## Duffy Blood Group System (ISBT 008)

### Structure and Function of the Duffy Protein

The Duffy gene encodes a glycoprotein of 336 amino acids with a molecular weight of 36kD. The Duffy glycoprotein has seven transmembrane  $\alpha$ -helical domains. The N-terminus is ectoplasmic and the C-terminus is intracellular (see Fig 8-2). Duffy protein functions as a chemokine receptor and is frequently

**Figure 8-1.** Schematic representation of the Kell/XK complex in the red cell membrane. The XK protein is a membrane protein with 10  $\alpha$ -helical transmembrane segments, while Kell has only one transmembrane domain, most of which is exposed on the ectoplasmic side. Due to multiple disulfide bonds, the ectoplasmic portion of Kell is a globular structure; however, it is represented here schematically so that the positions of the main alleles can be shown. A disulfide bond between Cys72 of Kell and Cys347 of XK connects the two proteins. The position of the pentameric sequence HELLH is shown. Sequences HEXXH are involved in zinc binding and catalytic activity of zinc endopeptidases. The K/k polymorphism at amino acid 193 changes the consensus sequence for N-glycosylation at Asn191, which is not glycosylated in K. This difference in glycosylation may be important for the marked antigenicity of K. Positions of two additional sets of antithetical antigens Kp<sup>a</sup>/Kp<sup>b</sup> and Js<sup>a</sup>/Js<sup>b</sup> at amino acids 281 and 597 are indicated.

**Figure 8-2.** Schematic depiction of proteins carrying the Duffy and Kidd blood group antigens. The Duffy antigen receptor for chemokines (DARC) consists of seven transmembrane segments. The N-terminus is located extracellularly, functions as both the chemokine and *P. vivax* attachment site, and carries the Fy<sup>a</sup>/Fy<sup>b</sup> polymorphism. Kidd protein has 10 transmembrane segments, both N- and C-termini are intracellular and the amino acid determining the Jk<sup>a</sup>/Jk<sup>b</sup> polymorphism is located in the fourth ectoplasmic loop.

called the Duffy antigen receptor for chemokines (DARC).<sup>17,18</sup> Duffy binds both CXC chemokines, such as interleukin-8 (IL-8) and melanocyte growth-stimulating activity (MGSA), as well as CC chemokines, such as regulated on activation, normal T-cell expressed and secreted (RANTES) and macrophage chemoattractant protein (MCP-1).<sup>17</sup> It is currently not known why a red cell, with its limited metabolism and response to chemokine binding, would carry a significant number of chemokine receptors at its surface. One possible explanation is that the chemokine receptor acts as a scavenger for locally released chemokines. However, individuals who do not express the Duffy protein either on erythrocytes or in all tissues are phenotypically normal, suggesting that the Duffy protein is dispensable.

Duffy also functions as a receptor for the human malarial parasite *Plasmodium vivax*, which infects the erythrocytes of Duffy-positive individuals.<sup>19</sup> The binding site for *P. vivax* is located in the N-terminal ectoplasmic domain of Duffy. *P. vivax*

merozoites invade primarily reticulocytes, although reticulocytes and mature erythrocytes do not substantially differ in Duffy expression. This suggests that an additional receptor has to play a role in erythrocyte invasion.

### Duffy in Transfusion Medicine

The two main alleles of the Duffy blood group system are the antithetical codominant antigens Fy<sup>a</sup> and Fy<sup>b</sup> whose genetic determinant is a Gly/Asp polymorphism in position 44 (Fig 8-2).<sup>20</sup> These two alleles occur with similar frequencies in persons of European ancestry, Fy<sup>a</sup> being somewhat more common. The Fy(a-b-) phenotype is extremely rare among Whites but approximately two-thirds of African Americans and more than 90% of native West Africans are Fy(a-b-). This is most likely caused by the genetic adaptation for resistance to *P. vivax* malaria. However, it is not clear why this genetic advantage would lead almost to fixation of the Fy(a-b-) phenotype

in the indigenous population of West Africa. In contrast to the other malarial parasites, *P. vivax* causes a relatively mild form of malaria.<sup>17</sup>

A long-standing conundrum of immunohematology has been the well-known fact that transfused Fy(a-b-) people of African ancestry never develop anti-Fy<sup>b</sup>. This mystery was solved by the characterization of the mutation causing the Fy(a-b-) phenotype in native West Africans. The underlying mutation is a T→C substitution in the GATA site of the promoter region.<sup>21</sup> This substitution prevents binding of the erythroid transcription factor GATA-1 and abolishes transcription of the gene in the erythroid cells, while leaving the transcription of the *FY* gene in other tissues unaffected. Because the mutation occurred in the *FY*\*B allele, the Fy<sup>b</sup> antigen remains expressed in certain endothelial, epithelial, and brain cells, and, consequently, the transfusion recipient does not form antibodies against Fy<sup>b</sup>.

Fy<sup>a</sup> antibodies are found relatively frequently, constituting 6% to 10% of the clinically significant antibodies identified by immunohematology laboratories. For reasons not well understood, Fy<sup>b</sup> is a relatively poor immunogen and, consequently, anti-Fy<sup>b</sup> is considerably less common. Both immediate and delayed HTRs caused by Fy<sup>a</sup> incompatibility have been described, ranging from mild to severe hemolysis. HDFN is usually mild; only a few cases of severe HDFN have been reported. In contrast, anti-Fy<sup>b</sup> is associated only rarely with cases of mild HDFN and is usually found in delayed HTRs, although on rare occasions it has caused severe acute hemolysis.

## Kidd Blood Group System (ISBT 009)

The two main antigens of the Kidd blood group system, Jk<sup>a</sup> and Jk<sup>b</sup>, are found with almost identical frequencies in White populations. Jk<sup>a</sup> is a better immunogen and anti-Jk<sup>a</sup> is found more frequently than anti-Jk<sup>b</sup>. Anti-Jk<sup>a</sup> may cause severe immediate or delayed HTRs and, occasionally, HDFN. It is one of the most dangerous immune antibodies because of its tendency to decrease to undetectable levels in between transfusions and its relatively low affinity for Jk<sup>a</sup>-positive red cells. For these reasons, it accounts for a large proportion of delayed HTRs. Anti-Jk<sup>b</sup> may also cause immediate or delayed HTRs, albeit less severe than those caused by anti-Jk<sup>a</sup>. Several cases of mild HDFN caused by anti-Jk<sup>b</sup> have been reported.

The finding that cells of the Jk(a-b-) phenotype are resistant to lysis by 2M urea led to the discovery of the function of the protein carrying the Kidd antigens. Based on this finding and on in-vitro expression of the cloned Kidd cDNA,<sup>22-24</sup> it is now known that the protein is a urea transporter, although the importance of urea transport for erythrocytes is not completely understood. Its presence or absence may not be critical for red cell structure and function, because carriers of the Jk(a-b-) phenotype have red cells indistinguishable from those of controls.

Kidd is an integral protein with 10 transmembrane domains and both N- and C-termini located intracellularly (Fig 8-2). Of the five ectoplasmic loops, the longest, third loop is

N-glycosylated, and the relatively short fourth loop carries an Asp280Asn polymorphism corresponding to the Jk<sup>a</sup>/Jk<sup>b</sup> antigens.<sup>25</sup> Kidd protein is expressed not only on the red cell surface but also on neutrophils and in the kidney.

## MNS Blood Group System (ISBT 002)

### Structure and Function of Glycophorins A and B

Antigens of the MNS blood group system are carried by glycophorin A (GPA) and glycophorin B (GPB). Both molecules are present in a very high copy number in the plasma membrane;  $0.5-1.0 \times 10^6$  copies of glycophorin A and  $1-3 \times 10^5$  molecules of glycophorin B. Glycophorins A and B are encoded by homologous genes at chromosome 4q28-q31 that undoubtedly arose by gene duplication. Both glycoproteins are integral membrane proteins with a single transmembrane  $\alpha$ -helical segment and with the N-termini located extracellularly (Fig 8-3). Glycophorin A was the first protein whose primary structure was determined by amino acid sequencing.<sup>26</sup>

GPA carries the M and N antigens. The antigenic difference is caused by substitutions in position 1 and 5. Serine in position 1 and glycine in position 5 correspond to the M antigen, while the N allele has leucine and glutamic acid in these positions (Fig 8-3 and Table 8-2). An important requirement for recognition of these antigens by human antibodies is that serines in positions 2 and 4 and threonine in position 3 are O-glycosylated.

GPB is homologous with GPA. Although the genes are greater than 95% identical, *GYPB* encodes a shorter protein because a point mutation at the 5' splicing site of the third intron prevents incorporation of exon 3 into the translated mRNA. Because *GYPB* arose by duplication of the N allele of *GYPA*, *GYPA*\*N, and the first 26 amino acids of GPB are therefore identical to those of GPA with N specificity, GPB expresses an N-like antigen designated as 'N' (Table 8-2 and Fig 8-3). The S and s alleles of GPB differ at amino acid position 29. The S allele contains methionine and the s allele, threonine. GPB also carries the U antigen whose epitope is adjacent to the point where GPB enters into the lipid bilayer (Fig 8-3).

As is frequently the case with genes arising by duplication and located next to each other, unequal crossing over or gene conversion may easily occur. Consequently, numerous hybrid molecules containing portions of GPA and GPB have been described. This phenomenon is partly responsible for the 46 currently known antigens of the MNS blood group system, particularly for many of the Miltenberger (Mi) variants.

GPA associates in the red cell membrane with the band 3 protein. The epitope of the Wr<sup>b</sup> antigen from the Diego blood group system (see below) is formed by both GPA and band 3. This clearly demonstrates the intimate association of GPA and band 3 in the plasma membrane.<sup>27</sup>

### MNS in Transfusion Medicine

The most commonly encountered antibodies are directed against the M, N, S, and s antigens. Anti-M is often found in the sera

**Figure 8-3.** Antigens of the Diego and MNS blood group systems in a scheme of band 3 and of glycophorins A and B. The membrane domain of band 3 with 14 transmembrane segments is shown. Mutations underlying the Diego blood group antigens are located in the putative first, second, third, fourth, and seventh ectoplasmic loops. Positions of the M and N antigens in GPA and of the 'N', S, s, and U antigens in GPB are indicated. Arrows point to the sites in band 3 and GPA that are involved in formation of the  $Wr^b$  epitope and, therefore, have to come into close contact in the membrane.

**Table 8-2.** N-Terminal Sequences of the M and N Alleles of Glycophorin A (GPA) and of the S and s Alleles of Glycophorin B (GPB)

| Antigen | Amino Acid Sequence                                                  |
|---------|----------------------------------------------------------------------|
|         | 1 5 26 29                                                            |
|         | ↓ ↓ ↓ ↓                                                              |
| M (GPA) | SSTTG <del>V</del> AMHTSTSSSVTKSYISSQTNDTHKRD <del>T</del> YAATPRA.. |
| N (GPA) | LSTTE <del>V</del> AMHTSTSSSVTKSYISSQTNDTHKRD <del>T</del> YAATPRA.. |
| S (GPB) | LSTTE <del>V</del> AMHTSTSSSVTKSYISSQTNGEMGQLVHRFTVPA..              |
| s (GPB) | LSTTE <del>V</del> AMHTSTSSSVTKSYISSQTNGETGQLVHRFTVPA..              |
|         | <---> ↑                                                              |
|         | M/N; 'N' S/s                                                         |

Differences between M and N reside in amino acids 1 and 5. First 26 amino acids of GPB are identical to GPA and GPB therefore expresses an N-like antigen 'N'. The differences between the S and s antigens correspond to a M/T polymorphism in position 29 of GPB. S = serine; L = leucine; G = glycine; E = glutamic acid; M = methionine; T = threonine.

of persons who have not been exposed to human red cells. M antibodies are mostly IgM; however, they frequently contain an IgG component and, occasionally, are exclusively IgG. Anti-M is rarely clinically significant; hemolytic anti-M is usually IgG and reactive at 37°C. Anti-N is rare, most likely because of the immune tolerance induced by the 'N' antigen on GPB. Strong and potentially clinically significant antibodies have been observed in persons of the rare phenotype M+N-S-s-U—who do not express GPB (hence 'N'). In contrast to anti-M and anti-N, antibodies to S, s, and U usually occur after exposure to

**Table 8-3.** Comparison of the Most Frequently Encountered Antibodies in the MNS System

| Anti-M and -N            | Anti-S, -s, and -U     |
|--------------------------|------------------------|
| Naturally occurring      | Exposure is required   |
| Cold IgM                 | Warm IgG               |
| Dosage                   | Minimal dosage         |
| Clinically insignificant | Clinically significant |

allogeneic red cells. All are capable of causing HTRs and HDFN. The most important antibodies of the MNS system are compared in Table 8-3.

## Diego Blood Group System (ISBT 010)

Antigens of the Diego blood group system are carried by erythrocyte band 3 protein (anion exchanger 1), the most abundant integral protein of the red cell membrane together with GPA (see above). Band 3 is also one of the most important proteins for the structure and function of the membrane because it maintains red cell integrity by linking the red cell membrane to the underlying spectrin-based membrane skeleton. It also mediates exchange of chloride and bicarbonate anions across the plasma membrane, thereby significantly increasing the carrying capacity of blood for carbon dioxide.

Band 3 consists of a cytoplasmic and a membrane domain. The membrane domain contains 14 transmembrane helices

connected by ecto- and endoplasmic loops<sup>28,29</sup> (Fig 8-3). The fourth loop of band 3 is N-glycosylated and the attached carbohydrate chain carries over half of the red cell ABO blood group epitopes.<sup>30</sup> Several disorders of red cell structure and function have been associated with mutations in the band 3 gene, including Southeast Asian ovalocytosis,<sup>31</sup> autosomal dominant spherocytosis,<sup>32-34</sup> and distal renal tubular acidosis.<sup>35</sup>

Despite being the most abundant protein of the red cell membrane, band 3 until recently has not been known to carry any red cell antigens with the exception of the ABO antigens residing on the attached carbohydrate chains. It was only in 1992 that Spring et al<sup>36</sup> reported that the Memphis II variant of erythroid band 3 protein carries the Di<sup>a</sup> blood group antigen. Di<sup>a</sup> was originally described in South American Indians by Layrisse et al in 1955.<sup>37</sup> The antithetical antigen Di<sup>b</sup> was reported by Thompson et al in 1967.<sup>38</sup> Di<sup>a</sup> and Di<sup>b</sup> represent codominantly expressed gene products. Di<sup>a</sup> is a low-incidence blood group antigen in persons of European ancestry who carry the antithetical high-incidence antigen Di<sup>b</sup>. Prevalence of Di<sup>a</sup> is as high as 8% in certain areas of Southeast Asia and reaches up to 40% in some groups of South American Indians.<sup>37</sup> Di<sup>a</sup> was used as one of the markers for studying migration of people from Southeast Asia across the Bering Strait and southward through the American continents. Cloning and sequencing of band 3 gene identified the substitution 854 Pro→Leu in the last ectoplasmic loop of band 3 as the molecular basis of the Di<sup>a</sup> antigen. Di<sup>b</sup> corresponds to the wild type band 3 with proline in position 854.<sup>39</sup>

Subsequently, the low-incidence blood group antigen Wr<sup>a</sup> was mapped to the fourth ectoplasmic loop.<sup>27</sup> The antithetical Wr<sup>b</sup> antigen is seen only when both GPA and band 3 protein are expressed in the erythrocyte membrane, which helped to characterize the site of interaction between band 3 and GPA (Fig 8-3). During the last several years, numerous additional low-incidence antigens have been associated with single point mutations on band 3 and included in the Diego system.<sup>40,41</sup> Positions of the mutated amino acids in the band 3 molecule are shown in Fig 8-3, which also indicates the regions of band 3 and glycophorin A that interact in the membrane and are involved in formation of the Wr<sup>b</sup> antigen.

Some antigens of the Diego blood group system have been localized to the regions of band 3 protein that have been implicated in the adhesion of abnormal red cells, such as sickle cells or malaria-infected erythrocytes, to vascular endothelium.<sup>42,43</sup> Erythrocytes from carriers of low-incidence blood group antigens in ectoplasmic loops of band 3 may serve as a model for evaluation of the sequence requirements for adhesion. The so-called “senescent” or “aging” red cell antigen may also be located in the ectoplasmic loops of band 3.

---

### Gerbich Blood Group System (ISBT 020)

As in the MNS system, antigens of the Gerbich system are located on glycophorins C and D. The glycophorin terminology is in fact

the only common feature of these two classes of glycophorins. There is otherwise no homology between the Gerbich and MNS genes. Unlike GPA and GPB, GPC and GPD are the products of a single gene and, unlike *GYP A* and *GYP B*, this gene is expressed in multiple tissues. The considerably less abundant and smaller GPD is produced from a shorter transcript than GPC. Although present in much smaller copy numbers than GPA and GPB, GPC plays an important role in the structural integrity of the red cell membrane. In the Leach phenotype, deletions of exons 3 and 4 or a frameshift mutation lead to complete absence of glycophorins C and D from the plasma membrane. The affected individuals have moderate elliptocytosis and decreased red cell deformability and mechanical stability. Antibodies in the Gerbich system are rare and, in the vast majority of cases, clinically insignificant.

---

### Colton and GIL Blood Group Systems (ISBT 015 and 029)

Antigens of these two blood group systems are carried by members of the large aquaporin family. Antibodies against the two antigens of the Colton blood group system, the high-frequency Co<sup>a</sup> and the less common, antithetical Co<sup>b</sup>, are rare and have only rarely been associated with mild HTRs and mild HDFN. These two antigens, and the Co3 antigen that is present on all red cells except those of the very rare null phenotype Co(a-b-), are carried by aquaporin-1,<sup>44</sup> a member of a large family of water channels.<sup>45</sup> It is present in the membrane as a tetramer. Expression of aquaporin-1 in *Xenopus* oocytes is associated with dramatic swelling and lysis of the cell.<sup>46</sup> At the same time, the Co(a-b-) phenotype is associated with only slightly abnormal red cells and with normal kidney function despite the fact that aquaporin-1 is the major water channel of human kidney.<sup>47,48</sup> The GIL antigen is carried by aquaporin-3, which differs from aquaporin-1 in that it transports glycerol, water, and urea.<sup>49</sup>

---

### Lutheran Blood Group System (ISBT 005)

The Lutheran blood group system contains multiple antigens; however, clinically significant antibodies are rarely encountered. The most important antigens are Lu<sup>a</sup> and Lu<sup>b</sup>. The frequency of Lu<sup>a</sup> is less than 10% in most populations, while Lu<sup>b</sup> is a high-frequency antigen with an average prevalence of 99.8% in all populations. Lutheran antigens are poorly developed at birth and, not surprisingly, anti-Lu<sup>a</sup> has been associated only rarely with mild cases of HDFN. It does not cause transfusion reactions. Lu<sup>b</sup> is somewhat more immunogenic and anti-Lu<sup>b</sup> has caused mild or moderate HTRs and mild HDFN. Of historical note, Lu and Se (Chapter 6) were the first two loci for which an autosomal linkage in humans was demonstrated.

Lutheran antigens reside on B-CAM/LU (Fig 8-4), a pair of spliceosomes (protein products arising from the same gene because of alternative splicing of hnRNA) that belong to the

**Figure 8-4.** Members of the immunoglobulin superfamily carrying blood group antigens. B-CAM/LU contains five immunoglobulin domains and carries antigens of the Lutheran blood group system. CD147, or neurothelin, contains two Ig domains and carries the Ok<sup>a</sup> antigen. CD147 is similar to the LW protein, which was discussed in Chapter 7.

immunoglobulin superfamily.<sup>50,51</sup> Basal cell adhesion molecule (B-CAM) is involved in adhesion of the basal surface of epithelial cells to the basement membrane. B-CAM/LU is a receptor for laminin.<sup>52</sup> Expression of B-CAM/LU is increased on red cells from patients with sickle cell disease<sup>52</sup> and on a number of malignant epithelial tumors, which also lose the polarity of B-CAM/LU expression found in normal tissues.<sup>51</sup>

The null phenotype, Lu(a–b–), is rare but quite interesting. It may result from three different patterns of inheritance. A recessive pattern of inheritance is associated with an exceedingly rare null allele. In the most common dominant type of inheritance, the expression of Lu can be suppressed by a single copy of the suppressor gene *In(Lu)*. In addition to reducing the expression of Lutheran antigens to levels undetectable by standard serologic techniques, *In(Lu)* also decreases the expression of antigens P1, i, In<sup>a</sup> and In<sup>b</sup> (see below), and AnWj, a receptor for *Haemophilus influenzae*. The third cause of the Lu(a–b–) phenotype is the presence of an X-linked recessive suppressor gene *XS2*.<sup>53</sup>

### Indian Blood Group System (ISBT 023)

The four antigens of this system, In<sup>a</sup>, In<sup>b</sup>, INFI, and INJA reside on CD44, an adhesion molecule expressed in leukocytes, fibroblasts, epithelial cells, and other tissues. CD44 is an important lymphocyte marker that functions as a hyaluronan receptor,<sup>54</sup> and a lymphocyte homing receptor (Fig 8-4). Transfection of

nonadherent cell lines with CD44 cDNA confers an adherent phenotype.<sup>55</sup> As with the Lutheran antigens, expression of In<sup>a</sup> and In<sup>b</sup> is suppressed by *In(Lu)*.

### Xg Blood Group System (ISBT 012)

The only antigen of the Xg system, Xg<sup>a</sup>, is carried by a glycoprotein of 180 amino acids.<sup>56</sup> The function of Xg glycoprotein in erythrocytes is not known. Designation of this blood group system reflects the fact that the *PBDX* gene,<sup>57</sup> which encodes Xg, is located on the X-chromosome. Xg is 48% homologous to CD99, an adhesion molecule. Xg<sup>a</sup> antibodies are clinically insignificant.

### Scianna Blood Group System (ISBT 013)

The seven antigens of the Scianna blood group system are carried by the erythrocyte membrane-associated protein (ERMAP), potentially a receptor/signal transduction molecule specific for erythroid cells.<sup>58</sup> Mild HDFN and mild postransfusion hemolysis caused by anti-Sc-2 and anti-Sc-3 antibodies have been reported.

### Chido/Rodgers Blood Group System (ISBT 017)

Antigens of the Chido/Rodgers blood group system are the only protein antigens that are not produced by red cells but instead adhere to the red cell surface (Lewis antigens are glycolipids). They are carried by the complement component C4. Although antibodies against the nine known antigens of the system are generally benign, a severe anaphylactic reaction following a transfusion of platelets to a patient with anti-Ch3 has been described.<sup>59</sup>

### Knops Blood Group System (ISBT 022)

Antigens are located on the C3b/C4b complement receptor 1 (CR1, CD35). CR1 protects erythrocytes from autohemolysis by inhibiting the classical and alternative complement pathways through cleavage of C4b and C3b. CR1 is a large 190- to 280-kD molecule. It contains 30 complement control protein domains (CCPD) of about 60 amino acids. Seven CCPDs form a long homologous repeat (LHR) of about 450 amino acids. Various forms of CR1 contain up to 6 LHRs. Erythrocyte CR1 binds immune complexes and carries them to the liver and spleen for removal. Expression of CR1 on erythrocytes varies widely from 20 to 1500 molecules and is decreased in hemolytic anemias, AIDS, systemic lupus erythematosus, and other autoimmune disorders. *Plasmodium falciparum*-infected erythrocytes deficient in CR1 have greatly reduced rosetting capacity, indicating an essential role for CR1 in rosette formation and raising the possibility that CR1 polymorphisms in Africans that influence the interaction between erythrocytes and parasite-encoded protein

PfEMP1 may protect against severe malaria.<sup>60</sup> CR1 could therefore be a potential target for future therapeutic interventions to treat severe malaria.<sup>61,62</sup>

### Blood Group Antigens on Phosphatidylinositol-Linked Proteins—Cartwright (ISBT 011), Dombrock (ISBT 014), Cromer (ISBT 021), and JMH (ISBT 026)

The common denominator of these antigens is the linkage of the carrier protein to the glycosylphosphatidylinositol (GPI) anchor (Fig 8-5). The Cartwright (Yt) blood group system consists of two antigens, Yt<sup>a</sup> and Yt<sup>b</sup>, which are located on red cell acetylcholinesterase. Most examples of anti-Yt<sup>a</sup> are benign.

The five antigens of the Dombrock system are located on a recently characterized glycoprotein.<sup>63</sup> Homology studies suggest that the Dombrock molecule is a member of the adenosine 5'-diphosphate (ADP)-ribosyltransferase ectoenzyme gene family. Dombrock expression is developmentally regulated during erythroid differentiation and occurs at highest levels in the fetal liver. Do<sup>a</sup> and Do<sup>b</sup> antigens differ in a single amino acid substitution within the RGD motif of the molecule.<sup>63,64</sup>

The Cromer blood group system contains 15 antigens located on decay accelerating factor (DAF, CD55), a complement regulatory protein. Although DAF is the first complement regulatory protein identified, it plays only a minor role in complement-mediated lysis, the more important being the MIRL (CD59) molecule. This was clearly demonstrated in the case of the null

phenotype, Inab, which is associated with lack of DAF expression on all circulating cells but not with increased hemolysis.<sup>65</sup>

The only antigen of the JMH blood group system resides on a GPI-linked protein semaphorin 7A (CD108) that is part of a plasma membrane complex associated with intracellular protein kinases.<sup>66</sup> CD108 is expressed in multiple tissues and may play a role in signal transduction. Semaphorin 7A is a surprisingly diverse molecule<sup>67</sup> and four new antigens have been recently added to the JMH blood group system.<sup>1</sup>

Antibodies in these four blood group systems have been associated only occasionally with mild HTRs or HDFN. Expression of all GPI-linked antigens is, not surprisingly, decreased in paroxysmal nocturnal hemoglobinuria, a disorder caused by defects in the X-linked phosphatidylinositol glycan class A (PIG-A) gene, which participates in an early step of GPI anchor synthesis.

### OK and RAPH Blood Group System (ISBT 024 and 025)

Each of these two blood group systems contains only one antigen. Ok<sup>a</sup> is a high-incidence antigen; rare Ok(a-) individuals have so far been reported only in Japan. Ok<sup>a</sup> is carried on an N-glycosylated protein with an apparent molecular weight of 35 to 69 kD, which is expressed in multiple tissues. The Ok glycoprotein is a member of the immunoglobulin superfamily. As with LW, its extracellular domain contains two immunoglobulin domains. The function of the Ok glycoprotein in erythrocytes is not known.

MER2 is the only antigen of the RAPH system. All MER2 antibodies so far reported have been found in patients on hemodialysis. The molecular basis of the antigen is not known.

**Figure 8-5.** Schematic representation of a GPI-anchored protein. The membrane anchor is provided by phosphatidylinositol. The inositol moiety binds to a glycan core via a molecule of N-glucosamine. The glycan core is attached via ethanolamine to the C-terminus of the protein.

### Summary

The century-long history of modern transfusion medicine and immunohematology practice led to the characterization of an enormous number of blood group antigens with often confusing terminology. These antigens have been arranged into a complex framework of blood group systems, collections, and low- and high-frequency antigens. Fortunately, advances in biochemical and molecular biology techniques in the past two decades led to a detailed structural characterization of most proteins carrying blood group antigens and to a better understanding of the relation between gene variations, amino acid polymorphisms, protein structure, and immunogenicity of individual antigens. Better understanding of the molecular biology, biochemistry, and immunogenicity of proteins carrying blood group antigens will undoubtedly contribute to accurate compatibility testing and to safe transfusion of red cells.

## Anemia and Red Blood Cell Transfusion

**Jeffrey L. Carson<sup>1</sup> & Paul Hébert<sup>2</sup>**

<sup>1</sup> Richard C. Reynolds Professor of Medicine, Chief, Division of General Internal Medicine, Robert Wood Johnson Medical School, University of Medicine and Dentistry of New Jersey, New Brunswick, New Jersey, USA

<sup>2</sup> Professor of Medicine, Surgery, Anesthesiology, and Epidemiology; University of Ottawa; Critical Care Physician, The Ottawa Hospital; Senior Scientist, Ottawa Health Research Institute Ottawa, Ontario Canada

Red cell transfusion is an extremely common medical intervention. About 75 million units of Red Blood Cells (RBCs) are collected worldwide,<sup>1</sup> and in the United States, 15.8 million allogeneic units were donated in 2006.<sup>2</sup> In Northern England, about 50% of units are given to medical patients, and 40% to surgical patients; hip replacement and coronary artery bypass graft (CABG) surgery were the most common surgical indications.<sup>3</sup> RBC units are also frequently administered to critically ill patients, as a supportive therapy to patients receiving chemotherapy and marrow transplants, and to patients with blood loss from medical conditions such as gastrointestinal bleeding.<sup>4</sup>

This chapter reviews the current knowledge about red cell transfusion and the risk posed by anemia. The adaptive physiologic mechanisms in response to acute blood loss are described, as well as more chronic decreases in red cell mass. These discussions include a review of oxygen transport, adaptive mechanisms in anemia, and microcirculatory effects of anemia. Some of these fundamental principles are followed by a review of clinical outcomes in patients with anemia. Similarly, the clinical consequences (both risks and benefits) of red cell transfusion are outlined. This overview summarizes preclinical, observational, and controlled trials. Guidelines on transfusion practices are examined. The first three sections are based on systematic reviews of the literature. The fourth section describes an approach to decision making in red cell transfusion that is occasionally evidence-based, but frequently based on the authors' views.

### Physiologic Adaptations to Blood Loss and Anemia

#### Overview of Oxygen Transport

Hemoglobin is a complex molecule that consists of four globin moieties, each incorporating an iron-containing heme ring where

oxygen is bound according to its partial pressure ( $PO_2$ ). The oxygen-binding affinity of hemoglobin is graphically represented by a sinusoidal relationship between hemoglobin oxygen saturation and  $PO_2$ . This relationship, referred to as the *oxyhemoglobin dissociation curve*, enables both efficient loading in the lungs at high  $PO_2$  and efficient unloading in the tissues at low  $PO_2$  (Fig 9-1). However, the affinity of hemoglobin for oxygen (the degree to which oxygen molecules saturate the hemoglobin binding sites at a given  $PO_2$ ) is altered by various disease states and may play a significant adaptive role in the response to anemia. The amount of oxygen delivered, either to the whole body or to specific organs, is the product of blood flow and arterial oxygen content. For the whole body, oxygen delivery ( $DO_2$ ) is the product of total blood flow or cardiac output (CO) and arterial oxygen content ( $CaO_2$ ), represented by the following equation (#1):

$$DO_2 = CO \times CaO_2$$

When ambient air is breathed under normal conditions, the oxygen present in arterial blood is bound to hemoglobin. When fully saturated, 1 g of hemoglobin binds 1.39 mL of oxygen. In addition, a small amount of hemoglobin also is dissolved in plasma water. The negligible amount of dissolved oxygen is directly proportional to the partial pressure and is calculated by multiplying  $PO_2$  by a constant ( $k = 0.00301$  mL/mm Hg), called the *solubility coefficient*. Thus, under most circumstances, arterial oxygen content can be approximated from the portion bound to hemoglobin with the following equation (#2):

$$CaO_2 \text{ (mL/L)} = \%Sat \times 1.39 \text{ (mL/g)} \times Hb \text{ (g/dL)}$$

When  $CaO_2$  from equation 2 is substituted into equation 1, the results are as shown in the following equation (#3):

$$DO_2 = CO \times (\%Sat \times 1.39 \times Hb)$$

Where CO is cardiac output in liters per minute, %Sat is hemoglobin oxygen saturation in percent, and Hb is hemoglobin concentration in g/dL.

**Figure 9-1.** Oxyhemoglobin dissociation curve. The  $P_{50}$  is a measurement of the partial pressure of oxygen when hemoglobin is 50% saturated. The solid line represents oxygen-binding affinity to the hemoglobin molecule at standard temperature ( $37^{\circ}\text{C}$ ) and pH (7.4). The  $P_{50}$  of this curve is usually between 26 and 28 mm Hg. The dashed lines represent hypothetical shifts in the curve. A rightward shift represents a decreased affinity of hemoglobin for oxygen or an increase in  $P_{50}$ . It may be caused by increased levels of 2,3-diphosphoglycerate (2,3-DPG), temperature, or decreased pH. A shift to the left represents an increased affinity of oxygen for hemoglobin and is measured by a decrease in  $P_{50}$ . A leftward shift may result from decreased temperature, levels of 2,3-DPG or increased pH.

Tissue hypoxia and anoxia eventually occur if oxygen delivery decreases to a level at which it is no longer adequate to meet the metabolic demands of the tissues. From Equations 1 and 3, it is apparent that tissue hypoxia can be caused by decreased oxygen delivery resulting from decreases in either hemoglobin concentration (anemic hypoxia), cardiac output (stagnant hypoxia), or hemoglobin saturation (hypoxic hypoxia). Each of the determinants of  $\text{DO}_2$  has substantial physiologic reserves, thereby enabling the human body to adapt to significant increases in oxygen requirements or decreases in one of the determinants of  $\text{DO}_2$  as a result of various diseases.

In health, the amount of oxygen delivered to the whole body exceeds resting oxygen requirements twofold to fourfold. For example, with a hemoglobin level of 15 g/dL, a hemoglobin oxygen saturation of 99%, and a cardiac output of 5 L/minute, oxygen delivery is 1032 mL/minute. At rest, the amount of oxygen required or consumed by the whole body ranges from 200 to 300 mL/minute. A decrease in hemoglobin concentration to 10 g/dL would result in an oxygen delivery of 688 mL/minute. Despite this 33% decrease in oxygen delivery, there remains a twofold excess of oxygen delivered compared with oxygen consumed. However, a further decrease in hemoglobin concentration to 5 g/dL with all other parameters (including cardiac output) remaining constant, decreases oxygen delivery to a critical level of 342 mL/minute. Under stable experimental conditions, this dramatic decrease in oxygen delivery still exceeds oxygen consumption. However, at the critical level or threshold of oxygen— $\text{DO}_2(\text{crit})$ —oxygen delivery equals oxygen consumption. Further

**Figure 9-2.** Relationship between oxygen consumption and oxygen delivery. The solid line shows the biphasic consumption and delivery. The dashed line illustrates the postulated changes in the relation with diseases such as sepsis and acute respiratory distress syndrome. The anaerobic threshold is shifted to the right, suggesting that patients need increased levels of delivery to avoid ongoing ischemic damage to vital organs.

decreases in hemoglobin concentration result in inadequate oxygen delivery to tissues. There is, therefore, a biphasic relationship between oxygen delivery and consumption (Fig 9-2). One phase is an oxygen delivery-independent portion, in which oxygen consumption is independent of oxygen delivery above the  $\text{DO}_2(\text{crit})$  delivery threshold. The other is a delivery or supply-dependent portion, in which oxygen delivery is directly related to oxygen consumption. The latter portion of this relationship below the  $\text{DO}_2(\text{crit})$  indicates the presence of tissue hypoxia. Both laboratory and clinical studies have attempted to determine the  $\text{DO}_2(\text{crit})$ . In the most rigorous clinical study,<sup>5</sup> the investigators found a threshold value of 4 mL/minute/kg. In other clinical and laboratory studies, investigators found values in the range of 6 to 10 mL/minute/kg.<sup>5,6</sup> The  $\text{DO}_2(\text{crit})$ , or the anaerobic threshold, is not a single, fixed value but varies substantially depending on factors such as basal metabolic rate, the specific organ or tissue, some disease states, and perhaps such complex factors as patient age or genetic composition. In the previous example, cardiac output did not increase as would otherwise be expected in anemia.

Once it is oxygenated, blood is distributed to all organs and tissues through the arterial tree into the microcirculation. Organ blood flow is controlled by arterial tone in medium-sized vessels and is primarily responsive to changes in autonomic stimulation and the release of locally generated vasodilating substances. Within organ systems, red cells are carried into the microcirculation, where oxygen is released to the tissues through a thin-walled capillary network. Once released, oxygen diffuses through the interstitial space, finally finding its way into the cell and its mitochondria to be used in cellular respiration. Each of these physiologic mechanisms can be altered in disease, as described later. Additional adaptive changes in the microcirculation enhance oxygen delivery in anemia.<sup>7</sup>

### Adaptive Mechanisms in Anemia

In anemia, oxygen-carrying capacity decreases, but tissue oxygenation is preserved at hemoglobin levels well below 10 g/dL (Table 9-1). After the development of anemia, adaptive changes include a shift in the oxyhemoglobin dissociation curve, hemodynamic alterations, and microcirculatory alterations. The shift to the right of the oxyhemoglobin dissociation curve in anemia is primarily the result of increased synthesis of 2,3-diphosphoglycerate (2,3-DPG) in red cells.<sup>8-10</sup> This rightward shift enables more oxygen to be released to the tissues at a given  $PO_2$ , offsetting the effect of reduced oxygen-carrying capacity of the blood. In-vitro studies have shown rightward shifts in the oxyhemoglobin dissociation curve with increases in temperature and decreases in pH.<sup>11</sup> Although clinically important shifts have been documented in a number of studies, hemoglobin oxygen saturation generally is measured in arterial specimens processed at standard temperature and pH. Therefore, current measurement techniques do not reflect oxygen-binding affinity or unloading conditions in the patient's microcirculatory environment, which may be affected by temperature, pH, and a number of disease processes. The shift in the oxyhemoglobin dissociation curve caused by decreases in pH (increase in hydrogen ion concentration) is the Bohr effect.<sup>11,12</sup> Because changes in pH rapidly affect the ability of hemoglobin to bind oxygen, this mechanism has been postulated to be an important early adaptive response to anemia.<sup>13</sup> However, the equations describing the physical process indicate that a very large change in pH is needed to modify the partial pressure of oxygen at which hemoglobin is 50% saturated

with oxygen ( $P_{50}$ ) by a clinically important amount ( $\sim 10$  mm Hg). As a result, the Bohr effect is unlikely to have significant clinical consequences.<sup>11,12</sup>

Several hemodynamic alterations occur after the development of anemia. The most important determinant of cardiovascular response is the patient's volume status, or more specifically left ventricular preload. The combined effect of hypovolemia and anemia often occurs as a result of acute blood loss. Acute anemia can cause tissue hypoxia or anoxia through both diminished cardiac output (stagnant hypoxia) and decreased oxygen-carrying capacity (anemic hypoxia).<sup>14</sup> The body primarily attempts to preserve oxygen delivery to vital organs by compensatory increases in myocardial contractility and heart rate as well as increased arterial and venous vascular tone mediated through increased sympathetic discharge. In addition, a variety of mechanisms redistribute organ blood flow. The adrenergic system plays an important role in altering blood flow to and within specific organs. The renin-angiotensin-aldosterone system is stimulated to retain both water and sodium. Losses ranging from 5% to 15% in blood volume result in variable increases in resting heart rate and diastolic blood pressure. Orthostatic hypotension often is a sensitive indicator of relatively small losses in blood volume not sufficient to cause a marked decrease in blood pressure. Larger losses result in progressive increases in heart rate and decreases in arterial blood pressure accompanied by evidence of organ hypoperfusion. The increased sympathetic tone diverts an ever decreasing global blood flow (cardiac output) away from the splanchnic, skeletal, and cutaneous circulation

**Table 9-1.** Physiologic Changes Associated with Anemia

#### Oxyhemoglobin dissociation curve

- Anemia shifts the oxyhemoglobin curve to the right because of increased 2, 3-biphosphoglycerate levels.
- Anemia causes clinically significant rightward shifts in the oxyhemoglobin curve because of the Bohr effect.
- The shift in the oxyhemoglobin curve has been clearly established in many forms of anemia (excluding hemoglobinopathies).
- The shift in the oxyhemoglobin curve has been clearly established in a number of human diseases.

#### Cardiac output

- Cardiac output increases with increasing degrees of normovolemic anemia.
- Increased cardiac output in normovolemic anemia is a result of increased stroke volume.
- The contribution of increased heart rate to the increase in cardiac output following normovolemic anemia is variable.

#### Other hemodynamic alteration

- Changes in blood viscosity result in many of the hemodynamic changes in normovolemic anemia.
- Normovolemic anemia is accompanied by increased sympathetic activity.
- Normovolemic anemia causes increased myocardial contractility.
- Normovolemic anemia causes a decrease in systemic vascular resistance.
- Normovolemic anemia results in a redistribution of cardiac output toward the heart and brain and away from the splanchnic circulation.
- Maximal global oxygen delivery occurs at hemoglobin values of 10 g/dL to 11 g/dL.
- Global oxygen delivery declines above and below hemoglobin values of 10 g/dL to 16 g/dL.

#### Coronary and cerebral blood flow

- Coronary blood flow is increased during anemia.
- Cerebral blood flow is increased during anemia.
- Coronary artery disease in the presence of moderate degrees of anemia (hemoglobin values below 9 g/dL) results in impaired left ventricular contractility or ischemia.
- Moderate anemia does not aggravate cerebral ischemia in patients with cerebrovascular disease.

toward the coronary and cerebral circulation. Once vital organ systems such as the kidneys, the central nervous system, and the heart are affected, the patient is considered in hypovolemic shock. Although the American College of Surgeons Committee on Trauma<sup>15</sup> has categorized the cardiovascular and systemic response to acute blood loss according to degree of blood loss, many of these responses are modified by the rapidity of blood loss and patient characteristics, such as age, coexisting illnesses, preexisting volume status, hemoglobin value, and the use of medications having cardiac effects ( $\beta$ -blockers) or peripheral vascular effects (antihypertensives).

The compensatory changes in cardiac output most thoroughly studied are the cardiovascular consequence of normovolemic anemia. When intravascular volume is stable or high after the development of anemia (as opposed to hypovolemic anemia and shock), increases in cardiac output have been consistently reported. Indeed, an inverse relationship between hemoglobin level (or hematocrit) and cardiac output has been clearly established in well-controlled laboratory studies (Fig 9-3).<sup>13,16-19</sup> Similar clinical observations have been made in the perioperative setting<sup>20</sup> and for chronic anemia.<sup>16</sup> Unfortunately, the strength of inferences from clinical studies is limited by confounding factors arising from major coexisting illnesses such as cardiac disease, a lack of appropriate control patients, and significant weaknesses in study design. Researchers have attempted to determine the level of anemia at which cardiac output begins to rise. Reported thresholds for this phenomenon identified in primary clinical and laboratory studies have ranged from 7 to 12 g/dL of hemoglobin.<sup>16</sup> Two major mechanisms are thought to be responsible for the physiologic processes underlying increased cardiac output during normovolemic anemia: 1) reduced blood viscosity and 2) increased sympathetic stimulation of the cardiovascular effectors.<sup>21</sup> Blood viscosity affects both preload and afterload,

two major determinants of cardiac output,<sup>21-23</sup> whereas sympathetic stimulation primarily increases the two other determinants, heart rate and contractility. Unlike the situation for hypovolemic anemia, in this setting the effects of blood viscosity appear to predominate.<sup>22,23</sup>

Complex interactions exist among blood flow, blood viscosity, and cardiac output. In vessels, blood flow alters whole-blood viscosity, and blood viscosity modulates cardiac output. Under experimental conditions in a rigid hollow cylinder, blood flow is directly related to the fourth power of the diameter and to driving pressure. It is inversely related to the length of the vessel and to blood viscosity (Poiseuille-Hagen law).<sup>7,21</sup> Also, blood viscosity increases as flow decreases because of increasing aggregation of red cells. Thus, viscosity is highest in postcapillary venules, where flow is the lowest, and viscosity is lowest in the aorta, where flow is the highest. In postcapillary venules, there is a disproportionate decrease in blood viscosity as anemia worsens, consequently augmenting venous return at a given venous pressure. If cardiac function is normal, the increase in venous return or left ventricular preload is the most important determinant of increased cardiac output during normovolemic anemia. The conclusion is based on experiments in which viscosity was maintained during anemia by means of high-viscosity colloidal solutions. In such studies, the cardiovascular effects of hemodilution were attenuated<sup>22</sup> compared with similar levels of hemodilution accompanied by reduced whole-blood viscosity. Decreased left ventricular afterload, another cardiac consequence of decreased blood viscosity, also may be an important mechanism for the increase in cardiac output as anemia worsens.<sup>22</sup>

Sympathetic stimulation can result in increased cardiac output through enhanced myocardial contractility<sup>24</sup> and increased venomotor tone.<sup>18,25</sup> The effects of anemia on left ventricular contractility in isolation have not been clearly determined, given the complex changes in preload, afterload, and heart rate. Only one before-and-after hemodilution study was performed with load-independent measures to document increased left ventricular contractility.<sup>24</sup> Chapler and Cain<sup>18</sup> summarized several well-controlled animal studies indicating that venomotor tone increases as a result of stimulation of the aortic chemoreceptors. If sympathetic stimulation is significant in the specific clinical setting, contractility is increased from stimulation of the  $\beta$ -adrenergic receptors.<sup>21,26</sup>

The inverse relationship between cardiac output and hemoglobin level has led investigators to attempt to determine the hemoglobin level that maximizes oxygen transport. Richardson and Guyton<sup>27</sup> evaluated the effects of hematocrit on cardiac performance in a canine model. They established that optimal oxygen transport occurred between hematocrits of 40% and 60%. Others determined maximum oxygen delivery to be in the lower end of the range, at a hematocrit of 40% to 45% (hemoglobin 13 to 15 g/dL).<sup>28,29</sup> However, in one of the most widely quoted studies addressing this topic,<sup>30</sup> investigators found peak oxygen transport to occur at a hematocrit of 30% (hemoglobin concentration, 10 g/dL). Unfortunately, global indices of optimal oxygen delivery mask any differences in blood flow between

**Figure 9-3.** The theoretic effect of hemoglobin concentration on cardiac output. The curves illustrate how cardiac output increases as hemoglobin concentration decreases. The solid curve is meant to describe the increase in a healthy adult. The dashed line on the top shows how the cardiac output response can be accentuated in a young athlete and the lower dashed line might correspond to someone with poor cardiovascular function.

specific organs.<sup>31,32</sup> In addition, attempting to identify a single optimal hemoglobin concentration that maximizes oxygen delivery neglects the large number of factors interfering with adaptive mechanisms during management of patients other than healthy, young patients with anemia.

Will the transfusion of allogeneic RBCs reverse any adaptive response to acute or chronic normovolemic anemia? Assuming that oxygen-carrying capacity is not impaired during storage and that hematocrit is restored after a transfusion, the cardiovascular consequences will be reversed. However, the storage process alters the properties of red cells. These alterations may impair flow and oxygen release from hemoglobin<sup>9</sup> in the microcirculation.

### Microcirculatory Effects of Anemia and Red Cell Transfusion

At the level of the microcirculation, three putative adaptive mechanisms increase the amount of oxygen supplied to tissues by capillary networks. In a model of the microcirculation proposed by Krogh,<sup>33</sup> oxygen supply to the tissues is enhanced through recruitment of previously closed capillaries, increased capillary flow, and increased oxygen extraction from existing capillaries. The degree of anemia, the specific tissue bed, and a variety of disease processes affect microcirculatory blood flow and oxygen supply.<sup>7,34</sup> As the degree of hemodilution becomes more pronounced and hematocrit decreases, blood viscosity decreases disproportionately in capillary networks. This occurs because the hematocrit is highest in the capillary network, as a consequence, there is a larger decrease in capillary viscosity.

Stored red cells have properties that differ from those of their in-vivo counterparts; many are related to the duration of storage. Characteristically, older RBC units have lower levels of 2,3-DPG. The result is a leftward shift in the oxyhemoglobin dissociation curve, which can impede delivery of oxygen to the tissues.<sup>13</sup> In addition, storage of red cells decreases the deformability of their membrane.<sup>35</sup> As a consequence, stored red cells may impede flow in the microcirculation<sup>36</sup> and may have limited ability to release oxygen to tissues. However, these storage lesions are reversible within 24 to 48 hours.<sup>37</sup>

There are reports<sup>38</sup> suggesting that disease processes such as sepsis impair red cell deformability. In conjunction with significant systemic microcirculatory dysfunction, the decrease in red cell deformability may dramatically affect tissue oxygen delivery in sepsis and septic shock.<sup>38</sup> This body of evidence suggests that RBC transfusions increase systemic oxygen delivery but may have adverse effects on microcirculatory flow.

### Interaction between Pathophysiologic Processes and Anemia

Several disease processes affecting either the entire body or specific organs potentially limit adaptive responses and make patients more vulnerable to the effects of anemia. Specifically, heart, lung, and cerebrovascular diseases have been proposed to increase the risk of adverse consequences of anemia. Age, severity

of illness, and therapeutic interventions also may affect adaptive mechanisms.

The heart, specifically the left ventricle, is particularly prone to adverse consequences of anemia. This is because the myocardium consumes 60% to 75% (extraction ratio) of all oxygen delivered by the coronary circulation.<sup>28,31,39</sup> Such a high extraction ratio is unique to the coronary circulation. As a result, oxygen delivery to the myocardium can increase substantially only with an increase in blood flow.<sup>40</sup> In addition, most left ventricular perfusion is restricted to the diastolic period, because pressures inside the left ventricle are too high to allow adequate coronary blood flow during systole. Thus, any shortening of its duration (eg, tachycardia) decreases blood flow. Laboratory studies have been performed to investigate the effects of normovolemic anemia on the coronary circulation.<sup>29,39,41</sup> There appear to be minimal consequences of anemia with hemoglobin levels in the range of 7 g/dL if the coronary circulation is normal.<sup>19,24</sup> However, myocardial dysfunction and ischemia either occur earlier or are greater in anemic animal models with moderate to high-grade coronary stenosis compared with controls with normal hemoglobin values.<sup>42</sup>

Data from studies with human subjects are inconsistent. Several clinical studies involving patients with coronary artery disease undergoing normovolemic hemodilution have not shown any increase in cardiac complications or silent ischemia during electrocardiographic monitoring.<sup>43</sup> In addition, a retrospective analysis involving 224 patients undergoing CABG surgery did not show a significant association between hemoglobin level and coronary sinus lactate level (an indicator of myocardial ischemia).<sup>44</sup> However, in two recent cohort studies, moderate anemia was poorly tolerated by perioperative<sup>45</sup> and critically ill patients<sup>46</sup> with cardiovascular disease. Thus, retrospective studies seem to support preclinical reports. It is also plausible that anemia results in considerable increases in morbidity and mortality among patients with other cardiac diseases, including heart failure and valvular heart disease, presumably because of the greater burden of the adaptive increase in cardiac output.

During normovolemic anemia, cerebral blood flow increases as hemoglobin values decrease. Investigators have observed increases ranging from 50% to 500% of baseline value in laboratory studies<sup>47</sup> and in one study with human subjects.<sup>48</sup> Cerebral blood flow increases because of overall increases in cardiac output, which is preferentially diverted to the cerebral circulation. As oxygen delivery begins to decrease, cerebral tissues are able to increase the amount of oxygen extracted from blood. A number of factors, including degree of hemodilution, type of fluid used for volume expansion, volume status (preload), and extent of cerebrovascular disease, are capable of potentially modifying global or regional cerebral blood flow during anemia.<sup>49</sup> The increase in global cerebral blood flow combined with the potential for improved flow characteristics across areas of vascular stenosis (improved rheologic properties of blood because of decreased viscosity) prompted a number of laboratory and clinical<sup>49-52</sup> studies to investigate hemodilution as therapy for acute ischemic stroke.<sup>50-52</sup>

The results of laboratory studies suggest that moderate degrees of anemia alone should rarely result in or worsen cerebral ischemia. None of the randomized clinical trials demonstrated that hemodilution in acute ischemic stroke improved clinical outcomes in patients. Because of the variety of variables that affect clinical outcomes, the negative findings may not fully rule out the possibility that hemodilution offers therapeutic benefit. Thus, the currently available evidence indicates that cerebrovascular disease does not appear to predispose patients to serious morbidity from anemia.

Changes in oxygen delivery to the brain during normovolemic anemia (either increases or decreases in blood flow) do not uniformly affect various cerebral pathologic conditions. For example, patients with high intracranial pressure from traumatic brain injury may be adversely affected by increased cerebral blood flow. However, after subarachnoid hemorrhage, mild degrees of normovolemic or hypervolemic anemia may improve overall oxygen delivery, possibly by overcoming the effects of cerebral vasospasm and thereby improving cerebral blood flow through decreased viscosity.<sup>53</sup> However, the effects of moderate to severe anemia in subarachnoid hemorrhage have not been assessed in laboratory or clinical studies.

One of the major consequences of redistributing some of the available cardiac output toward the coronary and cerebral circulation during normovolemic anemia is the shunting of flow away from other organs, including the kidneys and intestines. Critically ill patients may be adversely affected by this redistribution,<sup>54</sup> which could result in increased intestinal ischemia, bacterial translocation, and multiple-system organ failure.<sup>55</sup> Critical illness also can tax many of the body's adaptive responses. Specifically, cardiac performance may be impaired<sup>56</sup> or may already be at maximal capacity in response to increased metabolic demands. Pathologic processes affecting the microcirculation, particularly prevalent among critically ill patients, also may affect the patient's response to anemia and transfusions.

## Clinical Outcomes of Anemia and Red Cell Transfusion

Every medical decision must weigh risk vs benefit. The decision to administer RBC units must consider the risks of blood transfusion (see Chapters 44 through 56), the risk of anemia, and the level of anemia at which blood transfusion prevents the associated adverse outcomes.

### Risk of Anemia

#### Preclinical Laboratory Studies

The critical hemoglobin threshold is similar in different animals.<sup>1</sup> Results of studies suggest that healthy animals can tolerate hemoglobin levels between 3 and 5 g/dL after normovolemic hemodilution. Electrocardiographic changes consistent with ischemia occur at hemoglobin levels less than 5 g/dL, whereas

lactate production, depressed ventricular function, and death have occurred at hemoglobin levels of 3 g/dL or less. Some animals survive with hemoglobin levels as low as 1 to 2 g/dL.<sup>57</sup> However, results of studies with animals suggest a decreased ability to tolerate anemia in the presence of cardiac disease. In dogs with experimentally induced coronary stenosis varying from 50% to 80%, ST-segment changes or locally depressed cardiac function occurred at hemoglobin levels in the range of 7 to 10 g/dL.<sup>58,59</sup>

#### Human Studies

Studies involving patients who refuse blood transfusion for religious reasons provide critical insight into the effect of anemia on humans. The largest study was performed with 1958 adult surgical patients who refused transfusion for religious reasons.<sup>45</sup> The mortality was greatest among patients with the lowest preoperative hemoglobin concentrations. Among patients with underlying cardiovascular disease, the risk of death was markedly greater than for patients without cardiovascular disease, especially in those patients with a hemoglobin concentration less than 10 g/dL. Among patients without underlying cardiovascular disease, the difference in mortality at hemoglobin levels greater than or less than 10 g/dL was not as great (Fig 9-4). None of the 99 patients with hemoglobin concentrations between 7 and 8 g/dL died.<sup>60</sup> However, the risk of death rose sharply below a hemoglobin concentration of 5 g/dL. These results, as well as data on animals and physiologic data, suggest that anemia is not tolerated as well in the presence of cardiovascular disease.

In a series of studies, the effect of anemia was evaluated among healthy volunteers who underwent isovolemic reduction of hemoglobin level to 5 g/dL. Transient and asymptomatic electrocardiographic changes were found in five of the 87 volunteers

**Figure 9-4.** Association between preoperative hemoglobin level and mortality among patients with and without cardiovascular disease.<sup>45</sup> In a population of patients who refused blood transfusion, the risk of death was higher among patients with cardiovascular disease (top line) than among patients without cardiovascular disease (bottom line) for each preoperative hemoglobin level. (Used with permission from Carson et al.<sup>45</sup>)

included in two studies.<sup>61,62</sup> These changes occurred when the hemoglobin level was between 5 and 7 g/dL and in patients with faster heart rates.<sup>62</sup> Changes in critical oxygen delivery were not measured. Subtle but reversible changes in cognition were identified in nine volunteers younger than 35 years at a hemoglobin level between 5 and 7 g/dL.<sup>63</sup> Self-rated fatigue was found in eight volunteers when the hemoglobin level decreased to 7 g/dL. Fatigue increased as hemoglobin levels decreased to 5 g/dL.<sup>64</sup> The results of these studies suggest that important clinical effects can be detected in young, healthy humans with hemoglobin levels between 5 and 7 g/dL.

It is uncertain how these results apply to older patients with comorbid factors who are also under stress from surgery or acute illness. An analysis of 31,000 patients 65 years of age or older undergoing major noncardiac surgery examined the association between preoperative hematocrit and mortality or cardiac morbidity (cardiac arrest or Q-wave myocardial infarction).<sup>65</sup> Mortality rose monotonically when the hematocrit was less than 36%. Cardiac events were more frequent when the hematocrit was less than 39%. These results, in contrast to experimental data, suggest that mild anemia is associated with increased mortality and morbidity. However, anemia may be only a marker of underlying disease and studies are needed to demonstrate improved outcome if anemia is corrected by transfusion.

## Efficacy of Transfusion

### Observational Studies

Selected observational studies of the effect of RBC transfusion on clinical outcomes are described in Table 9-2. The results vary, although only one study has demonstrated a beneficial effect of RBC transfusion. The validity of these studies is uncertain because the decision to transfuse often correlates with the illness burden of the patient. It is likely that comorbidity was not adequately adjusted for in these studies. For example, there are many observational studies demonstrating that blood transfusion increases risk of bacterial infection,<sup>76</sup> yet none of the randomized clinical trials have confirmed this finding. Only randomized clinical trials can overcome this limitation.

### Clinical Trials in Adults

Ten randomized clinical trials contrasted the effects of different transfusion thresholds (Table 9-3).<sup>77-86</sup> The clinical settings varied, although each trial randomly assigned patients to transfusion on the basis of a restrictive or a liberal strategy. Restrictive triggers (specified hemoglobin concentrations that had to be attained) ranged from 7 to 9 g/dL.

Two trials specified a hematocrit of 25% or 30% for RBC transfusion. The liberal transfusion strategies specified the following triggers: 100% of normal red cell volume, two RBC units (immediately in one trial, postoperatively in another) irrespective of clinical state, and transfusion sufficient to maintain hemoglobin level at or above 10 g/dL in three trials and above 9 g/dL in another. Two trials specified the liberal triggers as transfusion to maintain hematocrit at 32% and 40% or greater. There is

overlap between the liberal and restrictive transfusion groups in these trials. One trial involving patients in the intensive care unit (ICU) contributed 47% of the patients and 82% of the recorded deaths. There were a total of 1780 trial participants.

Of the 10 trials, only three included more than 100 patients, and only one of these evaluated a transfusion strategy that included assessment for symptoms. In one of these trials, 428 patients undergoing first-time, elective CABG surgery were randomly assigned to study arms with transfusion triggers of 9 g/dL vs 8 g/dL.<sup>85</sup> The differences between perioperative hemoglobin levels were small, and the mean reduction in hemoglobin level during the admission was equal between the groups. The event rates were very low, and there were no differences in any outcome. The second trial included 127 patients undergoing knee arthroplasty. Patients were randomly assigned to receive autologous blood transfusion immediately after the operation (first unit in recovery room and second unit on return to the ward) vs autologous blood only if the hemoglobin level decreased to less than 9 g/dL.<sup>86</sup> The mean postoperative hemoglobin level was approximately 0.7 g/dL different, although only 25% of the restrictive group received a transfusion. There were no differences in outcome. In a third trial (pilot study), 84 patients with hip fracture undergoing surgical repair were randomly assigned to groups receiving either transfusion at a 10 g/dL threshold or transfusion for symptoms (transfusion was also allowed if hemoglobin level was less than 8 g/dL).<sup>83</sup> The mean hemoglobin level before randomization was 9.1 g/dL. The lowest mean hemoglobin level after randomization in the group with symptoms was 8.8 g/dL, and the highest mean hemoglobin level in the threshold group was 11.1 g/dL. There were no differences in outcomes (including functional recovery, mortality, and morbidity), although 60 days after the operation, five patients in the symptomatic group had died, as had two patients in the 10 g/dL group. In all of these trials (and the other trials in Table 9-3), the numbers of patients were much too small to evaluate the effect of lower transfusion triggers on clinically important outcomes such as mortality, morbidity, and functional recovery.

The Transfusion Requirements in Critical Care (TRICC) trial<sup>81,84</sup> is the only adequately powered study to evaluate clinically important outcome. In the main study, the investigators randomly assigned 838 volume-resuscitated ICU patients to a restrictive strategy in which patients received allogeneic RBC transfusions at hemoglobin levels of 7 g/dL (and were maintained between 7 to 9 g/dL) or to a liberal strategy of receiving RBCs at 10 g/dL (and were maintained between 10 and 12 g/dL). Average hemoglobin levels (8.5 vs 10.7 g/dL) and RBC units transfused (2.6 vs 5.6 units) were significantly lower in the restrictive as opposed to the liberal group. The 30-day mortality was slightly lower in the restrictive transfusion group (18.7% vs 23.3%), although the finding was not statistically significant ( $p = 0.11$ ). Mortality was lower in the restrictive transfusion group in patients less than 55 years of age ( $p < 0.02$ ) and less ill patients defined by APACHE II scores less than 20 ( $p < 0.02$ ). Furthermore, the restrictive transfusion group had fewer patients

**Table 9-2.** Summary of Nonrandomized Studies

| Study                               | Clinical Setting                   | Subjects                                                                                                                                                                                                                                                                               | Outcomes                                                                                                                                                                                                                                                                         |

**Figure 9-5.** Effect of restrictive transfusion triggers on 30-day all-cause mortality. Summary of data from randomized clinical trials comparing effect of restrictive vs liberal transfusion strategies on mortality (expressed as relative risks). (Used with permission from Carson et al.<sup>87</sup>)

with myocardial infarction (0.07% vs 2.9%;  $p = 0.02$ ) and congestive heart failure (5.3% vs 10.7%;  $p < 0.01$ ).

A meta-analysis combined data from five or more trials for six outcomes: probability of RBC unit transfusion, volume of red cells transfused, hematocrit, cardiac events, mortality at 30 days, and overall length of hospital stay.<sup>87</sup> The pooled data indicated that on average, a restrictive transfusion trigger reduced the probability of RBC transfusion by a proportional 42% (an average saving of 0.93 RBC unit per transfused patient) and resulted in a hematocrit 5.6% lower on average than in patients who received more liberal transfusions. The effects on length of hospital stay and the rate of cardiac events were not increased significantly by the use of restrictive transfusion triggers. Restrictive transfusion triggers were not associated with an increase in mortality (Fig 9-5). The TRICC trial<sup>84</sup> involving ICU patients contributed 83% of the information on mortality data in the meta-analysis.

Functional recovery is another potentially important benefit of higher hematocrit. Only one small pilot study evaluated the effect of RBC unit transfusion on the functional ability of patients with anemia.<sup>73</sup> The number of subjects was too small to detect clinically important differences. The results from the FOCUS trial, which will evaluate functional recovery in up to 2000 hip fracture patients with cardiovascular disease or cardiovascular risk factors, should be available in 2009.<sup>88</sup> Most of the other published data relating anemia to function were generated from clinical trials performed to evaluate the use of recombinant human erythropoietin in end-stage renal failure and patients undergoing cancer chemotherapy. These limited data suggest that increasing the hemoglobin level of patients with marked anemia (hemoglobin,  $<10$  g/dL) increases exercise tolerance.<sup>89</sup> The studies with negative findings<sup>90</sup> evaluated the effect of increasing hemoglobin level beyond the 10 g/dL threshold. A

review of the use of erythropoietin in the care of patients with cancer-related anemia<sup>90</sup> concluded that patients receiving erythropoietin had increased levels of energy and function. Two recent clinical trials compared use of erythropoietin to achieve a high hemoglobin concentration (13-15 g/dL) vs a lower hemoglobin concentration (10.5-11.5 g/dL) in patients with chronic renal insufficiency.<sup>91,92</sup> Only one study found improvement in function and quality of life measures.<sup>92</sup> The United States Food and Drug Administration has concluded that there is insufficient evidence to conclude that erythropoietin-stimulating agents alleviate fatigue or increase energy.

### Clinical Trials in Children

Blood is frequently transfused in critically ill infants and children. In a recent survey, 14% of patients in pediatric ICUs received blood transfusion.<sup>93</sup> There have been three clinical trials evaluating liberal vs restrictive transfusion thresholds in this population (see Table 9-4). One hundred hospitalized preterm infants with birthweights between 500 to 1300 g were randomly assigned to two transfusion levels.<sup>94</sup> The transfusion protocol adjusted the hematocrit level that led to transfusion depending on the respiratory status of the infant. A primary outcome was not designated among the 15 clinical events evaluated. Infants in the restrictive group received a median of 2 units less than the liberal group during the study and the mean difference in hemoglobin concentration was  $\sim 2$  g/dL. There were no differences between the liberal and restrictive transfusion groups for most outcomes including survival, patent ductus arteriosus, retinopathy, or bronchopulmonary dysplasia. Infants assigned to the restrictive group had more apneic events and more neurologic events (combined parenchymal brain hemorrhage or periventricular leukomalacia). These differences in outcomes should be interpreted as

hypothesis-generating because the composite neurologic outcomes were not designated *a priori*,<sup>97</sup> apnea was assessed by an unblinded nurse<sup>97</sup> and the differences were small, and the large number of outcomes increase the risk of false-positive results.

In the second study, 451 infants weighing less than 1000 g, whose gestational age was less than 31 weeks, and who were less than 48 hours old were randomly assigned to receive transfusion at either a low or high transfusion threshold.<sup>95</sup> The thresholds used varied by respiratory support using a prespecified transfusion algorithm. The primary composite outcome was in-hospital death, severe retinopathy, bronchopulmonary dysplasia, or brain injury on cranial ultrasound. The mean hemoglobin concentration was ~1 g/dL different between groups and the number of RBC transfusions were not significantly different. There was no difference in the composite outcomes (low threshold, 74.0% vs high threshold, 69.7%). This trial did not confirm the hypothesis that restrictive transfusion is associated with brain injury in preterm infants.

The largest study involved 637 children admitted to pediatric ICUs.<sup>96</sup> When a 7-g/dL threshold was compared to a 9.5-g/dL threshold, the mean hemoglobin concentration was ~2 g/dL lower in the restrictive group. RBC units were transfused to 46% of patients in the restrictive group and 98% in the liberal group. The frequency of new or progressive multi-organ dysfunction (primary outcome) was 12% in both groups and there were no significant differences in any of the secondary outcomes including death, which occurred in 4% of both groups.

## Transfusion Guidelines

Since the National Institutes of Health Consensus Conference developed landmark guidelines for transfusion of blood components, many organizations have issued guidelines with the intent of aiding clinical decisions. The administration of RBCs is based on the balance of benefits, risks, and costs. Physicians making transfusion decisions are faced with massive amounts of sometimes conflicting information. Since 1983, concerns about the transmission of human immunodeficiency virus and other viruses through blood components have significantly modified both real and perceived risks and benefits. Many organizations responded by issuing clinical practice guidelines advocating a more restrictive approach to the use of allogeneic RBC units and other components.<sup>87</sup>

Recommendations varied among the guidelines. Only one set of guidelines recommended a transfusion trigger; six advocated a range of transfusion thresholds based on clinical judgment, one recommended using clinical judgment only, and five did not comment on either clinical judgment or a transfusion trigger. Because of the paucity of clinical trials, the guidelines relied heavily on expert opinion, which sometimes (particularly more recently) valued the risks of virus transmission through blood components above all other consequences of the transfusion decision.

The recently updated guidelines developed by the American Society of Anesthesiology are by far the most rigorously

developed and methodologically sound.<sup>98,99</sup> As with several other guidelines, the American Society of Anesthesiology task force advised against a transfusion trigger, although it did suggest transfusion is usually indicated if hemoglobin concentration is less than 6 g/dL and is usually unnecessary if the hemoglobin concentration is greater than 10 g/dL. In patients with hemoglobin concentrations between 6 and 10 g/dL, transfusion decisions should be guided by the patient's risk of or actual bleeding, volume status, cardiopulmonary reserve, and vulnerability to complications of inadequate oxygenation. A recently published guideline for perioperative blood transfusion and blood conservation in cardiac surgery emphasized combined use of multiple factors, including interventions to reduce blood loss and institution-specific blood transfusion algorithms.<sup>100</sup>

## Decision Making in Red Cell Transfusion

### Approach to Evaluating a Bleeding Patient

In the care of a bleeding patient, the physician must first determine the degree of blood loss and rate of bleeding. As part of the initial assessment, the health-care team must rapidly address the patient's "ABCs" (airway, breathing, circulation). Although blood loss usually leads to circulatory compromise, the severe form, termed hemorrhagic shock, often leads to airway and breathing concerns. Once airway and breathing have been assessed and cleared, assessment of the heart rate and blood pressure—in addition to a rapid scan of the scene and the patient—will reveal obvious threats such as dramatic blood loss. During the initial assessment, patients must be completely uncovered and rapidly examined to rule out rapidly bleeding wounds, obvious signs of massive bleeding such as a rapidly expanding abdomen in patients with a ruptured abdominal aortic aneurysm, or severe hematochezia in patients with severe lower gastrointestinal bleeding. The focus is on possible causes of bleeding and important comorbid conditions, such as cardiovascular disease that could exacerbate any injury. An emergency complete blood cell count, type and crossmatch, prothrombin time, and partial thromboplastin time should be obtained. From these data and the clinical examination, the source and rate of bleeding are estimated. A decision can be made about the rate of RBC unit transfusion as well as any curative and supportive measures. For patients with gastrointestinal bleeding, consultations may be requested from the gastroenterology and possibly surgery departments. In the care of patients with postoperative bleeding, measures such as angiography or exploratory surgery should be considered.

In patients with active bleeding, the hemodynamic status and need for emergency intervention must be determined. Crystalloid is administered to maintain intravascular volume. Red cell transfusions are administered rapidly to maintain adequate oxygen-carrying capacity. Clinical judgment is needed to 1) estimate how much more bleeding may occur and how much lower the hemoglobin level will decrease, and then 2) perform expectant transfusion. Vital signs are examined for a decrease

in blood pressure and for tachycardia. The patient is asked about symptoms that can result from anemia, including cardiac ischemia (chest pain), congestive heart failure (dyspnea, paroxysmal nocturnal dyspnea, edema), fatigue, dizziness, weakness, and orthostatic hypotension unresponsive to intravenous fluids. The hemoglobin level is measured at regular intervals.

It is important to determine the presence of coronary artery disease because results of studies with animals and with human subjects suggest that patients with coronary artery disease are less tolerant of anemia. Review of the medical history for angina, myocardial infarction, and CABG surgery is essential. The electrocardiogram is examined for evidence of old myocardial infarction or ischemic changes. The chest radiograph is examined for cardiomegaly and other changes consistent with congestive heart failure. Patients with a history of peripheral or cerebral vascular disease are more likely also to have asymptomatic coronary artery disease.

In the care of patients with moderate to severe blood loss that has abated, there is more time for complete assessment of the source of bleeding, development of a course of management, and thorough evaluation of the patient. After bleeding has stopped and equilibration has occurred, the hemoglobin level stabilizes and the nadir hemoglobin level can be determined.

### **Surgical Patient**

Patients undergoing major surgical intervention often experience hemodynamic instability and frequently require RBC unit transfusion as a consequence of considerable blood loss. Various aspects of transfusion management for surgical patients are discussed in Chapters 37 through 40. One of the goals of resuscitation is to maintain oxygen delivery well beyond the anaerobic threshold. Hemoglobin concentration should be maintained above a value that maintains adequate  $\text{DO}_2$  and minimizes exposure to allogeneic RBC transfusion. However, optimal intraoperative thresholds have not been established. Current methods of monitoring effective circulatory blood volume and utilization of oxygen at the tissue level have limitations. Therefore, maintenance of adequate hemoglobin level has been recommended.<sup>98</sup> Frequent measurement can assist the anesthesiologist in administering one RBC unit at a time when blood loss is predictable. Blood loss exceeding 20% of blood volume in a short time may necessitate transfusion of multiple RBC units as well as administration of plasma and platelets. Reliable intraoperative measurements can be performed easily at the point of care with hemoglobin measurements obtained with standard blood gas analyzers. However, the accuracy of this measurement is influenced by the amount of intravenous fluid administered by the anesthesiologist and the fact that insufficient time has passed for equilibration to occur. Therefore, expert clinical judgment is required.

Standard anesthetic practice mandates intraoperative monitoring of cardiac function with measurement of continuous electrocardiographic and noninvasive or invasive blood pressure monitoring. Both monitoring techniques are essential but are insensitive to significant blood loss. This can delay recognition

of significant anemia until late in the process. However, optimal intraoperative thresholds have not been established and there are limitations to the current methods of monitoring effective circulatory blood volume and utilization of oxygen at the tissue level. A patient can have profound anemia without appreciable changes in either measurement. More sophisticated and invasive monitoring of cardiac function includes measurement of right- and left-sided ventricular filling pressure by means of central venous pressure and pulmonary artery catheters. Both techniques provide estimates of the effective circulating blood volume and are frequently used in high-risk surgery and in ICUs. Repeated measurement of central pressure and fluid challenges provide much more reliable assessment of effective circulating blood volume than does an isolated single measurement. Continuous monitoring of cardiac output with either pulmonary arterial catheters or esophageal Doppler techniques can be performed in many centers. Most of these techniques are reliable and frequently are used intraoperatively and during critical illness.<sup>101</sup> However, current monitoring techniques have a number of major limitations in guiding transfusion requirements. Careful clinical observation in conjunction with the physiologic data provide many of the necessary tools in the diagnosis and detection of clinically important anemia. The more difficult task is knowing how best to administer RBC units, intravenous solutions such as colloids and crystalloids, and vasoactive drugs.

Few data exist on whether invasive monitoring and different treatment strategies cause more harm than good. Most experienced anesthesiologists and critical care physicians have developed an approach to management of blood loss and hemodynamic instability. There is still enormous practice variation in selecting specific therapies. Randomized clinical trials are needed to assist in clinical decision making.

### **Chronic Anemia**

In chronic anemia, there is time for compensation to develop and for careful observation of the patient. Anemia is associated with an increase in blood flow resulting from decreased viscosity, greater release of oxygen caused by higher levels of 2,3-DPG, and an increase in cardiac output. There is time to determine whether these physiologic events are clinically important in the individual patient and carefully determine whether the patient has symptoms. Besides cardiac symptoms (angina, dyspnea), anemia can lead to nonspecific symptoms, such as fatigue, weakness, dizziness, reduced exercise tolerance, and impaired performance of activities of daily living. There also may be time to implement alternative treatments to correct anemia, depending on the cause. Iron, vitamin  $\text{B}_{12}$ , and folate can be replaced. Erythropoietin can be administered. It is important to correct preoperative anemia because the hemoglobin level strongly correlates with the probability of transfusion.<sup>102</sup>

### **Transfusion Threshold**

The optimal threshold for transfusion is uncertain in most clinical situations. The only adequately powered randomized clinical

trial showed it is safe to withhold blood until the hemoglobin level decreases to less than 7 g/dL.<sup>84</sup> The study was performed in critically ill patients and should be used to guide therapy in this setting. However, these patients are unique in that they are extremely ill, monitored very closely, and usually bedridden. It is uncertain whether the results should be applied to other clinical situations, such as care of postoperative surgical patients. There are no other randomized trials large enough to adequately guide clinical decision making in settings other than ICUs. Clinically important outcomes such as functional recovery have not been the subject of large-scale studies. In addition, different transfusion thresholds have not been adequately examined in high-risk patients with acute coronary syndromes or in patients with other forms of severe heart disease.

In the absence of evidence, it is necessary to rely on clinical judgment. In the authors' view, in patients who are symptom-free or who do not have active ischemic heart disease, a transfusion trigger of 7 g/dL should be used. For patients with an acute coronary syndrome, perhaps a higher transfusion threshold should be used (~8-10 g/dL). Patients with symptoms of anemia should be transfused as needed. No set of guidelines applies to every patient. In the end, careful clinical assessment of each patient with thoughtful consideration of risks and benefits should guide the transfusion decision.

### Dose and Administration

In patients who experience acute blood loss, the rate of administration of RBCs is guided by the rate of bleeding and hemodynamic compromise. In the treatment of rapidly bleeding patients, RBCs should be given at the rate necessary to maintain oxygen transport while definitive therapy is instituted. Rates may range from 5 to 10 units over 10 to 15 minutes in patients who are exsanguinating to rates in the range of 1 unit every 2 to 4 hours (1 mL/kg/hour) in patients with severe left ventricular dysfunction. When blood loss is predictable and not massive, RBC units should generally be administered one at a time. In the care of patients with chronic anemia, enough blood should be given to control symptoms. In most adult patients, 1 RBC unit increases the hemoglobin level approximately 1 g/dL and hematocrit approximately 3%. Ordinarily, 1 RBC unit is given over 1 to 2 hours. After transfusion of each RBC unit, measurement of hemoglobin level is repeated, and the patient reassessed.

### Future

During the next decade, advances and risks may dramatically alter transfusion practice. Research is under way to develop safe red cell components. Further clinical trials should be performed to better describe the clinical effect of different transfusion strategies. It is possible that within the next one or two decades, a cost-effective oxygen carrier will be developed that will reduce the use of allogeneic RBC units.

## Summary

Red cell transfusion is an extremely common treatment throughout the world. Blood is administered to improve oxygen delivery. Patients compensate for anemia through increased cardiac output and through redistribution of blood flow to the cardiac and cerebral circulation. Particular attention must be paid to maintaining adequate oxygen delivery to the heart. Results of the one adequately powered clinical trial, performed with ICU patients, suggest that a hemoglobin level of 7 g/dL is a safe threshold for red cell transfusion. For patients with cardiovascular disease, a higher transfusion threshold should be considered. RBC units should usually be administered one at a time, and the patient and hemoglobin level reassessed after each transfusion. Transfusion decisions should consider the rate of bleeding, the presence of underlying medical problems, the hemodynamic status of the patient, the presence of symptoms, and whether anemia is acute or chronic.

## Platelet Production, Kinetics, and Hemostasis

**Henry M. Rinder<sup>1</sup> & Aaron Tomer<sup>2</sup>**<sup>1</sup> Associate Professor of Laboratory Medicine and Internal Medicine (Hematology), Yale University School of Medicine, and Director, Hematology Laboratories, Yale-New Haven Hospital, New Haven, Connecticut, USA<sup>2</sup> Professor of Medicine, Faculty of Health Sciences, Ben-Gurion University of the Negev, and Director, Blood Bank and Transfusion Medicine, Soroka University Medical Center, Beer-Sheva, Israel

Megakaryocytopoiesis begins with the lineage commitment of hematopoietic stem cells (HSCs), and includes the proliferation, maturation, and terminal differentiation of megakaryocytic progenitors. Circulating levels of thrombopoietin (TPO), the primary growth factor for the megakaryocyte (MK) lineage, induce concentration-dependent proliferation and maturation of MK progenitors by binding to the c-Mpl receptor. Decreased platelet numbers result in increased free TPO levels, enabling the compensatory response of marrow MKs to increase platelet production. C-Mpl activity is orchestrated by a complex cascade of signaling molecules that drive MK proliferation and maturation. Mature MKs form proplatelet projections that fragment into circulating platelets. Newly developed thrombopoietic agents operating via the c-Mpl receptor have proven useful in clinical thrombocytopenia trials. This chapter reviews the regulation of megakaryocytopoiesis and platelet production in normal and disease states, and discusses new approaches to thrombopoietic therapy.

**Platelet Production****Megakaryocyte Development**

Megakaryocytes give rise to circulating platelets through commitment of the multipotent stem cell to the MK lineage, proliferation of those progenitors, and finally terminal differentiation of MKs. This process is characterized by DNA endoreduplication, cytoplasmic maturation and expansion, and release of cytoplasmic fragments as circulating platelets. Within the marrow, MKs are derived from HSCs, which evolve from the multipotential hemangioblast. The hemangioblast gives rise to all blood and blood vessel precursor cells. The HSCs, which give rise to the early common myeloid progenitors (CMPs), includes the multilineage (granulocyte, erythrocyte, MK, and monocyte)

colony-forming unit (CFU-GEMM). Erythroid and MK lineages arise from a common MK-erythroid progenitor (MEP) derived from the early CMP. CMP differentiation is orchestrated by molecular signals controlled by regulatory transcription factors. Two major transcription factors involved in CMP differentiation are GATA-1, which drives differentiation of MEP, and PU.1, which regulates granulocyte-monocyte precursors.<sup>1</sup> The down-regulation of PU.1 expression in the CMP is the first event associated with the restriction of differentiation to erythroid and MK lineages.<sup>2</sup> In response to environmental factors, cytokines, and chemokines, the bipotential MEP can develop into the highly proliferative, early MK burst-forming unit (BFU-MK), or the more mature smaller CFU-MK, both of which express CD34.<sup>3</sup> The proliferating diploid MK progenitors (megakaryoblasts) lose their capacity to divide, but retain their ability for DNA replication (endoreduplication) and cytoplasmic maturation.

**Megakaryocyte Maturation**

The hallmarks of MK maturation are endoreduplication (polyploidization) and expansion of cytoplasmic mass. Mature MKs give rise to circulating platelets by the acquisition of cytoplasmic structural and functional characteristics necessary for platelet formation and function.<sup>4,5</sup> MKs reach cell sizes of 50 to 100 microns in diameter, with ploidy ranges up to 128N.<sup>6,7</sup> Early megakaryoblasts have the highest nuclear/cytoplasmic ratio. These immature cells contain elevated RNA levels, prominent ribosomes, and rough endoplasmic reticulum; they also express platelet peroxidase, and contain  $\alpha$ -granules, dense bodies, and primitive demarcation membranes. As the MK matures, the polyploid nucleus becomes horseshoe-shaped, the cytoplasm expands, and platelet organelles and the demarcation membrane system are amplified.<sup>8</sup> This robust cytoplasmic mass forms proplatelet projections that give rise to newly circulating (reticulated) platelets.<sup>9</sup> While the large polyploid MKs are easily identified by morphology, the small MK progenitor and immature MK are more difficult to discern. Their identification is facilitated with the use of antibodies to major platelet membrane glycoproteins (GPs) including the integrin  $\alpha_{IIb}\beta_3$  (CD41a or GPIIb/IIIa complex), CD41b (GPIIb),

**Figure 10-1.** Ploidy distribution of normal human megakaryocytes (MKs) in unfractionated marrow using flow cytometry. (A) The distribution of marrow cells according to membrane-GPIIb/IIIa immunofluorescence and DNA content. Cells with background fluorescence represent the major marrow cell population with ploidy classes of 2N and 4N (bottom). The highly fluorescent cells represent the MK population with polyloid subclasses (top). (B) The DNA histogram of the MK population. The modal ploidy is 16N comprising about half of the MK population with approximately equal proportions of cells being  $\leq 8N$  and  $\geq 32N$ .

CD61 (GPIIIa), CD42a (GPIX), CD42b (GPIb), and CD51 (GPV), as well as to internal platelet  $\alpha$ -granule proteins, von Willebrand factor (vWF), platelet factor 4 (PF4),  $\beta$ -thromboglobulin ( $\beta$ -TG), fibrinogen, coagulation Factor VIII, and Factor V.<sup>10</sup> Immature 2N to 4N cells produce platelet peroxidase but have no detectable demarcation membrane or platelet  $\alpha$ -granules.<sup>8</sup> CD41 antibodies enable the detection of small “lymphoid” megakaryoblasts in marrow, as well as in CFU-MK by Day 4 or 5 of culture.<sup>11</sup>

Flow cytometry has been adapted to the direct analysis of human MKs in routine marrow aspirates.<sup>7,12</sup> Fluorescence-activated cell sorting has enabled the separation of pure ( $>98\%$ ) viable MK populations isolated on the basis of lineage markers. These cells respond to hematopoietic growth factors and synthesize both protein and DNA.<sup>6</sup> Moreover, flow cytometry has enabled the study of megakaryocytopoiesis in disease states, monitoring drug effects on human megakaryocytopoiesis, and studying the effect of hematopoietic growth factors on megakaryocytopoiesis in humans and primates.<sup>13–15</sup> Recent flow-cytometric studies have demonstrated that vWF is strongly expressed by early (2–4N) marrow MKs, enabling their complete resolution from other marrow cells at a level superior to that achieved with GPIIb/IIIa as a lineage-specific marker.<sup>10</sup>

Early MK differentiation is accompanied by the expression of GPIX, which exists as a complex with GPIb and GPV in the platelet membrane. In contrast, platelet GPIV and the thrombospondin (TSP) receptor (CD36) appear as late differentiation markers.<sup>16</sup> Following activation, platelet GPIIb/IIIa functions as a receptor for four adhesive proteins—fibrinogen, fibronectin, vitronectin, and vWF; however, GPIb is the major receptor for vWF,<sup>10</sup> as discussed later in this chapter.

The nuclear endomitotic cell cycle in MKs consists of a DNA replication S-phase, an M-phase with multiple pole spindles,

aborted anaphase B and cytokinesis, and a Gap-phase that enables reentry into the subsequent S-phase. Cyclin D3 is overexpressed in the G1-phase of maturing cells and is a key inducer of MK polyploidization.<sup>17</sup> Aurora-B/AIM-1, the fundamental regulator of mitosis, has normal localization and expression during prophase and early anaphase, but is absent or mislocalized in late anaphase MKs.<sup>18,19</sup> Chromosome segregation is asymmetrical with normal metaphase/anaphase checkpoints.<sup>20</sup> Ploidy classes are identified as geometric progressions of 2N (diploid), ie, 4N, 8N, 16N, etc.

The ploidy distribution obtained by flow cytometry in both fractionated and unfractionated normal human marrow demonstrates 16N in approximately half of the MK population, with the remainder of MKs split: 23% of cells being 8N or lower and 22% being 32N or higher<sup>12</sup> (Fig 10-1). The amount of surface GPIIb/IIIa, GPIIIa, GPIb, and CD36 correlates directly with cell size and ploidy. The mean diameter of MKs is  $37 \pm 4$  microns (mean  $\pm$  1 SD), compared with  $14 \pm 2$  microns for all marrow cells, and ranges from  $21 \pm 4$  microns for 2N cells to  $56 \pm 8$  microns for 64N cells.<sup>10</sup> The MK cytoplasmic mass is calculated as the product of the mean MK cytoplasmic volume and the total number of MKs.<sup>15</sup> By determining the ratio of MKs to nucleated erythroid precursors in marrow preparations by flow cytometry, the MK mass in patients with primary thrombocytosis was assessed.<sup>13,15</sup> Following treatment with anagrelide, both MK number and volume were decreased toward normal, resulting in decreased MK mass by about half, similar to the decrease in platelet count.<sup>15</sup> This finding was recently corroborated by in-vitro anagrelide studies.<sup>21</sup>

### Platelet Production and Release

During MK maturation, internal membrane systems, granules, and organelles are assembled in bulk. High-ploidy MKs form an extensive internal demarcation membrane, which is continuous

with the plasma membrane, and serves primarily as a reservoir for the formation of the precursor of cytoplasmic extensions called proplatelets. The open canalicular system, a channeled system for granule release and the dense tubular network, is formed before the initiation of proplatelet assembly.<sup>4</sup> Some platelet proteins, such as GPIb and GPIIb/IIIa, are synthesized and directed to the MK surface membrane, while other proteins are conveyed into secretory granules. Individual organelles migrate from the cell body to the proplatelet ends, with approximately 30% of the organelles/granules in motion at any given of time.<sup>5</sup> Fibrinogen is not synthesized but instead is taken up by MKs from the plasma through endocytosis and/or pinocytosis and selectively transferred to granules. Quantitative electron microscopic analysis has shown that MKs are located <1 micron from the marrow sinus wall, allowing rapid access of the newly formed platelets to the circulation.<sup>22</sup> Nascent platelets contain mitochondria and ribosomal RNA (the latter identifying them as reticulated platelets), as well as the components necessary for platelet hemostatic function. Platelets, however, do not contain nuclear material.<sup>4</sup>

Currently, there are two physical models of thrombopoiesis, which are not mutually exclusive. One model proposes platelet assembly and budding off the tips of proplatelets, which operate as assembly lines for platelet production.<sup>4</sup> The proplatelets extend into sinusoidal spaces, where they detach and fragment into individual platelets giving rise to about 2000 to 5000 new platelets/cell.<sup>23,24</sup> The other model of platelet biogenesis proposes that, within the MK cytoplasm, there are preformed territories with internal membranes demarcating prepackaged platelets, which are precipitously released upon fragmentation of the cytoplasm. In-vivo and ex-vivo observations of platelet release from MKs with phase contrast microscopy strongly support the explosive-fragmentation theory.<sup>25,26</sup>

### Regulation of Megakaryocytopoiesis

The processes of megakaryocytopoiesis and platelet production occur within a complex marrow microenvironment where chemokines, cytokines, and adhesive interactions play a major role.<sup>27</sup> Mechanisms regulating megakaryocytopoiesis operate at all levels of proliferation, differentiation, and platelet release.<sup>28,29</sup> In addition to steady-state megakaryocytopoiesis, which supplies  $10^{11}$  platelets every day and a new turnover every 7 to 10 days, MKs also respond to changes in requirements for circulating platelets, increasing more than 10-fold under conditions that demand platelet production.<sup>30</sup> Compensatory responses of marrow MKs increase platelet production through an increase in cell proliferation and maturation, and early release of platelets, which is evident within 24 to 48 hours after inducing thrombocytopenia. Following thrombocytapheresis and in thrombocytopenias caused by immune destruction, the marked increase in MK number and size is notable.<sup>7,31</sup> The normal frequency of human MKs in marrow is about one in 2000 nucleated cells. However, with a compensatory response, the number increases 10-fold<sup>32</sup> and the proportion of high-ploidy cells increases as

well.<sup>12</sup> Reciprocal decreases in MK size, ploidy, and volume occur with experimentally induced thrombocytosis.<sup>33,34</sup> These alterations, found in both experimental animals and human subjects, are primarily mediated by TPO.<sup>30</sup>

### Thrombopoietin

Thrombopoietin is the primary physiologic growth factor for the MK lineage. TPO also plays a central role in the survival and proliferation of HSCs.<sup>35,36</sup> TPO is the most potent cytokine for stimulating the proliferation and maturation of MK progenitor cells. It stimulates MKs to increase cell size and ploidy, and to form proplatelet processes that then fragment into single platelets.<sup>30</sup> In baboons, administration of recombinant human (rHu) TPO or a polyethylene glycol (PEG) derivative MK growth-and-development factor (PEG-rHuMGDF) produced a log-linear increase in marrow MK mass of up to 6.5-fold that was associated with a marked increase in cell ploidy. Concordantly, there was an increase in platelet count up to fivefold, reaching peak values after 2 to 4 weeks of TPO therapy (Fig 10-2). Because MK volume and ploidy attained predictable maximum values simultaneously, MK ploidy is an accurate measure of Mpl-ligand stimulation of megakaryocytopoiesis.<sup>13,14</sup> TPO can also act in synergy with other hematopoietic cytokines and has been used effectively to expand human HSCs and MK progenitor cells in vitro.<sup>35,37-39</sup>

TPO directly affects platelets as well; it enhances  $\alpha$ -granule secretion and aggregation induced by thrombin in a phosphoinositide-3 kinase (PI3K)-dependent fashion.<sup>40</sup> TPO also reduces the level of adenosine diphosphate (ADP), collagen, or thrombin necessary for aggregation,<sup>41,42</sup> and it stimulates platelet adhesion.<sup>43</sup> Thus, TPO affects mature platelets in a pro-aggregatory fashion.

Thrombopoietin is encoded by a single human gene, located on chromosome 3q26.3-3q27, which produces a 353-amino-acid precursor protein. The mature molecule, composed of 332 amino acids, is acidic and heavily glycosylated. Mutations (inversion or deletion) at its chromosomal locus are often found in megakaryocytic leukemia and other myeloproliferative disorders (MPDs) associated with thrombocytosis.<sup>44</sup> Mutations in regulatory regions of the TPO gene that result in overexpression of TPO and sustained intracellular signaling or disturbed regulation of circulating TPO cause familial essential thrombocythemia (ET) or familial thrombocytosis.<sup>30,45</sup> TPO shares high homology with erythropoietin (EPO) in its N-terminal half, reflecting a close evolutionary relationship between their receptor signaling pathways. TPO binds to the c-Mpl receptor on MKs and selectively initiates proliferation, maturation, and cytoplasmic delivery of platelets into the circulation.<sup>29,46</sup> TPO is produced constitutively by the liver and its circulating levels are regulated by the extent of binding to c-Mpl receptors on circulating platelets and marrow MKs, which results in the elimination of TPO-c-Mpl complexes.<sup>46,47</sup>

Messenger RNA specific for TPO is also found in the kidney, marrow stroma, and other tissues,<sup>48</sup> but the role of these tissues in megakaryocytopoiesis is unclear. Blood and marrow levels

**Figure 10-2.** (A) Effect of in-vivo administration of megakaryocyte-stimulating factors on marrow megakaryocytes in nonhuman primates: ploidy changes in baboons. Left panel: before treatment. Middle panel: after treatment with recombinant human granulocyte-macrophage colony-stimulating factor (rHu-GM-CSF) or interleukin-6 for 8 days; there is a marked increase in ploidy. Right panel:

after treatment with recombinant human megakaryocyte growth and development factor (rHuMGDF) for 7 days; the increase in ploidy is more prominent than that observed with rHu-GM-CSF. (B) The effect of rHuMGDF on megakaryocyte mass and platelet production in nonhuman primates. A concordant increase in both measurements is evident over 2 to 4 weeks of therapy.

of TPO are usually inversely related to marrow MK mass and peripheral platelet counts.<sup>30</sup> Plasma levels of TPO (normally  $95 \pm 6$  pg/L) are increased by several orders of magnitude in patients with thrombocytopenia secondary to aplastic anemia or myelosuppression, and TPO levels decline after platelet transfusion or recovery of hematopoiesis.<sup>46,49</sup> However, in states of massive platelet destruction, such as immune thrombocytopenic purpura (ITP), TPO levels are not as escalated as might be expected from the degree of thrombocytopenia, probably due to the markedly increased platelet turnover rate.<sup>50</sup> Thus, megakaryocytopoiesis is regulated by plasma levels of unbound TPO, which reflects the balance between constitutive production and the rate of platelet and MK binding that is generally dictated by overall platelet production. Exceptions to steady-state platelet production occur during ET<sup>51,52</sup> or inflammation when circulating TPO levels are increased<sup>46,53,54</sup> because of enhanced hepatic expression driven by the acute phase protein, interleukin-6 (IL-6).<sup>55</sup>

### c-Mpl

The TPO receptor (c-Mpl) is predominantly expressed on heman-gioblasts, MKs at all stages of differentiation, and platelets. While receptor display is modulated by TPO binding and receptor internalization, c-Mpl is usually constitutively expressed. TPO avidly binds and activates the c-Mpl receptors on MK, which undergo conformational changes to initiate signal transduction. The JAK family of kinases constitutively bind to the membrane-proximal cytoplasmic domains of c-Mpl and initiate signaling. The activated JAK kinase also phosphorylates tyrosine residues within the receptor itself, as well as downstream signal transducers and activators of transcription (STATs), PI3K, and the mitogen-activated protein kinases (MAPKs). This cascade drives cell survival and proliferation, requires PI3K activation, and activates SHP1 and SHIP1 phosphatases and suppressors of cytokine signaling to limit cell signaling.<sup>35,36</sup> In humans, elimination of a functional c-Mpl gene (located on chromosome 1p34) or the congenital

absence of c-Mpl in children, results in severe thrombocytopenia caused by decreased hematopoietic stem and lineage-committed progenitor cells.<sup>30</sup> A recent study suggests that c-Mpl does not control HSC numbers, as had been previously argued, but rather facilitates the early expansion of differentiating clones.<sup>57</sup> Multiple mutations, including nonsense, frameshift, splice-site alteration, missense, or amino-acid substitutions, have been identified. These mutations result in a total absence of the c-Mpl receptor or functionally defective TPO-binding and/or signaling,<sup>58,61</sup> such as in congenital amegakaryocytic thrombocytopenia Type I (CAMT-I) in children, which is characterized by persistently low platelet counts  $<20,000/\mu\text{L}$  and progression to marrow failure and pancytopenia.<sup>58,62</sup> Hematopoietic stem cell transplantation (HSCT) is currently the only curative treatment.<sup>63</sup> In CAMT Type II, patients have more gradual development of pancytopenia caused by residual activity of the TPO receptor.<sup>60,64,65</sup>

An activating mutation within the transmembrane domain of c-Mpl has been reported to be associated with familial ET.<sup>66</sup> A c-Mpl polymorphism (Mpl Baltimore), with a single nucleotide substitution unique to individuals of African ethnicity (7% incidence of heterozygosity), is associated with reduced protein expression of Mpl, but a clinical phenotype of thrombocytosis.<sup>67</sup> A similar decrease in c-Mpl receptor on the cell surface is seen in patients with polycythemia vera (PV) and other MPDs. Thrombocytosis may therefore be related to the hypersensitivity to cytokines and signaling abnormalities found in these disorders.<sup>30</sup> Mutations in the JAK2 gene are prevalent in patients with MPD.<sup>68</sup> The molecular phenotype involving an activating JAK2 tyrosine kinase mutation, JAK2V617E, is a somatic point mutation causing the substitution of valine by phenylalanine in the protein product.<sup>69</sup> Because a cytokine receptor scaffold is necessary for the transforming and signaling activities of JAK2, mutations can drive proliferative disease only in cells that express Type I cytokine receptors. In PV, the mutational frequency can be as high as 97% and in ET up to 57%. The mutation is also expressed in other MPDs.<sup>70</sup> At diagnosis, ET patients with the mutation are older and have higher hemoglobin levels and white cell counts; the mutation also portends an increased mortality.<sup>71</sup> However, understanding the molecular basis of ET and other MPDs has introduced optimism for new therapeutic approaches to thrombocytopenia.

### Additional Growth Factors

Although TPO is the main physiologic regulator of megakaryocytopoiesis, it is also thought to operate in conjunction with other factors.<sup>72</sup> Other pleiotropic hematopoietic growth factors that stimulate MK growth alone or in combination with TPO include granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3, IL-6, IL-11, stem cell factor, FLT ligand, fibroblast growth factor (FGF), and EPO.<sup>6,7,25,38,73,74</sup>

A novel MK growth-stimulating peptide (ARP26) derived from the cleavable C-terminus of the stress-associated form of acetylcholinesterase (AChE) has recently been described.<sup>75</sup> Stress-induced cholinergic signaling promotes

inflammation-associated thrombopoiesis. This peptide drives the proliferation of CD34+ hematopoietic progenitor cells and MKs in vitro, as well as MK progenitors in transgenic mice.

### Negative Regulators of Megakaryocytopoiesis

Several factors are known to inhibit MK development, including transforming growth factor-beta1,<sup>76</sup> PF4, and IL-4.<sup>77-78</sup> Src kinase inhibitors have also recently been shown to negatively regulate MK proliferation by inducing early MK differentiation and functional platelet-like fragment formation in vitro.<sup>79,80</sup> This important discovery may enable new therapeutic modalities for treating thrombocytosis. A recent study reported that the Rho/ROCK pathway, a regulator of the actin cytoskeleton, may act as a negative regulator of proplatelet formation.<sup>81</sup>

### Cellular Interactions and Chemokines

Megakaryocytopoiesis and thrombocytopoiesis also require cellular interactions between HSCs and marrow stromal cells.<sup>27</sup> Stromal-derived factor-1 (SDF-1) of the CXC family is the key chemokine involved in the retention of hematopoietic precursor cells in the marrow. SDF-1 supports megakaryocytopoiesis and homing of HSCs to the marrow during fetal development.<sup>82</sup> SDF-1 is produced locally by stromal cells and promotes the migration and contact of immature MKs with a permissive, endothelial-enriched marrow environment<sup>27,83</sup> in an  $\alpha 4\beta 1$ -dependent manner.<sup>84</sup> FGF-4 fortifies the adhesion of MK progenitors to marrow endothelial cells, supporting survival and maturation, and SDF-1 enhances the movement of MKs to the junctions between sinusoidal endothelial cells via vascular endothelial cadherin, thus driving thrombopoiesis.<sup>27</sup> The SDF-1 receptor, CXCR4, is expressed along the entire MK differentiation pathway from early progenitors to platelets.<sup>82</sup> CXCR4 signaling in MKs involves the serine/threonine MAPKs, MAPK, and AKT MAPK pathways. These, in turn, include extracellular signal-related kinase (MEK) and extracellular signal-regulated protein kinase (ERK)1/ERK2, to regulate cell proliferation and differentiation. Upregulation of the CXC cytokine, CTAP III, in MKs is associated with maturation and, as with other chemokines, is involved in cellular interactions with extracellular matrix and platelet production.<sup>85</sup>

### Nuclear Transcription Factors

Megakaryocyte development and thrombocytopoiesis are controlled by the concerted action of transcription factors, which form complexes that coordinately regulate chromatin organization to specifically activate the genes of MK lineage precursors and/or concurrently repress genes that support other cell types. Many MK-specific genes are coregulated by GATA and friend of GATA (FOG) together with acute myeloid leukemia/runt-related transcription factor 1 (AML/RUNX-1) and ETS proteins. Mutations in transcription factor genes result in the translation of aberrant proteins that may cause thrombocytopenia or thrombocytosis.

Megakaryocytic and erythroid lineages, which are derived from a common bipotential progenitor, share many early

lineage-restricted transcription factors.<sup>86</sup> The zinc-finger protein GATA-1 is the principal transcription factor directing MK development by forming complexes with other transcription factors (FOG, ETS, and RUNX-1).<sup>87</sup> One of the initial events during MK/E lineage restriction is downregulation of PU.1, the main transcription factor responsible for myeloid cell differentiation,<sup>1</sup> and upregulation of GATA-1. Reciprocal antagonism of PU.1 and GATA factors balances lineage commitment decisions.<sup>88,89</sup> GATA-1 mutations lead to severe diseases involving both erythroid cells and MKs.<sup>90,91</sup> A shorter isoform of GATA-1, GATA-1s, is considered to be an early stimulus in the leukemogenesis of trisomy 21.<sup>91,92</sup> The association of the N-terminal finger of GATA-1 with its cofactor, the nine-zinc finger FOG-1, is critical for embryonic hematopoiesis and MK development.<sup>93</sup>

RUNX-1 (or AML-1) is essential for generation of all definitive hematopoietic lineages. The RUNX-1/AML-1 core binding factor (CBFb) complex binds the N-terminal transcription activation domain of GATA-1, which enables the programming of MK lineage commitment.<sup>94</sup> Chromosomal translocations in the *RUNX-1* gene are frequently associated with leukemia, eg, the t(8;21) in AML resulting in a dominant-negative RUNX-1-ETO fusion protein. Germline mutations of RUNX-1 are found in the autosomal dominant familial platelet disorder with multiple platelet defects, reduced c-Mpl, and predisposition to AML.<sup>95</sup>

The ETS family of factors resides in close proximity to GATA sequences in MK-specific promoters.<sup>96</sup> Friend leukemia integration-1 (Fli-1), located on chromosome 11q24, is an ETS factor expressed in primary MKs and hemangioblasts. Its loss is associated with the Jacobsen/Paris-Trousseau syndrome<sup>97</sup> and thrombocytopenia with large fused granules within abnormal platelets.<sup>98</sup> Finally, nuclear factor erythroid 2 (NF-E2) controls terminal MK maturation, proplatelet formation, and platelet release<sup>89,99</sup> by regulating a panoply of MK genes that are crucial elements in the processes of platelet production.

### Clinical Use of Thrombopoietic Agents

It was expected that physiologic and powerful stimulators of thrombocytopoiesis, rHuTPO or the truncated cloned rHuMGDF, would be effective in reversing thrombocytopenia caused by myelosuppression. In nonhuman primates, administration of rHuTPO or PEG-rHuMGDF resulted in markedly positive responses<sup>13,14</sup> (Fig 10-2). However, in early human trials, cross-reacting neutralizing antibodies to endogenous TPO developed, which led to thrombocytopenia in some cases and the cessation of these trials.<sup>56,100</sup> In later studies, rHuTPO was used to increase the yield of plateletpheresis for transfusion purposes.<sup>101</sup> However, administration to patients following aggressive chemotherapy showed no positive effect on platelet recovery.<sup>102</sup> In addition, the administration of rHuTPO before or after stem cell transplantation and myeloablative therapy had no impact on the duration of severe thrombocytopenia, nor did it reduce the requirement for platelet transfusions after transplantation or in AML patients after chemotherapy.<sup>103-105</sup> The failure of escalated TPO levels to stimulate platelet production in these

circumstances may be related to the paucity of the marrow MK progenitor population.<sup>47,106</sup>

In a Phase I study by the Children's Oncology Group, Children's National Medical Center, children with solid tumors received rHuTPO with granulocyte colony-stimulating factor (G-CSF) after combination chemotherapy. Time to hematologic recovery and the median number of platelet transfusions were somewhat improved compared with historical controls receiving combination chemotherapy with G-CSF alone.<sup>107</sup> A recent review of thrombopoietic factors in chronic marrow failure suggests that, although the temporal pace of response appears to be relatively slow, durable responses can be achieved in patients given thrombopoietic factors for extended periods.<sup>108</sup> Thus, TPO may prove useful in thrombocytopenic states where stem cells have not been severely depleted and the marrow microenvironment is healthy enough to support thrombopoietic activity.

Human trials of therapy for thrombocytopenia have also employed the pleiotropic cytokines, IL-1, IL-3, and IL-6, but their clinical development was abandoned because of limited effectiveness or excessive toxicity.<sup>109</sup> The multilineage cytokine IL-11 has been shown to attenuate chemotherapy-induced thrombocytopenia, and IL-11 (Neumega, Wyeth Pharmaceuticals, Collegeville, PA) is currently the only drug approved by the US Food and Drug Administration (FDA) for treating thrombocytopenia. However, IL-11 has limited effectiveness with no clear cost benefit over platelet transfusion.<sup>108</sup> A new generation of thrombopoietic agents have invigorated the field, however, with positive clinical results reported in patients with ITP and other disorders.<sup>56</sup>

AMG531 is an engineered TPO peptide mimetic composed of a recombinant protein carrier Fc domain linked to multiple Mpl-binding domains, which affects megakaryocytopoiesis similarly to TPO.<sup>110</sup> In Phase I and II studies of ITP patients, 7 of 12 and 12 of 16 patients had a doubling of their platelet counts and a rise to >50,000/ $\mu$ L. In Phase II, a weekly injection was given for 6 weeks; average peak platelet counts were 135,000/ $\mu$ L and 241,000/ $\mu$ L, for 1  $\mu$ g/kg and 3  $\mu$ g/kg, respectively.<sup>111</sup> More than 100 patients from these initial AMG531 studies have enrolled in an open-label study of long-term treatment for ITP. Interim analysis of 36 patients, most treated with a stable weekly dose for more than 48 weeks, showed a consistent mean platelet count greater than 100,000/ $\mu$ L. Discontinuation of therapy has resulted in the return of platelet counts in all subjects to baseline. It is noteworthy that in all three studies, AMG531 was well tolerated, and the major reported side effect was mild headache. However, increased marrow reticulin formation has been identified in two patients, and this finding will need to be closely followed.

Eltrombopag is a small-molecule (546 D), nonpeptide TPO-receptor agonist<sup>110,112-114</sup> available in an oral preparation. It uses JAK2 and STAT signaling pathways to cause human CD34+ cells to differentiate into megakaryocytes and produce platelets.<sup>113</sup> In a Phase I trial of 73 healthy subjects, one daily oral dose given for 10 days produced a dose-dependent rise in platelet count up to 1.5-fold over baseline. For the highest dose, the rise started on Day 7 and peaked at Day 16, without

reported side effects. Eltrombopag has shown significant activity in ITP patients. In a randomized, double-blind, placebo-controlled Phase II trial, ITP patients were given daily oral treatment for 6 weeks.<sup>110</sup> Platelet counts rose to  $>50,000/\mu\text{L}$  in up to 86% of patients. The median peak platelet counts were  $183,000/\mu\text{L}$  compared to  $16,000/\mu\text{L}$  in the placebo group. As with AMG531, cessation of eltrombopag treatment caused the platelet count to return to baseline in most patients. No adverse effects were reported.

In a randomized Phase II trial,<sup>115</sup> thrombocytopenic patients with chronic hepatitis C were treated for 4 weeks with placebo or escalated daily doses of eltrombopag. The median platelet count increased to  $209,000/\mu\text{L}$  in patients at the highest dose. No worsening of liver function was reported. Following this phase, patients were eligible to undergo interferon treatment along with open-label eltrombopag.

A Phase I trial with a long-acting pegylated TPO-mimetic peptide (peg-TPOmp), was described<sup>116</sup> in which 40 volunteers were randomly assigned to receive this TPO receptor agonist or placebo as a single intravenous bolus. Platelet counts increased dose-dependently, reaching peak levels at Days 10 to 12, and returned to baseline within 3 to 4 weeks. Platelet function was normal, and no serious adverse events or detection of antibodies against peg-TPOmp were reported.

A minibody agonist of c-Mpl was recently used in a novel therapeutic approach to treat thrombocytopenia.<sup>117</sup> IgG antibodies were engineered against the TPO receptor with absent or very weak agonist activity; these agonist minibodies, which include diabody or single chain (Fv) 2 [sc (Fv) 2], were as potent as the natural ligand. Two minibodies were successfully constructed to bind and activate two mutant types of dysfunctional Mpl receptor that cause CAMT. Another TPO-agonist antibody (MA01G4G344) showed stimulation of a TPO-dependent cell line and increased human MK-CFCs in vitro. A single injection increased the platelet count in human-c-Mpl transgenic mice for  $>1$  month.<sup>118</sup>

New synthetic c-Mpl agonists under preclinical development have recently been described. One is an orally active, nonpeptidyl TPO receptor agonist, AKR-501 (formerly YM 477).<sup>119</sup> In-vitro AKR-501 stimulated the growth of TPO-dependent cell lines and increased growth of megakaryocytes from human CD34+ cells. Its in-vivo effect was examined in mice producing platelets from human HSCs after transplantation. Oral administration of AKR-501 showed a dose-dependent increase in the number of human platelets, up to 3.0-fold by Day 14. Oral doses have been tested in healthy human subjects,<sup>110</sup> elevating the platelet count up to 2.8-fold without adverse effects. Another synthetic c-Mpl agonist, NIP-004, induced the proliferation of various TPO-responsive cell lines, primary human hematopoietic progenitor cells, and human thrombocytopoiesis in a xenotransplant animal model; the latter showed a 1.5-fold increase of megakaryoblasts, a 3.0-fold increase of mature polyploid MKs, and a 6.0-fold increase in human platelets.<sup>120</sup> Similarly, SB-497115 is a nonpeptidyl TPO-R agonist that increased platelet counts in a dose-dependent fashion when administered orally to healthy volunteers.<sup>121</sup> It is

important to note that the efficacy and safety of all of these molecules in clinical settings have yet to be determined.

## Platelet Kinetics

### Platelet Production

Circulating platelets are anucleate cells between 2 and 4 microns in diameter with a volume of 6 to 11 fL. The normal platelet count ranges from 150,000 to 450,000/ $\mu\text{L}$ . The overall rate of platelet production under steady-state conditions in healthy humans ranges from 35,000 to 44,000 platelets/ $\mu\text{L}/\text{day}$ .<sup>122-126</sup> Steady state assumes that platelet removal is equivalent to platelet production when the platelet count is constant. As expected, the MK mass in a healthy marrow generally correlates directly with platelet turnover.<sup>13,14,127</sup> However, intramedullary destruction of platelets can occur or abnormalities of megakaryocytopoiesis can result in impaired transformation of the cytoplasmic MK mass to circulating viable platelets. This discrepancy detected between megakaryocytic mass and platelet turnover is called *ineffective thrombocytopoiesis*. Therefore, the reliability of platelet turnover estimates depends on the accuracy with which each of the three variables used in calculating platelet turnover can be determined—mean platelet life span, recovery of platelets in the circulation, and blood platelet count. The summation error may be considerable, as occurs among patients with ITP.<sup>124</sup>

Newly released reticulated platelets (RPs) are identified by their increased RNA content<sup>128</sup>; murine studies have directly confirmed that RPs are the platelet subset most recently released from megakaryocytes into the blood.<sup>129,130</sup> The RP% in humans correlates with thrombopoietic activity.<sup>131</sup> Analogous to red cell reticulocytes, RPs increase in response to destructive thrombocytopenia and decrease when megakaryocyte hypoproliferation occurs with chemotherapy or intrinsic marrow aplasia.<sup>132</sup> The absolute RP count in humans with normal platelet counts ranges from 15,000 to 48,000/ $\mu\text{L}$ ; this average platelet production agrees with isotopic labeling studies. RNase-based RP analysis allows for a protocol-defined standardized RP% measurement independent of platelet size<sup>133</sup> and, therefore, is amenable to inter-laboratory use.<sup>134</sup> Determination of the RP maturation index or immature platelet fraction further refines the sensitivity of RP detection of early increases in platelet production, which may predict recovery from chemotherapy-induced thrombocytopenia and independence from transfusion therapy.

### Platelet Distribution

In humans, approximately two-thirds of platelets are in the general circulation. The remaining platelets are reversibly sequestered, primarily in the spleen. The distribution between the general and splenic pools of platelets can be determined by measuring the proportion of radiolabeled platelets remaining in the general circulation after infusion. The size of the splenic pool has been estimated to be approximately 30% of whole-body platelet mass.<sup>122,123,126,135,136</sup> In persons without a spleen, nearly 100% of

infused platelets are recovered. In patients with splenomegaly, by contrast, as much as 90% of total-body platelet mass can be sequestered in the spleen.<sup>136</sup>

It is currently controversial whether splenic pooling alters platelet survival. Splenectomy has been shown in some studies to cause prolongation of platelet life span,<sup>137</sup> while other studies found no change in platelet survival after splenectomy.<sup>138</sup> However, data from an animal model demonstrated a significant (>40%) increase in platelet life span, after splenectomy.<sup>139</sup> Platelet accumulation in the spleen is rapid and reaches 90% of maximum activity within approximately 12.5 minutes after injection of labeled platelets.<sup>123,135</sup> Although the role of the spleen in the regulation of the platelet count is controversial, splenic pooling of platelets is itself reversible. For example, intravenous epinephrine, which reduces blood flow to the spleen and causes the organ to empty passively into the circulation, normally causes the platelet level to increase by 30% to 50%, but does not affect platelet concentration in asplenic individuals.<sup>136</sup> Massive splenomegaly results in sequestration of as much as 90% of the total platelet population within the enlarged spleen.<sup>140</sup> In patients with more moderate splenomegaly, such as seen in patients with cirrhosis and portal hypertension, splenic sequestration is less, and platelet counts generally range from 60,000 to 100,000/ $\mu$ L. Hepatic pooling of infused platelets is also significant initially, reaching a maximum of approximately 16% of whole-body dosing 6 to 8 minutes after injection of radiolabeled platelets. This activity reaches a steady state after approximately 45 minutes. At equilibrium, hepatic platelet activity accounts for approximately 10% of total-body platelets.<sup>123,135</sup> This percentage of hepatic pooling may be increased after the spleen is removed.

### Platelet Survival

The finite platelet life span in healthy persons is  $9.5 \pm 0.6$  days,<sup>122</sup> and platelet disappearance is generally linear, primarily reflecting platelet senescence.<sup>125</sup> However, in patients with consumptive thrombocytopenia, the platelet life span is shorter, and the disappearance pattern becomes exponential, primarily reflecting random platelet removal.<sup>141,142</sup> Platelet survival time has been shown to shorten progressively as the platelet count decreases to  $<100,000/\mu$ L.<sup>125,143</sup> Therefore, a shortened platelet survival time in patients with thrombocytopenia may not necessarily indicate a pathologic destructive process. Hanson and Slichter<sup>125</sup> proposed a model for platelet removal that predicted shortening of platelet survival time in relation to the level of thrombocytopenia. The analysis indicated that 82% of platelet turnover in healthy persons is caused by platelet senescence, and approximately 18% is caused by a fixed requirement of platelets to support vascular integrity. Hemostatic loss represents about 7000 to 10,000 platelets/ $\mu$ L/day; loss of platelets for hemostatic integrity appears to be a fixed absolute number. Thus, in thrombocytopenia caused by marrow hypoplasia, the daily proportion of platelets removed by hemostatic consumption rises dramatically.<sup>144</sup> When platelet life span measurements have been prospectively studied in patients with moderate to severe thrombocytopenia

**Figure 10-3.** Relationship between survival time of  $^{111}\text{In}$ -oxine-labeled autologous platelets and circulating platelet count. *Closed circles* indicate patients with megakaryocytic hypoplasia. *Open circles* represent patients with immune thrombocytopenia (ITP). *Solid line* represents the best fit-to-data obtained with the first patient group; therefore, platelet survival could be predicted on the basis of the platelet count in these patients. All data points contained within the *dashed lines* were consistent with a value of random platelet turnover that ranged from 15.1% to 28.0% of overall platelet turnover.

(10,000 to 150,000/ $\mu$ L),<sup>144</sup> the results in patients with megakaryocytic hypoplasia are predicted by the platelet count (Fig 10-3). All data points were consistent with values of platelet turnover that ranged from 15.1% to 28.0% of overall platelet turnover. In contrast, platelet life span in patients with ITP was much shorter than the value predicted by the platelet count.

The physiology of senescent platelet removal is postulated to include irreversible changes in membrane glycoproteins; increased platelet-associated immunoglobulin (with subsequent clearance of those high-immunoglobulin-expressing platelets by splenic macrophages); increased exposure of the negatively charged procoagulant lipid, phosphatidylserine, on the external platelet membrane; and decreased levels of surface sialic acid.<sup>145</sup> Not surprisingly, the RP% has proven valuable for detecting changes in overall platelet turnover. The RP% has been applied for predicting thrombopoietic recovery, transfusion independence, and thrombotic risk.

The latter has been demonstrated in several settings. An increase in the RP% was associated with subsequent graft-vs-host disease after allogeneic HSCT.<sup>146</sup> Similarly, an asymptomatic increase in the RP%, with no change in platelet counts, from the first to second trimester in pregnancy was associated with subsequent preeclampsia.<sup>147</sup> Asymptomatic patients with steady-state thrombocytosis and an elevated RP% or absolute RP count were at increased risk for subsequent thrombosis,<sup>148</sup> and

their relative risk was higher than the risk associated with a high platelet count alone. The RP% and absolute RP count in thrombocytosis decreases with either successful aspirin therapy<sup>149</sup> or hydroxyurea.<sup>150</sup>

A compensatory increase in platelet production and the corresponding rise in circulating RP% are well established in patients with ITP, in whom antibodies targeting platelet membrane epitopes<sup>151</sup> cause platelet clearance via splenic macrophage Fc receptors.<sup>152</sup> Platelet life span in severe ITP can be shortened to hours. Although the marrow can increase megakaryocyte mass by 10-fold,<sup>153</sup> this is insufficient to maintain a normal platelet count with ITP; the increased RP% confirms the compensatory marrow production response. Once successful therapy (steroids, intravenous immune globulin, Rh Immune Globulin therapy)<sup>154</sup> for ITP has been instituted, the RP% has been shown to decline before platelet count recovery. The RP% continues to decrease as the platelet count approaches the normal ranges, indicating that restoration of a normal platelet life span rapidly downregulates RP release from MKs.

However, even patients with severe ITP appear to have relatively normal hemostasis,<sup>155</sup> and most ITP patients, especially children, do not have significant blood loss despite very low platelet counts. One reason may be that overall circulating platelet function is preserved because of the higher proportion of robust RPs. In human studies of thrombocytopenia, younger platelet cohorts had greater aggregation and adherence responses compared with older platelet subsets.<sup>156</sup> In animals, RPs have a lower threshold for  $\alpha$ -granule release than older platelets.<sup>157</sup> By contrast, in human ITP,<sup>158</sup> RPs do not appear to have a lower threshold for  $\alpha$ -granule release; instead, RPs have twice as much  $\alpha$ -granule content as older circulating platelets. RPs also have an increased density of adherent membrane receptors<sup>159</sup> than older cohorts, perhaps accounting for the lesser extent of bleeding in ITP compared to chemotherapy patients with similar platelet counts.

### Platelet Destruction

When platelets disappear from the circulation, they are mostly taken up by the mononuclear phagocytic system.<sup>135,143</sup> It is evident that the spleen and liver are the major sites of removal of platelets; after injection of <sup>111</sup>In-labeled platelets, radioactivity in the liver increases significantly and linearly with time from a level of 9.6% at equilibrium to 28.7% of total-body radioactivity during clearance.<sup>123,135</sup> Mean splenic radioactivity increased from 31.1% to 35.6% during clearance of radiolabeled platelets. After labeled platelets are removed from circulation (approximately 10 days after administration), 30.3% of whole-body platelet radioactivity is neither in the liver nor in the spleen. Platelets not removed by these two organs are presumably removed by the mononuclear phagocytic cells of the marrow.<sup>160</sup>

### Platelet Kinetics and Transfusion Therapy

As mentioned previously, thrombocytopenia causes the fixed daily requirement of platelets needed to maintain hemostasis to increase to a greater proportion (>60%)<sup>144</sup> of overall

platelet turnover.<sup>125</sup> Platelet kinetics studies<sup>125,144</sup> have predicted that transfusion of sufficient platelets to increase the circulating count from the 10,000/ $\mu$ L range to the 100,000/ $\mu$ L range should result in prolongation of platelet survival from 2 to 3 days to 8 to 9 days. The required frequency of platelet transfusion consequently would be decreased. This conclusion was corroborated by a prospective study of acute leukemia patients, who were stratified to receive escalated doses of platelets, ranging from  $4 \times 10^{11}$  to  $>8 \times 10^{11}$ . There was a direct, linear correlation between platelet dose and both platelet increment and transfusion-free interval.<sup>161</sup>

Another prospective, randomized, blinded, cross-over trial comparing low- and high-dose plateletpheresis products also confirmed the benefits of an increased platelet dose.<sup>162</sup> Forty-six patients undergoing HSCT were each given 79 paired transfusions, with low-dose ( $3.1 \times 10^{11}$ ) and high-dose ( $5.0 \times 10^{11}$ ) products in random sequence. Mean increments of 17,000/ $\mu$ L were seen with the lower dose, compared to 31,000/ $\mu$ L with the higher dose; a significant prolongation in the interval between platelet transfusions was also seen with the latter. In nonrandomized studies, transfusion of apheresis products with higher platelet content to thrombocytopenic patients has led to significantly higher increments and longer intervals between platelet transfusions.<sup>163</sup>

---

## Platelet Hemostasis

The platelet is central to cell-based hemostasis. Platelet membrane receptors mediate binding to endothelium and sub-endothelial sites of damage, and this adhesion triggers transmembrane signaling, platelet activation, and procoagulant function, including release of procoagulant granule contents and exposure of internal membrane phospholipids. The procoagulant surface of the platelet causes assembly of the coagulation cascade, leading to thrombin formation, which, in turn, amplifies the procoagulant response and produces fibrin within the platelet matrix for superior hemostasis. Clot consolidation and protection from fibrinolysis are further augmented by platelet release of Factor XIII and PF4 into the clot milieu (Table 10-1). The following section details the physiology of platelet hemostasis and interaction with soluble coagulation factors, congenital and acquired platelet defects and their clinical phenotype, and the function of transfused platelets.

### Platelet Interaction with Blood Vessels

The vascular endothelium maintains a default anticoagulant surface by secreting factors that block soluble coagulation activity, including heparan sulfates, thrombomodulin, and tissue plasminogen activator. Antiplatelet factors are also intrinsic to the healthy endothelial cell lining; these include a net negative surface charge to repel similarly charged platelets, release of nitric oxide and prostacyclin to inhibit platelet aggregation, and surface expression of ADPase to inactivate platelet-Dreleased factors ADP.<sup>164,165</sup> The platelet-vessel wall interaction at the high flow

**Figure 10-4.** Platelet adhesion to subendothelial von Willebrand factor (vWF) in flowing blood. Endothelial injury exposes subendothelial collagen, which binds vWF and presents vWF attachment sites to platelets streaming along the vessel wall. Platelet GPIb rapidly attaches to its binding site on vWF, but this adhesion is short-lived, resulting in platelet rolling in close proximity to the subendothelium. The vWF-GPIb interaction causes transmembrane signaling, activating the platelet, and conformationally transforming platelet GPIIb/IIIa to avidly bind the RGD domain on vWF. This secondary adhesion is essentially irreversible, resulting in anchoring of the platelet to the exposed subendothelium, and allowing subsequent propagation of a platelet-fibrin clot.

GP = glycoprotein; vWF = von Willebrand factor; ADP = adenosine diphosphate.

velocities of the arterial circulation is shown in Fig 10-4, where parallel planes of blood are moving at different velocities,<sup>166</sup> which create shear stress. Shear rates at the vessel wall vary between 500sec<sup>-1</sup> in larger arteries to 5000sec<sup>-1</sup> in the smallest arterioles and can reach levels of 3000 to 10,000sec<sup>-1</sup> (and even higher) at the surface of atherosclerotic plaques with stenosis.

One of the forces enhancing platelet adhesion to the vessel wall in the arterial circulation is radial dispersion, the tendency of larger cells to stream in the center of the vessel where shear is lowest; this phenomenon effectively pushes the smaller platelets toward the vessel wall. This size-dependent flow may explain how the correction of severe anemia can slow or stop bleeding.<sup>167</sup> This effect also underscores the importance of platelets in arterial hemostasis; reductions in platelet number or function may be associated with catastrophic arterial hemorrhage. By contrast,

the lesser shear forces experienced in the venous circulation (20 to 200sec<sup>-1</sup>) permit more random cell movement and greater time for localized coagulation reactions to occur, making fewer demands for adequate platelet number and function.

Given the velocity of blood flow in an artery, platelets must rapidly activate and adhere to the injured vessel. Two molecules in the subendothelium are critical for this: vWF<sup>168</sup> and collagen. Control of bleeding in vessels under the highest shear stresses is dependent on adequate vWF concentration and function.<sup>169</sup> The largest multimeric forms of vWF, which are immobilized by adherence to exposed subendothelial collagen, bind platelet GPIb<sup>170</sup> in response to high shear stress (Fig 10-4). This is a rapid but low-affinity event that markedly slows the circulating platelets but does not firmly adhere them to vWF. With platelets now tumbling over the subendothelium, transmembrane signaling is produced by both high shear stress and the GPIb-vWF interaction<sup>171</sup>; this results in platelet shape change and a conformationally activated GPIIb/IIIa, which can bind either to fibrinogen or larger vWF multimers. The adhesion of GPIIb/IIIa-vWF is a higher affinity interaction than the GPIb-vWF bond and adheres platelets firmly into the subendothelial vWF. Once a layer of platelets is adherent, vWF bound to GPIb on the uppermost adherent platelets serves to recruit additional platelets from the vascular flow into the growing platelet plug.

At more moderate shear stress, GPIb-vWF adhesion is supplemented by subendothelial collagen binding itself to platelet GPIa/IIa (Table 10-1).<sup>172</sup> Thus, subendothelial vWF and collagen act cooperatively to initiate platelet adhesion, with the former predominating at higher shear rates. Collagen also directly activates platelets by binding to platelet GPVI at a second locus.<sup>173</sup> The congenital absence of any of these critical platelet adhesion receptors—GPIIb/IIIa, GPIb,<sup>52</sup> GPVI,<sup>174</sup> or GPIa/IIa<sup>175</sup>—results in a significant hemostatic defect, correctable only by platelet transfusion (see congenital platelet disorders below). Similarly, decreases in the concentration of vWF, especially the larger multimeric forms, or abnormal vWF function predispose to bleeding.<sup>176</sup>

### Platelet Activation

Adherent platelets undergo a series of interdependent processes collectively referred to as activation with five major sequelae: 1)

**Table 10-2.** Drugs that Inhibit Platelet Function

- ADP receptor antagonists (clopidogrel, prasugrel, ticlopidine)
- Antibiotics (cephalosporins, nitrofurantoin, penicillins)
- Anti-GPIIb/IIIa or anti-RGD compounds (abciximab, eptifibatide, tirofiban)
- Cardiac drugs (nitroglycerin, nitroprusside)
- Cyclooxygenase inhibitors (aspirin, nonsteroidal antiinflammatory drugs that are COX-1/2 nonselective)
- Heparin (unfractionated and low-molecular-weight)
- Miscellaneous (dextran, hydroxyethyl starch, garlic, ginkgo biloba)
- Phosphodiesterase inhibitors (cilostazol, dipyridamole)

ADP = adenosine diphosphate; GP = glycoprotein.

release of adhesive ligands that stabilize platelet-platelet binding, 2) recruitment of additional platelets from flowing blood, 3) vasoconstriction to slow bleeding, 4) localization and acceleration of platelet-associated fibrin formation, and 5) clot protection from fibrinolysis.

The basis of the platelet plug is a platelet-ligand-platelet matrix; fibrinogen and vWF serve as bridging ligands, and both are stored within platelet  $\alpha$ -granules. The  $\alpha$ -granules fuse with the open canalicular system following platelet activation, releasing both fibrinogen and vWF; GPIIb/IIIa binds to the fibrinogen molecule and to the larger vWF multimers via RGD sites, creating the platelet-ligand-platelet matrix.<sup>177</sup> GPIIb/IIIa is the most abundant glycoprotein on the platelet surface, with approximately 50,000 copies on the resting platelet; additional GPIIb/IIIa receptors within the cytosol are mobilized to the surface after activation. The importance of these platelet adhesive mechanisms is underscored by the potent antiplatelet drugs that target GPIIb/IIIa to block arterial clotting (Table 10-2).

Platelets are continuously recruited into the platelet plug by the actions of local agonists (collagen, epinephrine, and thrombin) and by localized release of additional agonists (ADP, serotonin) from adherent platelets. Both collagen (as noted above) and thrombin interact with specific platelet receptors to strongly activate platelets. Although epinephrine by itself is not a powerful platelet agonist, stimulation of the  $\alpha$ -adrenergic receptor on platelets primes them for synergistic activation to other agonists, including ADP. Another activating compound released directly from activated platelets is thromboxane  $A_2$ , which is formed in the platelet cytosol after cyclooxygenase cleavage of arachidonic acid and then released into the clot milieu.<sup>178</sup> Thromboxane  $A_2$  is both a platelet agonist and a vasoconstrictor, and it is rapidly degraded to its inert by-product, thromboxane  $B_2$ . Cyclooxygenase activity is *irreversibly* inhibited by aspirin, thereby blocking thromboxane  $A_2$  formation for the lifetime of that platelet, unlike nonsteroidal anti-inflammatory drugs (NSAIDs), which *reversibly* inhibit cyclooxygenase activity.

Other platelet agonists are liberated into the clot microenvironment by fusion of platelet dense granules and  $\alpha$ -granules with the platelet external membrane, producing extrusion of granule contents (Table 10-1) including fibrinogen, fibronectin, vWF, and thrombospondin. Translocation to the platelet membrane by

$\alpha$ -granules also results in external membrane expression of P-selectin, which contributes directly to platelet-heterotypic cell adhesion.<sup>179</sup> Adherence of activated platelets via P-selectin to neutrophils and monocytes in the blood has been demonstrated to be a marker for platelet activation in several clinical circumstances, including cardiopulmonary bypass,<sup>180</sup> thrombotic thrombocytopenic purpura,<sup>181</sup> and unstable coronary syndromes.<sup>182</sup> This P-selectin-mediated adhesive interaction may serve to target heterotypic cell populations to areas of inflammation or thrombosis,<sup>183</sup> upregulate procoagulant (tissue factor)<sup>184</sup> and/or inflammatory (TNF $\alpha$ ) activity,<sup>185</sup> and promote transcellular metabolic cooperation.<sup>186</sup>

Platelet dense granules contain serotonin which, like thromboxane  $A_2$ , is both a platelet agonist and a vasoconstrictor.<sup>187</sup> Another dense-granule constituent, ADP, acts purely as a platelet agonist without vasoactive properties (Table 10-1). The importance of thromboxane  $A_2$ - and serotonin-induced vasoconstriction is not entirely clear. However, by decreasing the vessel diameter, vasoconstriction may increase shear stress and thereby facilitate additional recruitment of platelets to the clot. The importance of dense-granule release to the maintenance of hemostasis is manifested by the severe hemorrhage noted in patients with congenital dense-granule deficiencies (eg, Hermansky-Pudlak syndrome and storage pool disease). Therefore, platelet activation serves to amplify platelet adhesion and optimize the platelet surface for fibrin-generating procoagulant activity by interaction of platelets with the soluble coagulation cascade.

### Platelet Interaction with Soluble Coagulation Factors

Tissue injury and low levels of circulating activated clotting factors physiologically initiate the clotting cascade, which is then propagated by enzyme complexes that efficiently assemble on the phospholipid membrane surface supplied by platelets. Tissue factor (TF) expressed after endothelial injury binds to circulating Factor VIIa, and the Factor VIIa-TF complex subsequently binds to its zymogen substrates, Factors IX and X, on the activated platelet membrane to form the extrinsic “tenase” complex.<sup>188</sup> Platelet activation increases external membrane expression of the negatively charged, procoagulant phosphatidylserine (PS) moiety, which can be detected either by calcium-dependent binding to annexin V or by procoagulant assays, the latter because PS on the activated platelet surface enhances both the tenase and prothrombinase reactions. Activated platelets also provide surface receptors for Factors Xa, IXa, and Va; Factor V is also secreted from the platelet  $\alpha$ -granule, and platelet-derived Factor V appears to significantly contribute to overall Factor V function, as noted in Factor V-deficient patients after platelet transfusion.<sup>188</sup> Platelet receptor binding simultaneously protects activated factors from circulating inhibitors and orients factors on the plasma membrane such that they interact closely with PS to accelerate thrombin generation.<sup>189</sup>

Physiologic cell-based hemostasis can therefore be modeled as: TF-VIIa converts Factor X to Xa and Factor IX to IXa, both

of which are bound to platelet receptors. The intrinsic tenase complex on the platelet membrane is formed initially by TF-induced Factor IXa formation; Factor IXa binds to its cofactor, Factor VIIIa, and its zymogen substrate Factor X to amplify production of Factor Xa on the platelet surface (Fig 10-5). The platelet Factor Xa receptor is closely associated with platelet-bound Factor Va; together with free  $\text{Ca}^{2+}$  and platelet membrane PS, these factors bind prothrombin (Factor II) to form the prothrombinase complex,<sup>190</sup> thereby generating thrombin, albeit in relatively small amounts. This initially formed thrombin feeds back to activate Factor VIII to VIIIa (which binds to platelet-bound Factor IXa), Factor V to Va (which binds to its platelet receptor), and Factor XI to XIa. Once these initial amounts of thrombin activate more platelets and generate appreciable quantities of Factor XIa<sup>191</sup> and cofactors Factor Va and VIIIa on the platelet surface,<sup>192</sup> activation of the more kinetically favorable intrinsic pathway occurs to amplify the clotting cascade, thereby increasing the rate of Factor Xa and thrombin generation exponentially.<sup>193</sup> This rapid thrombin generation cleaves fibrinogen to fibrin monomers, which combine to form a fibrin matrix integrated with adherent platelets. Factor XIIIa, a transamidase produced by the action of thrombin on either plasma or platelet-released Factor XIII, converts the soluble fibrin clot into an insoluble fibrin polymer and effectively incorporates  $\alpha_2$ -antiplasmin into the clot to inhibit plasmin-mediated dissolution.<sup>194</sup> Finally, the platelet plug undergoes clot retraction, which additionally protects the platelet-fibrin matrices from lysis by plasmin.<sup>195</sup>

### Acquired Qualitative Platelet Defects

The normal ability of platelets to adhere to damaged vessels and recruit additional platelets into the clot is critical for primary hemostasis, especially when patients are hemostatically challenged by trauma or surgery. Drugs are the most common cause of acquired platelet dysfunction. Aspirin irreversibly acetylates platelet cyclooxygenase-1, blocking activation via the arachidonic acid pathway; all exposed platelets are irreversibly affected even after aspirin is discontinued. By contrast, NSAIDs *reversibly* inhibit cyclooxygenase-1 such that platelet function is restored within 24 to 48 hours after discontinuation of the drug. However, surgical bleeding is often unaffected in the setting of either concomitant aspirin or NSAID therapy,<sup>196</sup> and aspirin is often continued through surgery in patients who are at risk for stroke or myocardial infarction. However, excessive surgical bleeding caused by aspirin-induced platelet dysfunction can be reduced by treatment with desmopressin acetate (DDAVP).<sup>197</sup> When DDAVP is ineffective, platelet transfusion consisting of 4 to 6 whole-blood-derived units or a single apheresis unit will restore primary hemostasis in aspirin-treated patients. Antiplatelet agents are also commonly used in combination, and beyond inhibiting the aggregation response, these drugs can also block platelet procoagulant function<sup>198</sup>; hence, platelet transfusion should be a consideration in any such patient facing major surgery or experiencing significant bleeding. Platelet dysfunction and bleeding caused by drugs other than aspirin or NSAIDs (Table 10-2) can

**Figure 10-5.** Platelet-based hemostasis. (A) Activated Factor VII – tissue factor (TF) complex converts Factor X to Xa and Factor IX to IXa, which are bound to platelet receptors. (B) Factor IXa binds to its cofactor, Factor VIIIa, and its zymogen substrate Factor X to form the tenase complex, creating Factor Xa on the platelet surface. The platelet Factor Xa receptor is closely associated with platelet-bound Factor Va; together with free  $\text{Ca}^{2+}$  and platelet membrane phosphatidylserine ( $\Theta$ ), these factors bind prothrombin (Factor II) to form the prothrombinase complex, thereby generating small amounts of thrombin (Factor IIa). (C) Thrombin feeds back to activate platelets and factors: Factor VIII to VIIIa (which binds platelet-bound Factor IXa), Factor V to Va (bound to its platelet receptor), and Factor XI to XIa (which forms more Factor IXa). Activation of the more kinetically favorable intrinsic pathway now occurs to exponentially increase the rate of Factor Xa and Factor IIa generation.

be similarly treated.<sup>199</sup> Proteins that accumulate in renal failure effectively poison platelet adhesive function.<sup>200</sup> Adequate dialysis and hematocrit maintenance preserve platelet function, but bleeding with acute renal failure is seen. Platelet transfusion may be used in life-threatening uremic bleeding, but transfused platelets rapidly acquire the uremic defect; therefore, acute uremic platelet dysfunction is generally treated with DDAVP or cryoprecipitate.<sup>201</sup> Long-term estrogen therapy has been shown to be efficacious in renal failure patients prone to chronic hemorrhage.

### Congenital Platelet Dysfunction

Inherited qualitative platelet defects include abnormalities of platelet receptors, platelet procoagulant activity, and granules. Two relatively rare, but well-characterized, platelet receptor disorders are Bernard-Soulier syndrome (BSS)<sup>202</sup> and Glanzmann thrombasthenia (GT).<sup>203</sup> BSS affects vWF binding to platelets via decreased surface expression of platelet GPIb (the primary vWF receptor) or diminished GPIb function. BSS is characterized by a mild-to-moderate bleeding disorder with mild thrombocytopenia, increased bleeding time, and large platelets; the diagnosis is occasionally not made until adulthood. Laboratory testing shows an absent platelet aggregation response to ristocetin (which agglutinates platelets through GPIb-vWF interaction) but with normal plasma vWF antigen and normal ristocetin cofactor activity. GT is characterized by bleeding in childhood with an increased bleeding time and abnormally low levels of platelet GPIIb/IIIa expression (a receptor for both vWF and fibrinogen) or normal expression but absent GPIIb/IIIa function. Platelet aggregation testing in GT shows absent or diminished response to all agonists (ADP, epinephrine, collagen, arachidonic acid) except ristocetin. Platelet transfusions are effective for bleeding symptoms in both BSS and GT. However, because of the high risk of alloimmunization with frequent platelet transfusions,<sup>204</sup> transfusion is usually reserved for life-threatening bleeding, and most patients are successfully managed with conservative therapy.

Inherited platelet granule disorders are defined by the type of granule that is absent or defective.<sup>205</sup> Storage pool disease is characterized by a relative decrease or absence of dense granules, resulting in symptoms of moderate-to-severe mucosal bleeding. Defective release of dense-granule constituents impairs the ability of platelets to recruit and activate other platelets in the microenvironment. The laboratory diagnosis of storage pool disease is characterized by diminished or absent secondary wave aggregation to weak platelet agonists such as epinephrine and ADP.<sup>206</sup> Hermansky-Pudlak syndrome is one form of dense-granule deficiency and is accompanied by oculocutaneous albinism and mild thrombocytopenia. Patients with Hermansky-Pudlak syndrome demonstrate excessive bleeding with trauma or surgery and occasionally have spontaneous bleeding. Chediak-Higashi disease is a general granule disorder characterized by mild bleeding, partial albinism, and recurrent pyogenic infections.

The absence of platelet  $\alpha$ -granules and/or their contents is gray platelet syndrome, so-called because platelets seen on the peripheral smear lack the normal basophilic staining.<sup>207</sup> Patients with gray platelet syndrome have a mild bleeding history, and

there is diminished platelet aggregation to epinephrine, ADP, and collagen. Patients with platelet granule disorders can be successfully treated conservatively by avoidance of aspirin and other antiplatelet drugs (Table 10-2), and hormonal control of menses. However, when significant bleeding occurs, platelet transfusions are necessary to correct hemostasis.

Patients with bleeding caused by the extremely rare Scott syndrome<sup>208</sup> have normal platelet aggregation and secretion,<sup>209</sup> but their platelets are unable to translocate anionic phospholipids from the internal to the external platelet membrane with activation.<sup>210</sup> These platelets also showed impaired ability to generate platelet microparticles, as well as a decrease in the number and function of inducible Factor Va receptors on the platelet surface. Thus, platelets in Scott syndrome do not provide a membrane surface that optimally provides sites for assembly of the intrinsic tenase and prothrombinase complexes.<sup>211</sup> As with another rare disorder of platelet procoagulant function (Factor V Quebec, a platelet defect in which most proteins of the  $\alpha$ -granules are probably degraded),<sup>212,213</sup> platelet transfusion is effective for clinically significant bleeding.

### Platelet Function and Survival After Transfusion

Preparation and storage of platelets for transfusion results in partial platelet activation and some loss of metabolic function. Stored platelets gradually lose their *de novo* ability to aggregate, and platelet-matrix adhesion capabilities are similarly compromised as measured by *in-vitro* assays.<sup>214-216</sup> Moreover, the longer platelets are stored, the shorter their subsequent survival in animal models<sup>217</sup>; however, in humans, the clinical status of the transfusion recipient also influences the recovery and survival of transfused platelets.<sup>218</sup> Despite the functional and survival lesions of platelet storage, transfused platelets will appear in the circulation and restore hemostasis in patients bleeding from thrombocytopenia or platelet dysfunction.

Platelet transfusion in humans with chemotherapy-induced thrombocytopenia results in a rapid increase in whole blood platelet aggregation and adenosine triphosphate release.<sup>215,219</sup> One reason for stored platelet recovery of function after transfusion is the restored milieu of normal pH and metabolic substrates for the transfused platelet.<sup>220</sup> This restoration of platelet function is especially convincing for platelet procoagulant abilities based on phospholipid expression to agonists. With respect to circulating transfused platelets, modeling data suggest that stored platelets can survive after transfusion in humans for an average of 6 days,<sup>221</sup> and these findings have been confirmed by *in-vivo* studies.<sup>222,223</sup> Based on these encouraging results of stored platelet function and survival, research<sup>224,225</sup> has been focused on finding methods to preserve stored platelets for longer periods without compromising function or increasing the risk of bacterial contamination.

---

## Summary

In conclusion, recently acquired knowledge of the molecular mechanisms that regulate megakaryocytopoiesis and platelet

production—together with new developments in the generation and availability of various thrombopoietic agents—provide a strong basis for future therapy of thrombocytopenic states. These thrombocytopenic pathologies can be qualified according to decreased production or increased clearance by the enumeration of circulating reticulated platelets. Pharmacologic thrombopoietin moieties have demonstrated promise at restoring platelet counts in both immunologic and hypoproliferative thrombocytopenias, especially for the latter when there is residual megakaryocyte mass. New understanding of platelet hemostatic mechanisms has led to multiple strategies for blocking pathologic platelet-dependent thromboses, as well as an improved ability to treat bleeding caused by platelet dysfunction and thrombocytopenia. Future investigations will likely result in improved thrombopoietin therapies to reverse low platelet counts and improved storage conditions for platelets in order to provide maximum hemostatic benefit for platelet transfusion recipients.

Platelets express a variety of immunogenic markers on the cell surface. Some of these antigens are shared with other cell types as in the case of HLA antigens, which are shared with virtually all nucleated cells in the body, whereas others are observed to be essentially platelet specific. This chapter reviews the antigens expressed on platelets, the various patterns of alloimmunization to these antigens, and their impact on platelet transfusion responses. Strategies to treat and prevent alloimmunization are summarized.

## Antigens on the Platelet Surface

### Antigens Shared with Other Tissues

#### HLA Antigens

HLA Class I antigens are the principal antigens shared by platelets and lymphocytes. Indeed, platelets are the major source of HLA Class I antigens in whole blood.

Although platelets ultimately derive from nucleated precursors (the megakaryocytes) and hence might be anticipated to acquire their HLA antigens through mechanisms in common with other nucleated cells, consensus as to the source of HLA Class I structures in circulating, mature platelets has developed only recently. Early studies<sup>1,2</sup> demonstrated that, in vitro, platelets do absorb and express soluble HLA antigens after incubation in plasma. Other studies showing that HLA Class I molecules can apparently be eluted from platelets by incubation in low pH chloroquine or citrate solutions<sup>3,4</sup> suggested that these antigens were not firmly embedded in the membrane and were likely absorbed from the surrounding plasma. These studies suggested that HLA absorbed from plasma contributed significantly to the total HLA Class I present on platelets. However, only small amounts of HLA were absorbed by platelets in these studies, and

it is now recognized that low pH treatment of platelets does not “strip” the HLA Class I heavy chain from the cell membrane of platelets. Rather, acid treatment of platelets actually disrupts the trimolecular complex of HLA Class I heavy chain, peptide, and  $\beta_2$ -microglobulin; destroying antigenic epitopes and preventing the binding of specific HLA antibodies.<sup>5,6</sup>

It is now clear that most HLA Class I molecules on platelets are integral membrane proteins persisting from the megakaryocyte stage of development. Evidence for this includes studies of phorbol ester stimulation of platelets that resulted in phosphorylation of their HLA molecules,<sup>7</sup> and mRNA from platelets that is capable of producing small amounts of HLA Class I<sup>8</sup>—both of which are consistent with HLA molecules being an integral part of the platelet membrane. In addition, peptides presented by HLA-A2 molecules on human platelets have been isolated and sequenced, and shown to be identical to those commonly expressed by HLA-A2 on nucleated cells.<sup>6</sup> One ubiquitously expressed peptide is derived from the megakaryocyte-platelet-specific glycoprotein (GP) IX. Detectable HLA Class I surface molecules that were removed by treatment with pH 3.0 citrate could be restored only after addition of exogenous  $\beta_2$ -microglobulin and peptide ligand. This indicates that platelets themselves are not able to load HLA molecules with endogenous peptides, but that this occurs during HLA protein synthesis at the megakaryocyte stage.<sup>6</sup> It is clear that the vast majority of HLA Class I molecules on platelets are intrinsic transmembrane proteins synthesized and acquired at the megakaryocyte stage before platelets become cytoplasmic fragments.

Another controversy centers around the number of HLA Class I molecules expressed on the platelet surface. Estimates vary from approximately 15,000 to 120,000.<sup>9,10</sup> Using a direct assay with a <sup>125</sup>I-labeled monoclonal antibody specific for the Fc portion of human immunoglobulin G (IgG), the number of anti-HLA IgG molecules binding to specific HLA antigens at saturation ranged from 870 to 11,000 per platelet per antigen, depending on the antigen.<sup>10</sup> The same number of HLA Class I antigens on platelets were found in a study of density-fractionated platelets.<sup>11</sup> A quantitative competitive binding assay for platelet-associated HLA

found a much higher number of molecules per platelet (up to 120,000).<sup>12</sup> A mean of 81,587 molecules per platelet was found in 12 healthy individuals.

Several studies attempting to quantitate HLA on platelets demonstrated variable expression of specific antigens in different individuals.<sup>9,12,13</sup> The co-variation of the quantity of Bw4/6 antigens with specific private HLA-B antigens and the variability of B44 expression have been demonstrated repeatedly.<sup>9,13</sup> Platelets from the same individual also seem to differ in HLA antigen expression in that lower-density platelet cohorts were found to have 42% more HLA-A2 molecules than high-density cohorts.<sup>11</sup> More variability in A2, B35, and B62 antigen expression on platelets was measured among different individuals. Here again, the levels of specific antigens varied three- to fivefold among individuals and also on the platelets of the same individual.<sup>12</sup>

Only HLA Class I molecules appear to be present on the platelet membrane, and of the Class I loci, only the A and B antigens appear to be significant causes of alloimmunization in transfusion recipients. HLA-C antigens are also present and reported to be expressed at approximately the same density as A antigens;<sup>14</sup> however, transfused patients are rarely sensitized to HLA-C markers.<sup>15</sup> HLA Class II molecules are not generally found on platelet membranes. An apparent exception is a report of their detection on platelets of a patient with acute autoimmune thrombocytopenia.<sup>16</sup> Although Class II antigens have been detected on megakaryoblasts from patients with myeloproliferative diseases and in megakaryoblast colony-forming unit colonies in cultures of normal marrow, this was the first report of Class II antigen expression on circulating platelets. The implications of this finding in the pathogenesis of autoimmunity are intriguing.

### ABH Blood Group Antigens

The ABH blood group system is another important non-platelet-specific antigen system on platelets. Similar to HLA antigens, the amount of ABH substance on platelets varies not only from person to person but also among platelets in the same person. The variable distribution of group A substance has been

demonstrated on platelets using flow cytometry.<sup>17</sup> This distribution of ABH could explain why, in some platelet transfusions, there is a rapid destruction of a subset of ABO-incompatible cells followed by near-normal survival of the remaining cells.<sup>18</sup> Greater recovery was seen for group B platelets than for group A platelets, attributable perhaps to the lower levels of B antigens on donor platelets<sup>19,20</sup> and the lower levels of B-specific isoagglutinins in recipient plasma.<sup>18</sup> The number of B sites on platelets is considered to be about half the number reported for A. The number of A antigens per platelet estimated using an IgG murine monoclonal antibody specific for A substance and immunofluorescence flow cytometry showed a wide range (2,100 to 16,000 molecules/platelet) and was donor dependent.<sup>19</sup> Individuals of the subgroup A<sub>2</sub> have no detectable A antigens on their platelets<sup>19-22</sup> (Fig 11-1), and A<sub>2</sub> platelets can be substituted successfully for group O, even for transfusion to refractory group O patients with high-titer anti-A,B.<sup>22</sup>

For many years it was thought that most ABH antigens on platelets (as for HLA antigens) were absorbed from the plasma. Group O platelets incubated in group A or group B plasma could be shown to acquire soluble A or B substance detectable with anti-A or anti-B typing reagents in agglutination tests.<sup>23,24</sup> More recent studies show that a great majority of blood group A, B, and H antigens on platelets are expressed on many of the integral platelet membrane glycoproteins including GPIIb, GPIIIa, GPIV, GPV, PECAM-1, GPIb/IX, GPIa/IIa, and CD109<sup>20,21,25-28</sup> with GPIa/IIa expressing the most ABH substance per GP molecule and GPIIb and PECAM-1 expressing the majority of ABH per platelet.<sup>19,21</sup> A- and B-UDP sugars are attached in the golgi of the megakaryocyte to the Type II H precursor chains present on these platelet glycoproteins. Studies by several groups using monoclonal probes specific for Type II H chains have demonstrated that this membrane-intrinsic form of H substance is present on platelets and detectable in varying quantities according to the ABO group of the platelet donor [greatest in group O and A<sub>2</sub> platelets; less in groups B, A<sub>1</sub>, and A<sub>1</sub>B; and least in O<sub>H</sub> (Bombay)].<sup>19,20,24,25</sup> Although it is likely that a small, but significant, amount of ABH on platelets is acquired by absorption of glycolipids

**Figure 11-1.** Fluorescence histograms of platelets after incubation with a fluorescent-labeled monoclonal antibody specific for the blood group A antigen and immunofluorescence detection by flow cytometry. Group A<sub>2</sub> platelets are not distinguishable from group O platelets—no A antigens detected. Normal group A<sub>1</sub> platelets (middle histogram) show great variation in A antigen expression—broad histogram. Platelets from a Type 1 high expresser, like the normal expresser, give a broad histogram, but have overall higher levels (histogram shifted to the right) of A antigen. Type II high expressers have much higher levels and show a more homogeneous (narrow histogram at top) expression of A antigens per platelet.

expressing these antigens from the surrounding plasma, the majority, as for HLA, is intrinsically derived at the megakaryocyte stage.

One report from Japan described a group O patient who failed to respond to two of 12 ABO-incompatible HLA-matched platelet transfusions.<sup>20</sup> Further evaluation determined that the platelets in the two unsuccessful transfusions were from donors who expressed unusually high amounts of group B substance on their platelets, up to 20 times that found on group B, HLA-matched platelets that were successfully transfused in this patient. Follow-up investigation of 313 healthy Japanese blood donors revealed that approximately 7% had platelets that carried significantly more A or B antigen than the mean level of these antigens on platelets determined for the entire group. This phenotype, designated “high expresser,” was found to be inherited as a dominant trait and was unrelated to secretor phenotype, but did correlate with elevated serum glycosyltransferase activity.<sup>20</sup> These findings were confirmed in studies of 200 blood donors of European ancestry that further defined two subgroups of high expressers of platelet A<sub>1</sub> antigens, termed Type I and Type II.<sup>19</sup> Type I high expressers had elevated platelet A<sub>1</sub> antigen levels (about three times the normal expression), elevated serum A<sup>1</sup>-glycosyltransferase activity, markedly decreased H levels, and a heterogeneous distribution of A<sub>1</sub> antigens on individual platelets (Fig 11-1). Type II high expressers were characterized as having platelet A<sub>1</sub> antigen levels that averaged seven times the normal expression, higher A<sup>1</sup>-transferase activity than even Type I individuals, a homogeneous distribution of platelet A<sub>1</sub> antigens (Fig 11-1), and the majority of the antigens were found to be expressed on platelet GPIIb and PECAM-1.<sup>19</sup> This marked interdonor variability in A and B substance expression on platelets may offer an explanation for the nonuniform refractory response some patients develop to ABO-incompatible platelet transfusions (see below). The high expression phenomenon might also explain some cases of fetal and neonatal alloimmune thrombocytopenia (FNAIT). Curtis et al<sup>29</sup> described two group B infants with moderately severe thrombocytopenia at birth who inherited the Type II high expresser phenotype from their A<sub>2</sub>B father. They were born to a group O mother and the thrombocytopenia was apparently caused by transplacentally acquired, high-titer maternal IgG antibodies specific for blood group B. Antibodies against platelet-specific antigens could not be detected in the mother’s serum, and she later gave birth to a third infant who inherited the A<sub>2</sub> blood group instead of group B and was born with a normal platelet count. Two unresolved cases of suspected FNAIT, in which the fathers were both Type II high expressers of platelet A antigens, have also been reported.<sup>19</sup> Maternal/fetal ABO incompatibility should, therefore, be considered as a possible cause of FNAIT when antibodies reactive with platelet-specific antigens cannot be demonstrated.

### Other Antigens on Platelets

Other red cell antigens have been sought on the platelet surface. Ii, Lewis, and P antigens were demonstrated by using flow cytometry,<sup>26</sup> but Rh, Duffy, Kidd, Kell, and Lutheran-b were not detected by a two-stage radioimmunometric assay.<sup>30</sup>

Platelet GP IV or CD36 is expressed on various human cells including platelets, monocytes/macrophages, capillary endothelium, erythroblasts, and adipocytes.<sup>31,32</sup> Some apparently normal individuals lack CD36 on their platelets (Type II deficiency) or platelets and monocytes (Type I deficiency).<sup>33</sup> CD36 deficiency is common in Asian populations (3-11%)<sup>34</sup> and African populations (3-6%),<sup>35,36</sup> but is extremely rare in European populations (0.1%).<sup>35,37</sup> It is interesting that the most common gene mutations responsible for CD36 deficiency in those of Asian ethnicity and African ethnicity are different—C→T<sub>478</sub> point mutation in exon 4 (Asians<sup>33,38</sup>) and T→G<sub>1264</sub> stop mutation in exon 10 (Africans<sup>39</sup>). The higher frequency of CD36 deficiency in the former groups is thought to be related to their living in regions of the world where malaria is endemic. CD36 is a known receptor for red cells infected with *Plasmodium falciparum*; thus, it is believed that CD36 deficiency may afford partial resistance to malaria infection. However, one report suggests CD36 deficiency may actually be a risk factor for more severe forms of malaria infection.<sup>39</sup> Type I CD36-deficient people can become immunized from transfusion or pregnancy and make antibodies against CD36 that have been implicated in cases of multiple platelet transfusion refractoriness,<sup>34,40-42</sup> posttransfusion purpura (PTP),<sup>43</sup> and FNAIT.<sup>37,44</sup> Transfusion of CD36-deficient platelets has been reported to be successful in supporting patients immunized against CD36.<sup>37,41,42,44</sup>

CD109 is a 175-kD glycoprotein found on activated T cells, cultured endothelial cells, several tumor cell lines, and platelets.<sup>45</sup> Two alloantigens named Gov<sup>a</sup> (HPA-15b) and Gov<sup>b</sup> (HPA-15a), were found on platelet CD109,<sup>46</sup> and unlike most platelet-specific alloantigens, both alleles are highly expressed: 77% (HPA-15a) and 65% (HPA-15b) in those of European ethnicity (Table 11-1). Recent cloning and sequencing of the CD109 gene showed that it is a member of the α<sub>2</sub>-macroglobulin/complement gene family,<sup>47</sup> and a single nucleotide polymorphism A→C<sub>2108</sub> resulting in a Tyr:Ser<sub>703</sub> change in the protein defines the HPA-15a/b alloantigens.<sup>48</sup> The number of HPA-15 antigens expressed on platelets is small (<2000 molecules/platelet), and the antigens are labile in storage, making detection of HPA-15 antibodies difficult with the use of currently available serologic assays. These properties of HPA-15 would suggest that alloimmunization to these antigens may be underreported. Results from several studies using optimal assay conditions show that antibodies to HPA-15a or HPA-15b are uncommon (0.2-1.0%) in sera collected from women having given birth to infants affected with FNAIT, but more frequent in sera from patients with PTP (2%) and platelet transfusion refractoriness (3-4%).<sup>49-51</sup> These data suggest that HPA-15 may be as immunogenic as the HPA-5 antigen system, which is second only to the highly immunogenic HPA-1a (PI<sup>A1</sup>) platelet antigen system.

### Platelet-Specific Antigens

Antibodies recognizing platelet-specific antigens have been discovered in three clinical situations: mothers who give birth to infants with FNAIT; patients who develop dramatic thrombocytopenia

**Table 11-1.** Human Platelet Antigens

| Antigens                    | Other Names          | Phenotypic Frequency*                       | Glycoprotein Location/Amino Acid Change    | Nucleotide Substitution                   |

after blood transfusion (PTP); and patients who have received multiple transfusions. To date, 23 platelet-specific alloantigens have been described,<sup>52</sup> including localization to platelet surface glycoprotein structures, quantification of their density on the platelet surface, and determination of DNA polymorphisms in genes encoding for them (see Table 11-1). Several others have been described serologically, but genetic polymorphisms underlying these have not yet been determined.<sup>52</sup> Many of the recognized platelet alloantigens have been implicated in cases of FNAIT and

PTP (see Chapter 23). Some also have been determined to be relevant in platelet transfusion responses (see below).

## Alloimmunization to Platelet Antigens

### Immunization to HLA Antigens

Pregnancy and transfusion account for the development of HLA alloimmunization, with exposure to leukocyte-containing blood

components resulting in high rates of antibody formation in patients receiving multiple transfusions over time. Antibodies to Class I and not Class II HLA antigens can significantly affect the recovery and survival of transfused platelets because the former and not the latter are expressed on the platelet surface. Among the Class I antigens, the HLA-A and -B markers are most important. HLA-C antigens are also present and reported to be expressed at approximately the same density as A antigens,<sup>14</sup> but with rare exceptions,<sup>53</sup> antibodies to HLA-C antigens do not appear to significantly affect transfused platelets.

The natural history of HLA sensitization in patients receiving platelet transfusions for hematologic diseases was studied in 1978,<sup>54</sup> before the advent of widespread use of leukocyte-reduced blood components. Sixty-three patients requiring transfusions of whole-blood-derived platelets were followed. By actuarial analysis, 60% of patients who were not positive for lymphocytotoxic antibodies at the beginning of the study were projected to develop them as early as 10 days after primary exposure or 4 days after secondary exposure if they had been transfused or pregnant in the past. The number of transfusions was not related to the likelihood of immunization, an observation that was confirmed in a later study.<sup>55</sup> Patients who were alloimmunized at the beginning of the study had the poorest responses; those who did not develop HLA antibodies had the best responses; and those whose antibodies developed during the period of observation had intermediate responses.<sup>54</sup> A more recent study of platelet preparation methods to reduce alloimmunization in newly diagnosed acute myelogenous leukemia (AML) patients found a similarly high HLA sensitization rate of 45% in the control group (131 patients) who received unmodified, pooled, whole-blood-derived platelet transfusions over an 8-week period.<sup>56</sup> Rates of alloimmunization in studies involving hematology-oncology patients receiving non-leukocyte-reduced blood components are summarized in Table 11-2.

The risk of HLA alloimmunization is influenced by several patient and blood component factors. Transfused patients who were exposed previously to allogeneic HLA via transfusion or pregnancy developed HLA antibodies sooner—and, in many studies, more often—than patients who were not exposed previously.<sup>56,61,63,64</sup> In the Trial to Reduce Alloimmunization to Platelets (TRAP) study,<sup>56</sup> 62% of previously pregnant women with AML receiving untreated blood components (control product) developed lymphocytotoxic antibodies compared with 33% of those who had not been pregnant or transfused previously. There is general agreement that primary alloimmunization to HLA antigens is unlikely to occur before 3 to 4 weeks after the first transfusion in patients receiving multiple transfusions, and that HLA antibodies detected sooner than this most likely represent secondary immune responses in patients with remote histories of transfusion or pregnancy.

The underlying disease for which patients require platelet transfusion also influences the rate of HLA alloimmunization. In one study, patients undergoing induction chemotherapy for AML were more likely to become alloimmunized than were

**Table 11-2.** Platelet Alloimmunization in Multitransfused Patients Receiving Non-Leukocyte-Reduced Blood Components\*

<sup>‡</sup>Platelet-specific antibodies determined by a variety of methods.

patients being treated for acute lymphoblastic leukemia (ALL).<sup>65</sup> Although both groups of patients received similarly intensive chemotherapy and required roughly the same level of transfusion support, HLA antibodies developed in 44% of the AML group, compared with 18% of the patients with ALL ( $p = 0.00002$ ). The authors postulated that the difference may be attributable to either an additional immunosuppressive effect of the high-dose corticosteroids given in ALL or to a decreased immune responsiveness in patients with ALL caused by their underlying disease.<sup>65</sup> Others have corroborated this finding and have noted, moreover, that alloimmunization seems to occur sooner in patients with AML than in those with ALL.<sup>61,66</sup>

Except for prospective solid organ transplant recipients, there have been limited studies of HLA alloimmunization in patients who received transfusions of Red Blood Cell (RBC) or Whole Blood units, but interest in sensitization rates in such patients has increased, particularly with the advent of marrow transplantation for hemoglobinopathies such as sickle cell disease. Sensitization to HLA can inhibit platelet transfusion responses (see below), increasing the risk of thrombocytopenic hemorrhage in patients undergoing marrow transplantation who require multiple platelet transfusions. One study of chronically transfused sickle cell disease patients determined that 85% of those with at least 50 past red cell transfusions had evidence of platelet-reactive antibodies, predominately anti-HLA, whereas 48% of those with fewer than 50 past exposures were sensitized. HLA antibodies were not detected in those patients who had no

past exposure to transfusion.<sup>67</sup> A second study of 60 thalassemia patients examined the development of HLA antibodies and found that 32 (53%) were positive for HLA antibodies at baseline and seven more became sensitized in the follow-up period of 1 year, for a total HLA sensitization rate of 65%.<sup>68</sup> The type of blood components used for these two groups of patients may have contributed to these significant rates of alloimmunization. Details about the type of RBC transfusions provided in the first study were not provided in the report, but there did not appear to be any systematic attempts to give leukocyte-reduced units. Washed RBCs were routinely used in the second study, and these were estimated to have residual leukocyte content of  $>5 \times 10^6$  per unit. Therefore, neither study used RBC units that were leukocyte reduced to the extent that HLA sensitization would be lessened (see below).

Still other investigators have sought to document the rates of HLA alloimmunization in nonhematologic conditions requiring shorter periods of transfusion support. In a study of 117 cardiac surgery patients who were exposed to a single episode of RBC transfusion, 18% became sensitized.<sup>69</sup> In contrast, in a second study of 40 more seriously ill patients requiring placement of left ventricular assist devices as a bridge to cardiac transplant, 45% formed Class I HLA antibodies after a course of support that included a number of platelet as well as red cell transfusions. By actuarial analysis, 63% of those who received more than six transfusions of pooled whole-blood-derived platelets were projected to become HLA immunized.<sup>70</sup> This rate was strikingly similar to that of the patients with hematologic malignancies followed in the earlier study noted above.<sup>54</sup>

These studies documenting HLA alloimmunization in patients with non-hematologic-oncologic conditions suggest that apart from patients with ALL, most patients who require repeated red cell and/or platelet transfusions for treatment of their hematologic-oncologic condition are at risk of becoming sensitized to HLA at a rate similar to patients who would be assumed to have normally functioning immune systems.

Both the number and type of platelet products also have an impact on the sensitization rate. There is some disagreement in the literature regarding the importance of a dose-response relationship between platelet transfusions from different donors and the risk of alloimmunization. One study<sup>55</sup> failed to note such a relationship in a group of patients with AML receiving induction therapy. However, most of the patients in this study were exposed to more than 20 different platelet donors. Indeed, animal data<sup>71</sup> and human transfusion trials<sup>72</sup> suggest that with fewer donor exposures (ie, less than 20), there is a dose-response relationship between the number of exposures and the rate of alloimmunization. Fewer donor exposures can be achieved using apheresis platelets, which provide adequate doses of platelets from a single donor rather than pooled platelet concentrates. Alloimmunization can be delayed and perhaps reduced using this type of platelet product.<sup>72</sup>

Despite the established correlation between HLA antibodies and refractoriness to platelet transfusions (see below),<sup>73,74</sup>

lymphocytotoxic antibodies are frequently a transient complication in patients with hematologic-oncologic diagnoses requiring repeated platelet transfusions. Studies document that 17% to 67% of patients demonstrating these antibodies eventually lose them (Table 11-2).<sup>57,58,61,62,65,75,76</sup> The loss of lymphocytotoxic antibodies may be related to discontinuance of the antigenic exposure after marrow recovery or to switching of platelet transfusion support to HLA-matched homologous or frozen autologous platelets; however, it can occur despite continued exposure to whole-blood-derived platelet transfusions.<sup>62,65,75,77</sup> One interesting report<sup>58</sup> found that two-thirds of patients with decreasing anti-HLA reactivity despite continued exposure had developed antiidiotypic antibodies that reacted with the V region of anti-HLA IgG. In 36% of these patients, the serum actually inhibited binding of the patient's own prior anti-HLA to appropriate lymphocyte targets. A history of pregnancy did not affect the ability to produce these antiidiotypic antibodies. In contrast, those patients with persistently detectable anti-HLA did not develop antiidiotypic reactivity. HLA antibodies that are detected before the onset of transfusion therapy (ie, because of remote transfusion or pregnancy) tend to persist throughout the current period of transfusion therapy, whereas those antibodies that develop *de novo* during a transfusion support episode are more likely to be transient and to decrease in strength or disappear altogether despite continued exposure to allogeneic blood and platelets.<sup>62</sup>

The major route of primary HLA immunization in transfused platelets involves the donor leukocytes, and not the platelets, *per se*. In-vitro experiments showed that highly purified HLA-A2+ platelets could not induce allo-cytotoxicity in HLA-A2-negative peripheral blood mononuclear cells (PBMCs)—not even in the presence of helper HLA-A2-negative PBMCs.<sup>6</sup> Studies in humans show that when platelets devoid of white cells are transfused, primary immunization to HLA is very much delayed or does not occur at all,<sup>56,78-80</sup> whereas unmodified platelet concentrates are associated with a rate of HLA immunization ranging from 19% to 71% (Table 11-2). These observations implicate the leukocytes in both platelet and red cell transfusions as the source of primary immunization. Animal studies confirm that the production of major histocompatibility complex (MHC) antibodies requires recognition of Class II MHC molecules on donor antigen-presenting cells (APCs) by recipient T cells.<sup>81</sup> Moreover, animal studies also suggest that cell-free plasma supernatants from platelet concentrates stored without prior leukocyte reduction contain immunizing fragments thought to have been derived from white cells,<sup>82</sup> and these fragments are not significantly removed by leukocyte reduction filters.<sup>83</sup>

### Immunization to Platelet-Specific Antigens

The importance of platelet-specific antigen systems in the clinical syndromes FNAIT and PTP is undisputed and is described in Chapter 23. However, the relevance to platelet transfusion practice is controversial.

One kind of evidence implicating platelet-specific antibodies in the destruction of transfused platelets is the failure of some

transfusions of HLA-matched platelet concentrates given to patients who are refractory to whole-blood-derived platelets.<sup>78</sup> The poor responses to these platelet transfusions, despite HLA matching, indicates that other antigens, perhaps platelet-specific markers, are involved. The other kind of evidence involves the demonstration of platelet-reactive antibodies in the absence of lymphocytotoxic or anti-HLA activity. The conclusion drawn is that antibodies directed at platelet-specific antigens cause these reactions.<sup>77,78,84</sup> In contrast to antibodies to HLA antigens, the majority of platelet-specific antibodies identified using these strategies do not seem to be associated with poor transfused platelet recovery or survival.

With the advent of Phase III platelet antibody assays that detect platelet glycoprotein-specific reactions, it is now possible to assay directly the sera from multitransfused patients for platelet-specific antibodies. Using one such method, the monoclonal antibody-specific immobilization of platelet antigens (MAIPA) assay, one group documented that among 252 patients with hematologic-oncologic diagnoses receiving platelet transfusions, 20 (8%) developed platelet-specific antibodies with clear-cut specificities. The most common specificity in these patients was for HPA-5b in 10 of the 20; followed by HPA-1b in four; HPA-5a in two; and one each with HPA-2b, HPA-1a, HPA-1b plus HPA-5b, and HPA-1b plus HPA-2b.<sup>85</sup> This study confirmed earlier findings in the TRAP study; where 8% of the 530 patients formed platelet-specific antibodies, the most common being anti-HPA-1b.<sup>56</sup>

These two studies confirm the finding that many of the best-documented platelet-specific antibodies detected in patients who receive transfusions are directed against platelet antigens, the phenotypic frequencies of which are less than 30% in the blood donor population.<sup>56,69,85</sup> Therefore, it is difficult to attribute refractory responses to whole-blood-derived and/or HLA-matched platelet transfusions to these antibodies alone. Indeed, the majority of refractory patients with platelet-specific antibodies also have HLA antibodies. Alloimmunization to high-frequency platelet-specific antigens would be expected to present a major challenge in finding compatible platelets to support a patient requiring multiple platelet transfusions. Fortunately, these cases are extremely rare.<sup>69,86</sup>

Although there are a few well-documented cases of transfusion failures attributable to platelet-specific antibodies,<sup>87-89</sup> most platelet glycoprotein reactivity lacking definite specificity in transfusion recipients does not seem to influence transfusion responses.<sup>56,60,76,90</sup> One interesting report suggests that in a cohort of 106 patients who received multiple transfusions, 42% developed platelet-specific antibody, as detected by chloroquine-treated platelets in a platelet antibody screening test. Western blotting on these sera identified a number of bands to which IgG in the sera reacted, most commonly with molecular weights of 80 to 83 kD. In three of the sera the reactivity was not detected against thrombin-treated platelets, indicating that the antibodies might be directed against platelet GPV. No correlation with platelet transfusion responses was reported, and more than half of these "platelet-specific" antibodies were transient and not detected in follow-up testing.<sup>59</sup>

There have been several reports of platelet transfusion refractoriness caused by antibodies to GPIV (CD36) in patients who are GPIV deficient.<sup>34,36,40</sup> These patients are difficult to support because virtually all platelet products available for transfusion would be incompatible (GPIV positive). In several reports, GPIV-negative platelets were obtained by large-scale screening of donor populations with a higher frequency of GPIV deficiency (African), and transfusion of those platelets resulted in good platelet increments for the patients.<sup>40-42</sup>

### Immunization to Blood Group Antigens

Several studies have documented the effect of ABO incompatibility on platelet transfusion therapy. In an early report of 91 alloimmunized thrombocytopenic patients receiving 389 transfusions, 24-hour transfused platelet recovery was reduced by 23% in ABO-incompatible donor-recipient pairs (donor-group A, B, or AB; recipient-group O, B, or A).<sup>91</sup> In the aggregate, patients receiving multiple platelet transfusions have been thought to demonstrate a statistically significant but clinically unimportant decrease in platelet recovery after transfusion of ABO-incompatible platelets (especially group A). In a subset, however, as many as 20% of group O patients could develop severe refractoriness to group A platelets.<sup>20,22,92</sup> Failure to respond to HLA-matched platelet transfusions in the absence of nonimmune clinical factors should prompt the clinician to examine the ABO group of the recipient and of the donors to determine whether ABO incompatibility might be responsible for the unexpected poor responses.

Heal et al<sup>93</sup> have examined the importance of ABO blood groups in platelet transfusion therapy. Forty patients with hematologic diseases receiving platelet transfusions were randomly assigned to receive either ABO-identical or ABO-unmatched platelets. The responses in the group of patients receiving ABO-unmatched transfusions (that is, when either the recipient would be expected to have isoagglutinins to the ABH antigens on the transfused platelets, or the donor had such antibodies directed at the recipient's blood type) were significantly worse than those observed in patients receiving ABO-identical platelet transfusions. Analysis of the first 25 transfusions in each group showed a significantly better response in the ABO-identical arm [mean corrected count increment (CCI), 6600 vs 5200;  $p < 0.01$ ]. This effect was most important in the first 10 transfusion episodes and tended to predict subsequent alloimmunization and refractoriness to platelet transfusions.<sup>93</sup> This finding seemed to be in conflict with earlier reports in which a minor, clinically insignificant impact of ABO mismatching was observed. The newer data were then reanalyzed using the earlier definitions of ABO "compatibility" (the patient lacks isoagglutinins to recipient ABO antigens) and "incompatibility" (the patient has isoagglutinins reactive with donor ABO antigens). In the reanalysis, no benefits of ABO compatibility were detected,<sup>94</sup> suggesting that there is a significant negative impact of both major and minor ABO incompatibility in platelet transfusions. An increased frequency of refractoriness in patients receiving ABO-unmatched platelet

transfusions was also observed in a study of 26 patients (69% vs 58%;  $p = 0.001$ ).<sup>95</sup>

The mechanism for platelet destruction in platelet ABO-incompatible transfusions (the recipient has isoagglutinins against donor ABH) is not difficult to ascertain. Presumably, IgM and IgG anti-A or anti-B in the recipient interact with A and B substances on the transfused platelets, resulting in their premature exit from the circulation. Explanations offered for the biphasic survival curves of ABO-incompatible platelets include: 1) the elution of a portion of group A substance from the platelet surface; 2) the nonhomogeneous distribution of group A substance on donor platelets with resultant rapid destruction of the subpopulation with highest expression; and 3) secondary injury to a subset of transfused platelets caused by the reaction between anti-A isoagglutinins and A red cells in the platelet concentrate.<sup>18,19</sup>

The suboptimal response of the *plasma*-incompatible transfusions (the donor has isoagglutinins against recipient ABH) is more difficult to explain. One report postulates that immune complexes involving soluble recipient ABH substance and donor A or B antibodies form. These immune complexes secondarily interact with the transfused platelets via the  $\text{Fc}\gamma\text{RII}\alpha$  receptor, or the complement receptors  $\text{cC1q-R}$  and  $\text{gC1q-R}$ , and mediate their destruction.<sup>96</sup> Some experimental evidence supports this theory, in that anti-A has been detected in an immune complex fraction of group A recipient plasma after transfusion with group O platelets, and these immune complexes bind to IgG  $\text{Fc}\gamma\text{RII}\alpha$  and the  $\text{cC1q-R}$  and  $\text{gC1q-R}$  receptors on group O platelets.<sup>96</sup> Indeed, in at least one study, plasma-incompatible platelet transfusions were even less effective than platelet-incompatible transfusions.<sup>93</sup> Immune complexes involving other plasma proteins such as C2, C4, albumin, and fibrinogen likewise have been implicated in refractory responses to platelet transfusion.<sup>96-98</sup>

Adverse effects of ABO-incompatible platelet transfusions may extend beyond reducing platelet transfusion increments and stimulating alloimmunization. In one retrospective cohort study of cardiac surgery patients, those patients who received mismatched ABO platelets were compared with those who received ABO-identical platelets. The mismatched group experienced significantly longer hospital stays, more days of fever, increased health-care costs, and more red cell transfusions. Other negative outcomes including mortality and time in the intensive care unit were also increased in the mismatched group, but these differences failed to reach statistical significance. The authors postulated that the negative effects of ABO-mismatched platelet transfusions were again related to immune complexes that stimulated inflammatory pathways, leading to increased postoperative morbidity in these patients.<sup>99</sup> Although intriguing, these findings have yet to be confirmed by other groups. In fact, a later retrospective study involving more cardiac surgery patients failed to identify negative effects of ABO-mismatched platelet transfusions.<sup>47,100</sup>

An indisputable risk of ABO plasma-incompatible transfusions, particularly those involving group O donors and non-group-O

recipients, is acute hemolytic transfusion reaction caused by high-titer isoagglutinins in the donor plasma. With the marked shift from pooled whole-blood-derived platelet concentrates to apheresis platelets, the risk of transfusing large volumes of ABO-incompatible plasma with potent ABO isoagglutinins is increased. Many blood providers have taken steps to alleviate this risk by reducing the volume of incompatible plasma or screening group O donors for high-titer isoagglutinins.<sup>101</sup>

## Transfusion Refractoriness

*Alloimmunization* is an immune response in a recipient stimulated by foreign donor cells. In the platelet transfusion setting, these responses involve the production of antibodies directed at donor platelets. *Platelet refractoriness* describes a clinical condition in which patients do not achieve the anticipated platelet count increment from a platelet transfusion. It is possible to be alloimmunized to platelet antigens without being refractory to platelet transfusions, and also to be refractory to platelet transfusions without being alloimmunized. *Alloimmune refractoriness* occurs when the level of alloimmunization, as measured by the breadth of antibody response to platelet antigens, is sufficient to affect the majority of randomly selected platelet products.

The detection of alloimmunization is straightforward using standard laboratory techniques to detect antibodies in the patient's serum reactive with HLA or platelet-specific antigens. In contrast, the definition of the refractory state is less precise.<sup>102,103</sup> A standard dose of platelets (six units of pooled whole-blood-derived platelet concentrates or one apheresis platelet unit) generally increases the platelet count by about 5000 to 7000 platelets/ $\mu\text{L}$ /unit in a 70-kg adult. This would result in a posttransfusion increment of about 30,000 to 40,000 platelets/ $\mu\text{L}$  1 hour after platelet transfusion.<sup>102</sup> The TRAP study defines the refractory state as a CCI [normalizing transfusion responses for patient blood volume estimated using body surface area (BSA) and platelet dose] of <5000 after two sequential ABO-compatible platelet transfusions.<sup>56</sup> Another measure of platelet transfusion response is the percent platelet recovery (PPR). Similar to the CCI, the PPR uses platelet dose and patient blood volume; the latter is estimated using the patient's body weight in kg rather than BSA. Studies in normal autologous platelet donors show an average 1 hour PPR of approximately 66%.<sup>74</sup> Recovery less than 20% to 30% at 1 hour after the transfusion indicates a refractory response.<sup>103</sup>

The PPR and CCI have been criticized as measures of posttransfusion platelet response because both calculations, which correct for patient size and dose of platelets, fail to provide information about the impact of these two variables on the posttransfusion platelet count increment.<sup>104</sup> For example, a small dose of platelets given to a large patient might result in an acceptable PPR or CCI but a poor absolute platelet count increment. In order to better examine the impact of patient size and platelet dose, as well as other factors that affect the quality of the platelets

(storage time, postcollection manipulations, etc) regression analysis of posttransfusion platelet increments is suggested. It is also recommended by the same authors that because both the CCI and PPR calculations are biased in favor of platelet preparation techniques that provide fewer platelets, neither should be used to define platelet refractoriness. Regardless of which method is used, the actual platelet increment in patients who are highly refractory because of alloimmunization is extremely small to negligible.

It is important to recognize that refractoriness does not necessarily imply alloimmunization. Indeed, the major cause of refractoriness to platelet transfusion is not alloimmunization, but rather nonimmune factors that result in shortened platelet survival and/or markedly decreased platelet recoveries in patients who receive transfusions.<sup>74,105</sup> Multiple linear regression analysis has been used to demonstrate a number of factors related to clinical refractoriness including HLA alloimmunization as well as splenomegaly, amphotericin therapy, disseminated intravascular coagulation, or recent allogeneic marrow transplantation.<sup>106</sup> Other studies have also demonstrated factors with negative effects on transfused platelets such as sepsis, fever, and drugs.<sup>107,108</sup> Individual patients may have significantly different responses to the same nonimmune causes of refractoriness, with some patients experiencing minimal impact and others having markedly impaired response to platelet transfusions. Some patients, particularly those with multiple clinical complications (sepsis, fever), appear to respond poorly to platelets that are approaching the end of the recommended storage interval (5 days). Such patients may experience an improvement in their platelet response after receiving “fresh platelets”—platelets that were collected less than 48 hours earlier.<sup>102,109</sup>

A cause of non-alloimmune refractoriness that can be overlooked in the infected, neutropenic, hematology-oncology patient is development of drug-dependent platelet-reactive antibodies. Vancomycin, a drug often used to treat serious gram-positive bacterial infections in such patients, has been implicated. Drug-dependent platelet-reactive antibodies should be suspected in refractory patients when there is no evidence of alloimmunization or they fail to respond to HLA-selected platelets, and the refractory responses are temporally related to therapy with a drug.<sup>110,111</sup>

## Treatment of the Refractory Alloimmunized Patient

The refractory state in which patients fail to benefit from whole-blood-derived platelet transfusions develops in 13% to 100% of patients receiving multiple transfusions.<sup>56,61,112,113</sup> The refractoriness, if related to HLA immunization, can be transient or persistent. Several approaches can be considered to provide such patients with adequate platelet support—including provision of HLA-matched platelets, platelets selected by crossmatch tests, and maneuvers to reduce alloimmunization.

## Platelet Selection

### HLA-Selected Platelet Transfusions

A standard approach to supporting a patient who is refractory to whole-blood-derived platelet transfusions is to supply HLA-matched apheresis platelet concentrates. Because the primary cause of immune refractoriness to platelet transfusion is alloimmunization to Class I HLA antigens, it follows that avoidance of incompatible HLA specificities should result in a more successful platelet transfusion response. In practice, up to 90% of alloimmune refractory patients benefit from an HLA-matched product. This was first demonstrated in a study that showed patients who were refractory to platelets from unselected donors could be successfully supported by HLA-matched family member platelet transfusions.<sup>114</sup>

Certain “private” HLA antigens can be segregated into so called cross-reactive groups (CREGs), defined by antibodies directed against shared “public” determinants.<sup>115</sup> Indeed, these shared determinants are the basis for the cross-reactivity and are different than the private determinants, which account for the highly polymorphic HLA system. Selection of platelet donors with antigens in the same CREGs as the antigens in the patient, so called cross-reactive antigens, was demonstrated to be nearly as successful in supporting alloimmune platelet refractory patients as HLA-identical transfusions.<sup>116</sup> This appeared to be due to the relative inability of the patient’s immune system to recognize these cross-reactive antigens as different, thereby greatly increasing the number of potentially successful platelet donors in a given pool.<sup>117,118</sup>

A disadvantage of relying on HLA-matched platelets, even using selective mismatching with CREG associations, is that a pool of 1000 to 3000 or more HLA-typed potential apheresis donors is generally necessary to find sufficient HLA-compatible matches to support a typical patient.<sup>119</sup> Moreover, donor selection on the basis of HLA type can lead to the exclusion of donors whose HLA types, although different from that of the recipient, may still be effective.<sup>120</sup>

In alloimmune refractory patients, the best increases in CCI occur with the subset of grade A and B1U or B2U HLA-matched platelets, but platelets mismatched for some antigens (eg, B44, 45) that are poorly expressed on platelets can also be successful.<sup>120</sup> Although alloimmunized patients with high panel-reactive antibody (PRA) values benefit only from platelet products that lack any incompatible Class I antigens (match grades A, B1U, B1X, B2U, B2UX, see Table 11-3), patients with lesser degrees of sensitization can sometimes benefit from less well-matched platelets. In one study, 73% of HLA single-antigen mismatched platelet transfusions (grade C match) were successful when provided to patients with PRA values less than 60%.<sup>121</sup> On the basis of these data, some experts suggest extending donor searches for alloimmunized patients to include single-antigen mismatches (grade C matches), particularly if the PRA is less than 60%.

Even with the additional donors that the above cited studies may make available, HLA-matched platelets are frequently unavailable for many refractory patients. Use of the patient’s HLA

**Table 11-3.** Classification of Donor/Recipient Pairs on the Basis of HLA Match

|      |                                                                                                     |
|------|-----------------------------------------------------------------------------------------------------|
| A    | All four antigens in donor identical to those in recipient.                                         |
| B1U  | Only three antigens detected in donor; all present and identical in recipient.                      |
| B1X  | Three donor antigens identical to recipient; fourth antigen cross-reactive with recipient.          |
| B2U  | Only two antigens detected in donor; both present and identical in recipient.                       |
| B2UX | Only three antigens detected in donor; two identical with recipient, third cross-reactive.          |
| B2X  | Two donor antigens identical to recipient; third and fourth antigens cross-reactive with recipient. |
| C    | One antigen of donor not present in recipient and non-cross-reactive with recipient.                |
| D    | Two antigens of donor not present in recipient and non-cross-reactive with recipient.               |

antibody specificity as an additional basis for selection of platelet products has been demonstrated to increase the numbers of potentially compatible donors. Antibody specificity prediction (ASP), allows procurement of platelet products from donors who lack HLA antigens to which the patient has raised an antibody. Such platelet donors often have frank mismatches for some or all of the Class I antigens in the refractory patient. One study compared ASP platelets to those selected by standard HLA matching criteria and by platelet crossmatching. HLA-matched, crossmatched, and ASP-selected platelet transfusions were found to have similar platelet recoveries, while randomly selected control platelets had significantly lower PPR. For 29 alloimmunized patients, the mean number of potential donors found in a file of 7247 HLA-typed donors was only six when grade A HLA matches were required and 39 when BU matches were added. However, 1426 potential donors (20% of total) were identified by the ASP method. The authors suggest that careful HLA antibody specificity identification could greatly enhance the number of potential donors by identifying nonmatched products that lack these HLA antigens.<sup>122</sup> Other investigators using a computerized analysis of the lymphocytotoxicity (LCT) assay for private and public HLA Class I epitopes in platelet recipients confirmed that there is value in carefully identifying HLA antibody specificities, allowing selection of many more donors by simply avoiding the HLA antigens against which the antibodies are directed.<sup>123</sup>

Regardless of the method planned to select HLA-compatible platelets for alloimmune refractory patients, the HLA type of the patient should be determined before myeloablative therapy, and HLA antibody screening should be obtained periodically (preferably weekly) so that HLA-selected platelets can be provided when and if alloimmune refractoriness is diagnosed.

In a small number of patients who fail to respond to HLA-matched platelets and for whom no other nonimmune explanation can be found for refractoriness, platelet-specific

alloantibodies may be the cause of the poor platelet increments. Approximately 7% to 8% of platelet multitransfused patients develop platelet-specific antibodies.<sup>56,124</sup> Many of these patients are also alloimmunized against HLA. One recent report described six patients who were highly alloimmunized to HLA but also had human platelet alloantibodies to HPA-1b or HPA-5b.<sup>125</sup> These patients were successfully supported with a pool of HLA-matched platelets that were typed for the HPA antigens.

### Platelet Crossmatching

Although the use of HLA-matched and selectively mismatched donors provides support for the majority of patients who are alloimmune refractory, there are limitations to this strategy. As many as 20% to 25% of refractory patients fail to respond adequately to HLA-matched platelets. In the absence of nonimmunologic clinical factors that can decrease platelet transfusion recovery and survival, these failures might be explained by ABO incompatibility, platelet-specific antibodies, and undetected HLA incompatibility.<sup>126</sup> These immune causes of transfusion failure cannot be addressed with HLA matching alone. In addition, many facilities do not have access to adequately sized HLA-typed donor files, so that alternative methods of selecting compatible platelets for alloimmune refractory patients must be considered.

Many platelet and leukocyte antibody detection methods have been assessed as platelet compatibility tests. One method that has gained wide acceptance is the commercially available solid-phase red cell adherence (SPRCA) assay. The test is rapid and sensitive, particularly for the detection of HLA antibodies, and is therefore suitable for routine platelet crossmatching.<sup>127,128</sup> Good correlation between test results and posttransfusion platelet counts have been achieved with the SPRCA assay.<sup>128-131</sup>

To date, few studies have compared the efficacy of HLA matching to that of platelet crossmatching for supporting alloimmune refractory patients. One multicenter study<sup>132</sup> compared HLA selection and platelet crossmatching using three different techniques—the indirect immunofluorescence test for platelets, an enzyme-linked immunosorbent assay (ELISA), and a radioimmunoassay were used to test apheresis platelet concentrates. At least one pair of apheresis platelet components was transfused to each patient. One unit was selected by HLA matching and the other by crossmatching. The results of the two donor selection methods were compared. Although the difference was not statistically significant, HLA-selected transfusions were slightly more successful than the crossmatch-selected transfusions when 1-hour posttransfusion recoveries were compared. However, after 24 hours the HLA-selected transfusions were significantly more successful. This was even more apparent when only A and BU matches were considered. The authors concluded that when HLA-typed donors are available, A or BU matches were preferable to randomly chosen products selected by any of the crossmatch methods used in their study. The quality of the HLA match is paramount to the transfusion success rate as shown in a study in which HLA matching apparently did not improve on the success rate of crossmatch-selected platelets.<sup>130</sup> Here, however,

the HLA-selected platelets were seldom of A or BU match grade with the recipients.

The degree to which a patient is alloimmunized has an impact on the success of platelet transfusions selected by crossmatching assays. Using platelet concentrates from whole blood units and a radiolabeled antiglobulin technique, one study found that 70% of transfusions selected by the test were successful in supporting moderately alloimmunized patients.<sup>133</sup> In contrast, others found that only 41% of transfusions selected by either an ELISA or the SPRCA test were successful in a highly alloimmunized group of leukemia patients.<sup>129</sup> Moreover, only 15% to 24% of platelet concentrate segments tested were negative in these tests, indicating that many whole-blood-derived platelet concentrates had to be screened in order to identify sufficient compatible platelets to pool for the transfusions. In the latter study, the most compatible platelet products selected by crossmatching were less successful in supporting the refractory patients than were HLA-matched platelets (mean CCI of 4300 to 9500 with “crossmatched-compatible” platelets; mean CCI of 17,100 with HLA-matched platelets).<sup>129</sup>

A more recent report of an automated version of the SPRCA assay demonstrated how large numbers of platelet concentrates could be routinely tested to identify compatible pools of whole-blood-derived platelets for refractory patients. In this study, a daily inventory of 100 to 120 whole-blood-derived buffy coats were assessed to provide platelet support for 40 consecutive alloimmune refractory patients.<sup>134</sup> Platelets collected from routinely obtained donor samples, rather than from the concentrates themselves, were tested with patient serum. Using this system, up to 94 different platelet samples could be tested for each patient. Buffy coat platelets from five or six donors whose platelets yielded negative results were then pooled and transfused to the patient. The authors were able to demonstrate significant improvement in both 1-hour and 18- to 24-hour increments with the crossmatch-negative pools compared with random pools given in the month before the patients’ meeting the criteria for refractoriness in the study (two consecutive 1-hour post-transfusion CCIs <5000).

The cost of the kits for achieving each “successful” platelet increment (posttransfusion platelet count >10,000/ $\mu$ L) was about 450 euros. This did not include any costs for labor or administration of the crossmatching program. The authors noted that although the automated crossmatching strategy allowed rapid identification of compatible platelet pools from available inventories, a larger study, preferably a randomized controlled trial of this method vs HLA matching, would be necessary to confirm the value of this approach and more accurately capture the costs involved.

Experience using both the LCT assay and the SPRCA for analyzing antibodies to HLA and platelet antigens has been reported to aid in identifying patients who will benefit from either HLA-selected or crossmatch-selected platelets.<sup>135</sup> With the LCT assay, investigators found that if the PRA was <70%, adequate transfusion responses were seen in approximately 80% of

transfusions that were selected simply by HLA criteria (ASP and CREGs). However, when the PRA was >70%, only about 25% of patients did well. When analyzing the results using crossmatching, patients with PRAs <80% did well with crossmatch-selected platelets; but when the PRA was 80% to 100%, there were many failures with the crossmatch-compatible products. It was suggested that at high levels of alloimmunization, crossmatching misses significant antibodies. A recent report compares the monoclonal antibody-specific immobilization of platelet antigens (MAIPA) assay to the LCT test for the detection of HLA antibodies. This study showed the MAIPA assay to be more sensitive, detecting apparent HLA antibodies missed by the LCT assay. Moreover, these MAIPA-positive, LCT-negative HLA antibodies may be clinically relevant and affect the posttransfusion platelet count increment.<sup>136</sup> The advent of more sensitive methods for screening patients for HLA antibodies, when used to identify patients who are alloimmune refractory to platelet transfusions, may prove to be superior to the LCT assay for this purpose.<sup>137</sup>

With the considerable effort and expense entailed in their procurement, HLA- or crossmatch-selected platelet products should be reserved for those refractory patients who have definite evidence of alloimmunization either by HLA or platelet antibody testing. In the latter case, alloimmunity can be established in the context of performing a platelet crossmatch test if at least some of the platelet products tested with patient serum are reactive in the assay. In practice, when refractoriness is first recognized during use of random donor platelets, provision of a few HLA-selected products may be warranted before the results of definitive testing to document alloimmunization are available. In the event that such testing fails to document alloimmunity (ie, no HLA- or platelet-reactive antibodies are identified), then support with randomly selected platelet products should resume.

The one report of improving platelet transfusion increments by use of crossmatch-compatible platelets without establishing that the refractory patients were indeed alloimmunized, actually excluded all patients who did not have evidence of platelet-reactive antibody in the crossmatch test and therefore was consistent with the recommendation to document alloimmunity to platelets before committing patients to receive either HLA-matched or crossmatched platelets.<sup>138</sup>

Although the incidence of platelet-specific antibodies causing patients to be refractory to most or all attempted platelet transfusions is very small, this possibility should be investigated when most of the attempted crossmatches are positive or when HLA-matched transfusions fail. If platelet-specific antibodies are present, donors of known platelet antigen phenotype or family members, who may be more likely to share the patient’s phenotype, should be tested.

### Overcoming Established Alloimmunization

Strategies attempting to reverse established alloimmunity to HLA antigens have met with only limited success to date. Previously attempted methods include: 1) methods to temporarily block the immune-mediated destruction of platelets; 2) suppression

of the immune response to decrease the production of relevant antibodies; and 3) provision of modified platelets or alternative (nonplatelet) hemostatic compounds.

### Blocking Immune Destruction of Platelets

Several studies investigated the utility of high-dose intravenous immunoglobulin (IVIG) to increase the platelet count in association with transfusion in refractory patients. The results of these studies have been highly variable.<sup>139-141</sup> Initial uncontrolled trials were conducted with very small numbers of patients using whole-blood-derived platelet transfusions. Studies using somewhat larger numbers of patients have been inconclusive. One study treated 11 refractory patients with 0.4 g/kg/day for 5 days with no benefit in the 1-hour posttransfusion recoveries.<sup>139</sup> Another found a modest beneficial effect of IVIG in a randomized placebo-controlled trial with 12 alloimmunized thrombocytopenic patients.<sup>140</sup> The same donor platelets were used before and after treatment with IVIG. The posttreatment 1-hour CCIs in the IVIG group (seven patients) were significantly greater than in the five patients receiving placebo treatment—8413 and 1050, respectively. However, by 24 hours after the transfusion, there was no residual benefit of IVIG. The authors concluded that the use of IVIG could not replace HLA-matched platelet transfusions in supporting alloimmunized refractory patients.

Using very high-dose (6 g/kg) IVIG, other investigators could reverse the refractory response in some patients who failed to respond to HLA-selected LCT-compatible platelet transfusions.<sup>141</sup> Before treatment with IVIG, the patients had been refractory to HLA-matched platelet products. Following therapy, 13 of 19 patients responded with improvement in 1-hour posttransfusion platelet count increment using HLA-matched platelets. Those patients with PRAs <85% responded better than those who were more highly alloimmunized.

After initial reports of success with IVIG to improve platelet responses in immune refractory patients, other investigators examined the role of Rh Immune Globulin (RhIG) infusions in preventing refractory responses from developing. In this randomized control trial, patients treated with weekly intravenous RhIG infusions had rates of refractoriness similar to those treated with placebo, indicating that this form of reticuloendothelial system blockade was not helpful in preventing refractory responses.<sup>142</sup>

### Suppression of the Immune Response to Decrease Antibody Production

Other strategies evaluated to overcome the platelet refractory state include use of vinblastine-loaded platelet transfusions,<sup>143</sup> treatment with cyclosporin A,<sup>144</sup> immunoabsorption using staphylococcal protein A columns, and plasmapheresis.<sup>145,146</sup> Each strategy has had some limited success.

### Provision of Modified Platelets or Alternative (Nonplatelet) Hemostatic Compounds

A novel approach has been developed involving transfusion with acid-treated whole-blood-derived platelets. Treatment of platelets

with citric acid modifies HLA Class I antigens on the platelet surface, making them less recognizable to the immune system.<sup>4,5</sup> A small number of patients have been treated with such products but with very limited success and studies are still ongoing.

Several potential platelet substitutes are currently being investigated. These include lyophilized platelets, infusible platelet membranes, thromboerythrocytes, and thrombospheres. Whether these will have clinical relevancy remains for future investigation.<sup>147,148</sup>

The role of platelet growth factors in the treatment of patients who have undergone highly myeloablative therapy is not totally defined. Studies support the use of both interleukin (IL)-11 and recombinant human thrombopoietin in shortening the duration and blunting the severity of thrombocytopenia after chemotherapy. However, toxicity and the development of thrombopoietin neutralizing antibodies have halted trials using the latter agent.<sup>149</sup> Less success has been demonstrated with these agents in the setting of myeloablation with stem cell transplantation. These drugs may play more of a role in preventing rather than managing platelet refractoriness because responsive patients would require fewer platelet transfusions. Currently, only one product, recombinant human IL-11 (Neumega, Genetics Institute, Cambridge, MA), is licensed in the United States for the prevention of severe thrombocytopenia and the reduction of the need for platelet transfusion following myelosuppressive but not myeloablative chemotherapy in patients with nonmyeloid malignancies.<sup>150,151</sup>

---

## Prevention of Alloimmunity

Alloimmunization to HLA antigens appears to be transient in some patients; however, for most patients, once the alloimmune refractory state is established, it is very difficult to reverse. Therapy for the refractory state is expensive and frequently requires more transfusions than therapy for patients who are not refractory.<sup>152,153</sup> Therefore, attention has turned to prevention of alloimmunization as a more practical way to ensure continued successful platelet support. Figure 11-2 represents an approach to managing platelet transfusions that encompasses both prevention of and platelet selection for refractoriness to platelet transfusions.

Several strategies have been used to prevent alloimmunization to platelet products. Antigenic exposure can be limited by the use of apheresis platelet transfusions. Both animal studies and trials involving humans have shown that HLA alloimmunization can at least be delayed (if not reduced) by the provision of apheresis platelets. Apheresis platelet products provide adequate platelet doses for adults from single donors rather than pools of whole-blood-derived platelet concentrates, which typically expose patients to five to eight different donors.<sup>72</sup> Indeed, the majority of platelet transfusions in the United States are now provided from apheresis collections, in part in order to reduce the rates of alloimmunization and refractoriness.<sup>154</sup>

A second promising method is treatment of blood components with ultraviolet B (UVB) irradiation.<sup>155</sup> UVB irradiation prevents the interaction of donor dendritic cells with recipient T

### Algorithm for Managing Platelet Support

**Figure 11-2.** Algorithm for managing platelet support.

lymphocytes, which is the major route of primary HLA alloimmunization to platelet transfusions. Additional studies have provided evidence that the inability of donor and recipient immune cells to interact following UVB irradiation may indicate a state of immunologic tolerance to a blood transfusion. Preliminary studies with UVB-treated platelets in thrombocytopenic patients

with cancer demonstrated a reduced rate of HLA antibody formation. The TRAP study found that UVB irradiation could reduce the incidence of alloimmunization and platelet refractoriness.<sup>56</sup> Despite its effectiveness in reducing alloimmunization, UVB irradiation of platelet products is currently not approved for use in the United States.

Because the major pathway of primary alloimmunization against HLA Class I involves antigen presentation in the context of HLA Class II molecules on donor APCs,<sup>81</sup> significant work has centered on removing leukocytes from the donor blood components as a means of preventing alloimmunization. Clinical trials have demonstrated that reduction of leukocytes to a level  $<5 \times 10^6$  in blood components is sufficient to reduce the risk HLA alloimmunization.<sup>56,78-80</sup> Removal of leukocytes is most often accomplished by passing the components through third-generation leukocyte reduction filters. These filters remove the leukocytes by a combination of adhesion and pore size and are capable of producing a three- to four-log reduction in leukocytes. This process results in products that easily meet the Food and Drug Administration's requirement for leukocyte-reduced blood components ( $<5 \times 10^6$  total leukocytes). Although such filters can be used at the bedside, the preferred method is prestorage leukocyte reduction in the laboratory. The latter allows leukocyte-reduced blood components to be manufactured according to good manufacturing practice regulations with well-defined quality control. It also prevents leukocyte fragments, shown to be capable of passing through filters and sensitizing recipients in animal studies, from accumulating in stored blood components.<sup>82,83</sup> Leukocyte reduction of platelet products can be accomplished using either of two techniques. With apheresis technology (by which the equivalent of six whole-blood-derived platelet concentrates can be obtained from a single donor) the product is leukocyte reduced as it is collected. Alternatively, pools of whole-blood-derived platelet concentrates can be filtered before a 5- to 7-day storage period.

The majority of trials to date support the use of leukocyte reduction to reduce alloimmunization to blood components. In 1998, 18 clinical trials (some randomized controlled and some nonrandomized) using leukocyte-reduced red cells and platelets to prevent alloimmunization were reviewed.<sup>156</sup> Fourteen of the trials showed positive results using leukocyte-reduced blood to prevent HLA alloimmunization and platelet refractoriness, whereas three of the trials showed no benefit. In addition, a recent meta-analysis of eight randomized controlled trials demonstrated a clear, protective effect of white cell reduction in the prevention of HLA alloimmunization and platelet refractoriness.<sup>157</sup>

The most definitive clinical trial demonstrating the importance of leukocyte reduction in the prevention of alloimmunization and refractoriness to platelet transfusion was the TRAP study.<sup>56</sup> This trial compared four groups of patients: 1) patients receiving pooled platelet concentrates (control); 2) patients receiving leukocyte-reduced (filtered), pooled platelet concentrates; 3) patients receiving UVB-irradiated pooled platelet concentrates; and 4) patients receiving filtered platelets obtained by apheresis. All patients received leukocyte-reduced red cell components. Evidence of alloimmunization (by LCT assay) developed in 45% of the control group compared with 17% to 21% in the treated groups ( $p \leq 0.0001$  for each treated group as compared with controls). There were no differences among

the treated groups in rates of alloimmunization. In the control group, 13% of patients became refractory compared to 3% to 5% in the treated groups ( $p \leq 0.03$  for each treated group as compared with controls). Individual treatments did not differ.

Several other important findings were noted in the TRAP study: 1) Clinical outcomes were similar in all four groups of the study with no significant difference in the incidence of deaths caused by hemorrhage. 2) The incidence of refractoriness to platelet transfusions was low in the control group relative to previous reported studies. 3) Patients who had never been pregnant had a lower risk of developing refractoriness than those who had previous pregnancies. 4) Only about 8% of the patients in the study developed platelet-specific antibodies. The treatment groups had no impact on this type of immunization. 5) The presence of platelet-specific antibodies did not correlate with refractoriness. 6) A small percentage of patients in all groups were refractory to platelet transfusions yet did not have lymphocytotoxic antibodies. Most likely, these patients had either clinical factors or drug-related causes of refractoriness.

A more recent, large, single-institution, retrospective study was reported from Canada, where universal leukocyte reduction (ULR) of blood components was instituted between 1997 and 1999.<sup>57</sup> The study examined rates of alloimmunization and refractoriness in cohorts of patients undergoing chemotherapy for acute leukemia or stem cell transplantation before and after the introduction of ULR. Investigators found that alloimmunization to HLA, alloimmune refractoriness, and the need for HLA-matched platelets were all significantly reduced in the ULR cohort. Even taking into account the lower numbers of platelet transfusions given to the ULR patients, which likely resulted, in part, from changing the platelet transfusion trigger from 20,000/ $\mu$ L to 10,000/ $\mu$ L, leukocyte-reduced transfusions remained a significant independent variable driving the lower rates of alloimmunization and refractoriness in this patient population.

From the studies cited above, it is clear that both leukocyte reduction and UVB irradiation are capable of reducing the incidence of alloimmunization and platelet refractoriness. At the present time, leukocyte reduction of blood components is the most practical means of reducing the incidence of alloimmune platelet refractoriness and should be recommended for all patients at risk.

The identification and characterization of platelet antigens together with increased understanding of immunologic responses to these markers have been crucial in developing optimal platelet transfusion practices. Our understanding of the causes and mechanisms of both the immunologic and nonimmunologic aspects of the refractory response allows for improved strategies in the care of the potentially refractory patient.

---

## Summary

Platelets express a variety of immunogenic markers on the cell surface. Some of these antigens are shared with other cell types

as in the case of HLA antigens, which are shared with virtually all nucleated cells in the body. Other antigens are observed to be essentially platelet specific. This chapter has reviewed the antigens expressed on the platelet, the various patterns of alloimmunization to these antigens, and the impact on platelet transfusion responses. Strategies to treat and prevent alloimmunization were also summarized.

## Preparation, Preservation, and Storage of Platelet Concentrates

**Ralph R. Vassallo, Jr.**

Heritage Division Chief Medical Officer, American Red Cross Blood Services, and Adjunct Associate Professor of Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, USA

Platelets may be obtained for transfusion by centrifugation of 450 to 500 mL of whole blood drawn in citrate-based anticoagulants or by various apheresis instruments that selectively collect platelets over 50 to 100 minutes. In the United States, platelets collected by either method are suspended in autologous plasma at an average concentration of  $1500 \times 10^9/\text{L}$ , six times the mean blood platelet concentration. Modern manufacturing techniques isolate 70% to 75% of the platelets from a whole blood donation ( $0.6\text{--}1.2 \times 10^{11}$ ).<sup>1</sup> Pooling of 4 to 6 whole-blood-derived (WBD) units provides a single transfusable adult dose. Alternatively, high-efficiency apheresis separators are able to harvest 65% to 75% of platelets from the 2 to 6 L of blood cycled through the machine ( $3\text{--}14 \times 10^{11}$ ), resulting in as many as three adult doses.<sup>2</sup>

Apheresis units represented approximately 86% of the platelet concentrates (PCs) transfused in the United States in 2006.<sup>3</sup> This is because of their convenience (pretransfusion pooling is not required) and because of improved safety from superior screening technology for bacterial contamination. Whole-blood-derived units, in some areas, have been relegated to a supplementary role when apheresis capacity is suboptimal or when cost-cutting measures are necessary (WBD platelets are more economical to produce).<sup>4</sup> However, because WBD pool-and-store platelet technology has now been licensed by the Food and Drug Administration (FDA), prestorage-pooled WBD platelets are also being tested for bacterial contamination employing the same culture methods used for apheresis platelets.

### Preparation of Platelets from Whole Blood—the Platelet-Rich Plasma Method

Until the late 1960s, whole blood donations had been placed on ice or refrigerated at 1–6°C since the cold sensitivity of platelets

was not appreciated. Following the introduction of plastic containers in the late 1940s, platelets were transfused primarily as platelet-rich plasma (PRP), directly infused after soft centrifugation to separate the infranatant red cells.<sup>5</sup> Further attempts to concentrate platelets from PRP resulted in an irreversibly clumped mass at the bottom of the refrigerated bag. Success at augmenting recipient platelet counts was limited both by volume constraints and because platelets, separated and stored in the cold, circulated poorly in recipients.<sup>6</sup> Mourad recognized that if PRP were allowed to come to room temperature before hard centrifugation, following supernatant plasma expression into another container, the platelet pellet could be gently resuspended in approximately 50 mL of residual plasma after a short resting period.<sup>7</sup> Building upon this finding, Murphy and Gardner revolutionized platelet therapy by demonstrating that platelets maintained at room temperature (20 to 24°C) throughout their entire ex-vivo interval were easily concentrated and circulated quite well in recipients.<sup>6</sup>

Since the early 1970s, room-temperature citrated whole blood has been transported from the collection site to a manufacturing facility and processed into Red Blood Cells (RBCs), plasma, and room-temperature PC components [Fig 12-1(A)]. Small changes to this process have been introduced over the years (eg, optimization of bag materials and centrifugation protocols, introduction of new anticoagulants, integration of leukocyte reduction filters into collection sets), but production of PCs from a PRP intermediate remains the only FDA-licensed method of WBD platelet production in the United States today. Room-temperature whole blood storage was initially limited to 4 hours after collection, but current guidelines allow an 8-hour period between venipuncture and platelet production.<sup>8,9</sup> There is increasing interest in extending this period for operational reasons. The overnight hold of whole blood donations eliminates the need for multiple transport runs from remote collection sites to the manufacturing facility and allows manufacturing on one rather than multiple shifts. Data exist to support the maintenance of PRP platelet quality after an overnight hold, but RBC quality and leukocyte reduction issues remain to be addressed.<sup>10,11</sup>

**Figure 12-1.** Platelet production methods.

RBC = Red Blood Cell; FFP = Fresh Frozen Plasma; LR = leukocyte reduced; PC = platelet concentrate.

Platelets derived from whole blood are known as Platelets (colloquially, random-donor platelets). AABB and the FDA require that a unit of Platelets contains at least  $0.55 \times 10^{11}$  platelets.<sup>12(p35-36)</sup> Modern concentrates actually contain an average of  $0.9 \times 10^{11}$  platelets with a relatively wide ( $\sim 0.27 \times 10^{11}$ ) standard deviation.<sup>1</sup> This requires a pool of at least five concentrates to ensure that, after a 6% to 10% loss during pooling, 99% of pools contain a dose of  $3 \times 10^{11}$ , the AABB/FDA-stipulated minimum content of Apheresis Platelets.<sup>12(p36)</sup> Prestorage leukocyte reduction is increasingly accomplished routinely during manufacture (Platelets, Leukocytes Reduced) with a loss of 4% to 5% of platelet content in the filter.<sup>13</sup> Leukocyte reduction results in a  $\geq 3$  log reduction in white cell (WBC) content to a level below AABB and FDA requirements for  $<0.83 \times 10^6$  WBCs per PC (one-sixth of the  $<5 \times 10^6$  threshold required for Apheresis Platelets).<sup>12(p30)</sup> PRP-PCs are suspended in autologous plasma anticoagulated with citrate-phosphate-dextrose (CPD), or CPD

with either twice the amount of dextrose (CP2D) or adenine (CPDA-1).

Platelets and Platelets, Leukocytes Reduced may be pooled into a licensed container specifically validated for prestorage pooling. This pool, produced by blood suppliers, has a 5-day outdate (midnight of the 5th day following collection). However, Platelets or Platelets, Leukocytes Reduced that are pooled after storage as individual concentrates outdate 4 hours after pooling.

## Preparation of Platelets from Whole Blood—the Buffy Coat Method

In Europe, concern about white cell content in RBC components and the need for plasma derivatives resulted in a different method of component production.<sup>14</sup> Initial hard centrifugation causes the density-dependent partition of plasma, a platelet- and white-cell-containing buffy coat (BC), and red cells. Both manual and automated devices exist to force plasma and red cells into different containers, leaving the BC in the primary container. Four to six BCs are combined, resuspended in plasma from a male donor (in the United Kingdom) or in a platelet additive solution (continental Europe) and soft centrifuged to remove red cells and white cells [Fig 12-1(B)]. The resultant product is passed through a leukocyte reduction filter to produce a prestorage pooled, leukocyte-reduced PC. This process results in lower initial white cell content, facilitating compliance with European standards for leukocyte reduction, which require  $<1 \times 10^6$  WBCs in the resultant pooled product.<sup>15</sup> Compared with the PRP manufacturing process, the BC process yields an average platelet product with a nearly equivalent platelet content. In addition, the RBC component has about 20 mL fewer red cells and 1 log fewer white cells. There is also about 30 to 75 mL more recovered plasma.<sup>16</sup> In 2004, the Canadian Blood Services initiated a switch from PRP to BC production because of perceived advantages, the most important of these being logistical. BC production employs butanediol plates within transport containers to rapidly cool and hold whole blood at 20 to 24°C for up to 24 hours before manufacturing. Newly available automated pooling technology contributes to process control, making BC production even more economical.<sup>17</sup>

In Europe, there is an approximately 50:50 split between the use of BC- and apheresis-derived PCs.<sup>14</sup> In Canada (Quebec excepted), 70% of platelets are derived from whole blood donation.<sup>18</sup> Denmark, Finland, and the Netherlands prepare 85% to 95% of their concentrates by the BC method.<sup>14,18</sup> These countries demonstrate that a national platelet supply can be derived almost entirely from collected whole blood rather than relying upon apheresis PC production.

In contrast to PRP-PCs centrifuged against the platelet container, BP-PCs are centrifuged against cellular elements of the whole blood unit. This may lead to less platelet activation during PC production relative to PRP-PCs.<sup>19</sup> Activation is one mechanism of platelet loss during storage.

## Preparation of Platelets by Plateletpheresis

Support of HLA-alloimmunized platelet-refractory patients requires platelets from a single donor. Apheresis-derived platelets are known as Apheresis Platelets (colloquially, single-donor platelets). In the mid-1970s, automated instruments were developed to replace high-volume, dedicated-donor PC collections (serial whole blood donations alternating with red cell and plasma reinfusion). As these cell separators became more widely available, inevitably, the economics of supporting plateletpheresis programs drove collections beyond these niche needs and apheresis-derived units were offered as a substitute for WBD units. Improved computer controls allowed apheresis technology to evolve beyond tedious cycles to continuous processing, which has significantly decreased procedure time and extracorporeal blood volumes. As the efficiency of apheresis separators improved and platelet yields increased well beyond the content of “standard” pools of six WBD-PCs, blood centers began to “split” apheresis units, providing therapeutic doses for two and sometimes three adults. In-process leukocyte reduction became possible with better separation controls, so Apheresis Platelets, Leukocytes Reduced now routinely contain  $<5 \times 10^6$  WBCs. Unlike WBD-PCs, red cell content in apheresis PCs is quite low in most units, often (but not always) below the dose of red cells known to produce RhD alloimmunization.<sup>20,21</sup>

The various apheresis instruments collect platelets in slightly different ways, leading to subtle differences in platelet populations and postprocedure activation. (See Chapter 41 for more detail.) Several variations on the earliest models employ a disposable plastic centrifuge chamber from which a layer of concentrated platelets is siphoned into a collection bag. More commonly employed instruments use a spinning channel with two-stage plastic inlays to initially separate the red cells from the PRP, followed by plasma removal before collection of the final platelet product. Yet another technology uses an elutriation mechanism to move larger platelets away from the red cell layer, separates the PRP, and then hyperconcentrates platelets along a collection bag wall before plasma resuspension in a storage container. This heterogeneity of collection technologies means that apheresis products are not necessarily similar nor will they always produce equivalent platelet increments in a given recipient.<sup>22</sup>

## Alternative Sources of Platelets

Although not currently cost-effective, efforts to generate platelets *ex vivo* from hematopoietic progenitor cells or cell lines may eventually be feasible. The equivalent of two WBD-PCs has been isolated from serial culture and *in-vitro* processing of a cord blood unit using various biological response modifiers.<sup>23</sup> These platelets appear morphologically and functionally normal *in vitro*. Development of this technology, however, faces a number of hurdles that make it unlikely to be implemented within the near future.

## Storage Conditions

Once the importance of room-temperature processing and storage was appreciated, platelets were kept for up to 3 days in the first generation of plastic containers. As improvements were made in platelet storage technology, shelf life was first increased to 5 days, and then to 7 days. In the mid-1980s the FDA mandated a return to 5-day shelf life because of increasing reports of bacterial sepsis associated with prolonged 20 to 24°C storage.<sup>24</sup> With the introduction of bacteria detection methods in 2004 (discussed in detail in Chapter 49), shelf life was again extended an additional 2 days for apheresis platelets screened using specific technologies.<sup>25</sup> Recurring concerns in early 2008 regarding bacterial contamination has yet again, resulted in a move away from 7-day platelet storage. Future improvements in bacteria detection technology, however, might for a third time, reverse the trend back to 7-day platelet storage.

Platelets survive for approximately 9 to 10 days in the circulation unless they are removed by senescence, activation associated with basal maintenance of vascular integrity (normally consuming platelets at a level of  $\sim 7.1 \times 10^9/\text{L/day}$ ) or used to correct pathologic bleeding.<sup>26</sup> Room-temperature storage appears to slow platelet metabolic activity by almost 60% compared with *in-vivo* activity at 37°C.<sup>27</sup> This suggests that 7 days of storage may lead to only 3 days' worth of *in-vivo* senescent loss. Storage conditions that minimize platelet loss by inhibiting platelet activation, apoptosis, or metabolic exhaustion might, in theory, permit the extension of PC shelf life well beyond 7 days. The critical variables affecting stored platelet health are: 1) temperature, 2) metabolic fuel availability, and 3) respiratory capacity. The latter is dependent on platelet content, gas diffusion through the plastic container, and agitation. Activation occurring during collection and processing appears to be mostly reversible, but excessive activation may also lead to platelet loss.

## Metabolic Concerns During Storage—Temperature

When platelets are exposed to the cold, their plasma membranes undergo phase transitions that bring lipid rafts together, clustering activating phosphoinositides and exposing neoepitopes.<sup>28–30</sup> This *in-vivo* platelet cold-sensitivity presumably facilitates activation at wound sites on the cooler body surface, while resulting in the removal of repetitively primed platelets to prevent core thrombosis.<sup>29,30</sup>

When platelets are stored in the cold, time- and temperature-dependent elevation of intracellular calcium results in sphering of normally discoid platelets as calcium-dependent gelsolin activation cleaves actin cytoskeletal elements.<sup>29,31</sup> Reversibility of this initial shape change after brief cold exposure is dependent upon the integrity of the circumferential platelet microtubular array, which is also

cold-sensitive.<sup>32</sup> Membrane phase transitions at temperatures below 30°C bring phosphoinositide-rich lipid rafts together.<sup>29</sup> These phosphoinositides promote actin polymerization, resulting in spiny projections on platelets stored in the cold.<sup>29,33</sup> Spherical and dendritic shape changes are early manifestations of agonist-induced platelet activation and, presumably, prime cold-exposed platelets for activation. Cold-exposed platelets are still able to function normally despite morphologic changes, although such changes correlate negatively with the ability of transfused platelets to circulate.<sup>6,34-36</sup> More recent investigations may explain this apparent paradox. Repeated or prolonged hypothermic platelet priming results in clustering of the principal von Willebrand factor receptor, glycoprotein (GP) Ib/IX/V.<sup>30</sup> Function of the receptor, however, is not affected by clustering. Lectin-binding domains of hepatic macrophage  $\alpha_M\beta_2$  receptors recognize clustered GPIb $\alpha$  subunits and remove these platelets. Efforts to block in-vivo platelet destruction by glycosylating newly exposed  $\beta$ -N-acetylglucosamine residues on clustered GPIb $\alpha$  molecules have thus far been successful on murine, but not human platelets.<sup>37,38</sup>

Not unexpectedly, the reversibility of cold-induced platelet injury is both time- and temperature-dependent. Figure 12-2 shows the effect of 18 hours of storage at various temperatures upon the half-life of radiolabeled autologous platelets after reinfusion into healthy volunteers. Temperatures above 20°C resulted in normal platelet survival.<sup>6</sup> Holme et al<sup>41</sup> reported that significant loss of predicted platelet viability occurred after 24 hours at 18°C, 16 hours at 16°C, 10 hours for 12°C and 6 hours at 4°C. Storage above the 20 to 24°C temperature described as optimal by Murphy and Gardner did not result in measurable damage, but was accompanied by increased metabolism compared with room temperature storage. The salutary metabolic effects of room temperature storage include decreased in-vitro aging and slower accumulation of toxic metabolites within the platelet container.

## Metabolic Concerns During Storage—Metabolic Fuel Availability

Stored platelets must catabolize substances within their suspension medium to regenerate adenosine triphosphate (ATP), the principal “energy currency” of the cell spent in the maintenance of cellular integrity. Figure 12-3 shows the pathways for ATP regeneration.

Seminal studies of glucose consumption and lactate production in PRP-PCs revealed a 1:2 ratio consistent with predominantly anaerobic metabolism of glucose.<sup>40</sup> Pyruvate dehydrogenase, which produces acetic acid for the aerobic citric acid cycle, appears to be downregulated in stored platelets. Glucose metabolism in platelets ends with the production of only 2 moles of ATP per mole of glucose consumed. Lactic acid is buffered primarily by plasma bicarbonate, which results in the production of CO<sub>2</sub>.<sup>41</sup> This CO<sub>2</sub>, a volatile acid, diffuses through

**Figure 12-2.** In-vivo survival of radiolabeled autologous platelets stored at various temperatures for 18 hours.

**Figure 12-3.** Pathways of platelet adenosine triphosphate (ATP) regeneration from inorganic phosphate (P<sub>i</sub>) and adenosine diphosphate (ADP). Metabolic fuels are underlined. Energetic intermediates are underlined. Carbon dioxide (CO<sub>2</sub>) is produced from hydrogen ion (H<sup>+</sup>) buffering and oxidative metabolism of acetyl CoA. GDP/GTP = guanosine di-/triphosphate; NAD/NADH = nicotinamide adenine dinucleotide/reduced NAD; FADH/FADH<sub>2</sub> = reduced flavin adenine dinucleotide forms.

the storage container wall. Progressive depletion of bicarbonate thus occurs through lactic acid buffering as well as slow spontaneous dissociation to  $\text{CO}_2$  and water. Once bicarbonate is consumed, continued lactic acid production ultimately results in a deleterious decrease in product pH.

Aerobic metabolism through the citric acid cycle and oxidative phosphorylation is a far more efficient source of energy, yielding 8 to 9 moles of ATP and 2 moles of  $\text{CO}_2$  per mole of acetic acid entering the cycle. Comparison of platelet oxygen consumption (6 moles of ATP produced per mole of  $\text{O}_2$  consumed) with lactate production (1 mole of ATP per mole of lactate) suggests that approximately 85% of platelet energy is derived from aerobic metabolism.<sup>40</sup> Studies using radiolabeled palmitate point to free fatty acids derived from plasma triglycerides as the predominant metabolic fuel for platelets stored in plasma.<sup>42</sup> A small, rather insignificant component results from metabolism of the amino acid glutamine.<sup>43</sup> Efforts to identify plasma-sparing platelet additive solutions (PAS) led to the discovery that acetate could serve as an effective alternative fuel to fatty acids.<sup>44</sup> As described below, acetate also provides a valuable lactate-buffering function through consumption of a hydrogen ion during its metabolism.

Under low oxygen conditions, glycolysis is upregulated six- to sevenfold, the so-called Pasteur effect.<sup>45</sup> Although this effect satisfies energy requirements in the absence of aerobic metabolism, it results in a considerable increase in lactic acid production, which can exacerbate plasma buffer exhaustion and produce deleterious declines in pH. Mechanical factors also affect platelet metabolism. Mitochondrial oxygen starvation can occur with the interruption of agitation during excessively long periods of shipping, accompanied by an expected increase in lactate generation and pH decrements.<sup>46</sup> Studies have shown that platelets begin to suffer deleterious effects below a pH of 6.5 to 6.8 at room temperature (22°C) and are irreversibly damaged in the face of a sustained pH below 6.2 at 22°C.<sup>41,47</sup> Efforts to extend platelet storage have been limited by the relatively constant glycolytic production of lactate, even with maintenance of adequate oxygenation. The availability of suitable lactic acid buffers may not be the only metabolic challenge. Attempts to develop glucose-free additive solutions to minimize the production of lactate have not been successful. Despite the presence of sufficient amounts of alternate fuels (such as acetate), once PCs exhaust their supply of glucose, they increase their metabolic rate and deplete their adenine nucleotides, leading to cell death.<sup>44</sup> The reasons for this are poorly understood.

Adenine nucleotide depletion during storage has been characterized in PRP-PCs.<sup>48</sup> ATP and adenosine diphosphate (ADP) are present in platelets in both metabolic and storage pools. The former provides for the metabolic needs of the platelet (ATP:ADP ratio 8:1) and the latter, present in delta granules and released upon platelet activation, serve as autocrine/paracrine second messengers (ATP:ADP ratio 2:3). Both pools were noted to decline equally throughout storage in experiments employing radiolabeled adenine, suggesting some element of platelet activation or lysis in addition to metabolic turnover. After 7 days of

storage, adenine nucleotide levels in PCs decline to 70% of those initially present.<sup>49</sup> Supplementation of the anticoagulant with adenine (CPDA-1 instead of CPD) resulted in better ATP maintenance throughout storage. Unlike red cells, however, there is no evidence that adenine-containing media preserve platelet function better than those without adenine.

---

## Metabolic Concerns During Storage—Respiratory Capacity

Maintenance of aerobic metabolism requires a  $\text{PO}_2$  above 5 to 10 mmHg.<sup>40</sup> Because oxygen consumption is relatively constant per platelet, presence of a high total platelet bag content stresses the oxygen permeability of the storage container. When PC consumption exceeds the ability of the container to transport oxygen, the  $\text{PO}_2$  will decline to hypoxic levels over several days, leading to upregulation of glycolysis, lactic acid accumulation, and a deleterious decrease in pH. Gases diffuse across storage container walls driven by their gradients once the plastic is saturated. Each manufacturer's container has a different gas permeability related to wall thickness and the plastic's unique gas transport capacity. Oxygen delivery also depends upon the container's ratio of volume-to-surface area as well as continuous agitation, which promotes gas diffusion and helps maintain normal platelet oxygen consumption.

Kilkson et al<sup>40</sup> demonstrated that across the  $\text{CO}_2$  concentrations seen in PCs stored in the least permeable containers (10 to 100 mmHg), little pH change is attributable to formation of carbonic acid from aqueous  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Lactate concentration was shown to be the principal determinant of pH. Thus, high  $\text{CO}_2$  permeability is not as critical as is good oxygen permeability. High  $\text{CO}_2$  permeability, in fact, can lead to an early increase in pH as the  $\text{PCO}_2$  falls from physiologic levels, unbalanced by significant lactic acid accumulation. A pH >7.4 at 22°C may result, which has been associated with cellular damage with earlier forms of agitation. Although European regulators have set 7.4 pH as the upper limit of acceptable end-storage at 22°C, a recent study noted that using modern forms of agitation, a pH >6.3 at 22°C had no predictive value for platelet viability (in PCs compliant with licensed maximum and minimum platelet contents and concentrations).<sup>50</sup>

From the foregoing discussion of metabolic fuel requirements, it is evident that platelet storage is limited by the ability of suspension medium buffers to handle constitutive glycolytic lactate production. High platelet content increases lactate production rates even further, because high platelet concentrations result in fewer plasma buffers per respiring platelet. Less evident is the deleterious effect of low platelet contents and concentrations. Adverse effects in these situations result from low  $\text{CO}_2$  and lactate production, which initially result in an increase in PC pH. Why these products develop metabolic exhaustion and adenine nucleotide depletion is not entirely clear, but some forms of agitation further increase this effect at higher pH values.

The very first containers, made of polyvinylchloride (PVC) plasticized with di-(2-ethylhexyl) phthalate (DEHP) were originally designed for freezing plasma. Serendipitously, they allowed enough oxygen and CO<sub>2</sub> diffusion across their walls to permit room temperature platelet storage of relatively lower content PCs for 3 days before the pH decreased to unacceptable levels. Containers were later specifically designed for improved gas permeability as trial and error revealed that PCs stored in more gas-permeable containers had lower rates of pH failure (pH <6.2 at 22°C).<sup>51</sup> So-called second-generation containers appear to be able to store PRP-PCs for at least 7 days without deleterious pH decrements. Because apheresis PCs and prestorage pooled PRP-PCs have such heterogeneous contents, each unit must be assayed to ensure that total platelet content and concentration limits validated by the container manufacturer are not exceeded. The platelet concentration of donor blood limits individual WBD-PC content to values below those accommodated by newer storage containers. Second-generation containers currently in use are manufactured from polyolefin, or PVC that is thinner or plasticized with different compounds such as triethyl hexyl trimellitate and butyryl-tri-hexyl citrate.<sup>52</sup> These bags provide nearly twice the oxygen permeability of first-generation DEHP-plasticized PVC containers.<sup>53</sup>

The need for continuous agitation was also recognized as a means of facilitating oxygen utilization.<sup>51,54</sup> Several different types of platelet rotators have been used over the years. Ferris wheel and elliptical rotators have given way to face-over-face tumblers (3-6 rpm) and flatbed platform shakers (50-70 cpm) because of inefficient maintenance of pH or damage to platelets at pH >7.4 at 22°C.<sup>41</sup> Initially thought to promote the diffusion of oxygen throughout the PC, agitation appears to exert a more complex effect on platelet metabolism. Several groups have shown that PO<sub>2</sub> was maintained in unagitated PCs and that mixing of products even once a day could prevent injurious pH decrements in relatively lower content platelet products.<sup>55,56</sup> Agitation, therefore, may also facilitate oxygen utilization by platelet mitochondria or prevent settling and a platelet contact-mediated switch from oxidative to glycolytic metabolism.<sup>57</sup> In any case, even with relatively higher content PCs, agitation may be safely interrupted for 24 hours (as during shipping) without undue lactate accumulation and subsequent development of injuriously low pHs.<sup>57,58</sup>

## The Platelet Storage Lesion

Stored platelets experience a progressive decline in function accompanied by characteristic morphologic changes. Studies document up to 20% loss of platelet recovery through 5 days of storage.<sup>59</sup> In containers currently licensed in the United States, Day 7 recovery is approximately 83% of Day 5 recovery.<sup>60,61</sup> This progressive damage has been termed the platelet storage lesion.<sup>62</sup> Well-characterized changes are seen in common tests assessing platelet morphology, activation, cell metabolism/function, and senescence (apoptosis). Some, but not all, of these changes are reversible upon platelet transfusion.<sup>63</sup>

The gold standard for evaluating product efficacy has been adjusted count increments after patient transfusion, ideally accompanied by bleeding time studies demonstrating improved hemostasis. In practice, however, such studies are not often performed because count increments and bleeding times are affected by uncontrollable patient variables, thus requiring very large studies to document the impact of storage condition changes on the platelet storage lesion. An acceptable alternative involves the reinfusion of healthy volunteers with autologous stored platelets radiolabeled with chromium-51 or indium-111. (Cell kinetic studies are described in greater detail in Chapter 21.) Percent recovery and survival may be calculated by serial assay of postinjection blood radioactivity. Platelet recovery is significantly affected by individual differences in splenic sequestration (usually ~33%) and blood volume estimation errors during calculations. In an effort to standardize interpretation, Murphy proposed that products be evaluated against concurrently injected fresh autologous platelets to establish a fixed standard.<sup>64</sup> This will facilitate comparison of interventions designed to ameliorate the storage lesion. Although in-vitro tests have attempted to predict rapidly and economically the ability of transfused platelets to circulate, only extreme values have documented any correlation with outcomes.<sup>65</sup> Accordingly, batteries of tests are often examined to ensure product equivalency after minor changes, or as the first step in assessment of more substantive changes in storage methods.

Alterations from normal discoid morphology are observed during platelet storage. Kunicki described a scoring system that assigned 4 points to discs, 2 to spheres, 1 to dendritic forms, and none to ballooned platelets.<sup>66</sup> Multiplied by the percentage of each form seen under phase contrast microscopy, scores decline from a maximum of 400 as changes associated with the storage lesion progress. Others have advocated simply reporting the percentage of discoid forms. The assay of the extent of shape change uses aggregometry to measure the decrease in light transmission after ADP stimulation of stirred PRP in the presence of EDTA to prevent aggregation.<sup>67</sup> Because only discoid platelets can change shape and block more light, the assay provides a more objective measure of the percentage of discoid platelets. All three approaches appear to correlate somewhat with in-vivo recovery and survival at high or low assay values, but predict less well for in-between values. Mean platelet volume decreases throughout storage when membrane loss from dendritic forms occurs or when activation or apoptosis result in microvesiculation.<sup>68</sup>

Platelet activation during processing and throughout storage is accompanied by surface expression of sequestered granular membrane proteins (P-selectin and CD63) and conformational changes of the fibrinogen receptor, GP-IIb/IIIa. Release of specific granular contents into the supernatant (β-thromboglobulin, platelet factor 4, etc) also occurs throughout platelet storage as a manifestation of activation. This may not be specific for activation, however, because granular content release also occurs with platelet lysis. Similarly, platelet procoagulant activity (surface expression of membrane phosphatidylserine), appears not only with activation, but also during cellular apoptosis. None of these indicators of platelet

activation appear to correlate reliably with platelet recovery and survival. Studies of storage medium supplementation with activation inhibitors, however, suggest that activation contributes in part to the platelet storage lesion.<sup>69</sup> Use of activation inhibitors in storage media has not gained widespread acceptance because of inconsistent results, toxicity, and the expense of licensing novel storage systems.

The ability of stored platelets to function normally has been assessed in several ways, only one functional assay of which—hypotonic shock response—has proven to be of value in assessing platelet viability. Measurements of platelet ATP levels do not consistently provide reliable information.<sup>49</sup> Aggregation studies similarly fail to predict platelet viability. Responsiveness to single agonists rapidly declines during storage, but can recover with plasma rescue or in-vivo reinfusion.<sup>63</sup> Responses to agonist mixtures, while better preserved, are still not helpful in assessing viability.<sup>70</sup> The hypotonic shock response or osmotic reversal reaction exposes platelets to a hypotonic environment. Metabolically active platelets rapidly extrude water after initially swelling. Recovery of normal intracellular water content can be quantified using light transmittance. Significant changes in values for this assay have been shown to correlate with in-vivo recovery and survival.<sup>67</sup>

Markers associated with cellular apoptosis accumulate throughout platelet storage with evidence of caspase activation, structural protein degradation, and changes in mitochondrial membrane potential.<sup>71,72</sup> Apoptotic inhibitors, while ameliorating some of these changes, have not resulted in improvements in platelet viability, casting doubt upon cellular senescence as a significant contributor to the platelet storage lesion.

## Platelet Additive Solutions (Synthetic Storage Solutions)

In the United States, all platelets are stored in plasma. In Europe, synthetic storage solutions, also called platelet additive solutions,

have been used routinely for at least a decade.<sup>73</sup> The use of PAS allows: 1) greater plasma recovery from whole blood donations for transfusion or fractionation, 2) a minimizing of the adverse effects mediated by plasma (eg, allergic reactions), 3) use of photochemical pathogen reduction technologies, because the presence of plasma may interfere with the technology system, and 4) potential improvements in platelet storage through engineered manipulation of the storage medium.<sup>74,75</sup> It is likely that some PAS will be licensed and made available for use in the United States in the near future, considering the mandate to reduce the level of plasma in platelet concentrates as a strategy to mitigate transfusion-related acute lung injury.<sup>76</sup>

Early studies demonstrated the feasibility of suspending PRP-PCs in a commercially available neutral intravenous crystalloid solution, Plasmalyte A (composition listed in Table 12-1).<sup>77</sup> The 10% to 20% plasma carried over in the storage medium provided the sole source of glucose and bicarbonate. In-vitro results were quite encouraging but although previous versions of this PAS containing additional glucose and citrate were shown to be promising in vivo, the solution was not successfully commercialized.<sup>78</sup> When Murphy tested another balanced salt solution, the in-vivo results were disappointing.<sup>79</sup> In retrospect, the deletion of acetate from Murphy's so-called PSM-2 solution was likely responsible for the pH failures seen in-vitro. The poor in-vivo recoveries of a phosphate-buffered version of this PAS may have been caused by glucose exhaustion due to the absence of acetate, despite continued free fatty acid availability. Acetate can efficiently substitute in the citric acid cycle for free fatty acids, the presumed primary substrate for oxidative metabolism (Fig 12-3), decreasing both the glycolytic rate and lactic acid generation.<sup>80</sup> Acetate must also be transformed to acetic acid to enter the cycle, removing hydrogen ions produced by the anaerobic metabolism of glucose. This bicarbonate-sparing buffering effect also helps preserve pH. From Murphy's experience and other studies, it appears likely that some glucose must be available throughout storage. Holme

and Gullikssen both noted the association of glucose exhaustion (even in the presence of alternate fuels) with adenine nucleotide depletion and loss of platelet viability.<sup>44</sup> The addition of glucose to PAS, however, is technically difficult because glucose caramelizes upon heat sterilization at the neutral or slightly basic PAS pHs best suited to maintain PC pH. Accordingly, most commercially available PAS do not contain additional glucose and require 20% to 40% plasma carryover. One PAS adds glucose to a low pH additive solution in combination with bicarbonate tablets in the storage container to re-adjust the storage pH.<sup>81</sup> Table 12-1 lists the components of commonly used PAS.

In addition to sparing bicarbonate, PAS contents have been designed to modulate the glycolytic rate and downregulate platelet activation. Citrate, important in maintaining an anticoagulant environment, upregulates glycolysis and renders platelets more susceptible to activating stimuli. Consequently, use of the lowest possible concentrations of citrate in the medium appear desirable.<sup>44</sup> Phosphate similarly has both salutary and detrimental effects in PAS.<sup>82</sup> Phosphate serves as a buffer and in apheresis platelets suspended in acid-citrate-dextrose (ACD) instead of the CPD/CP2D used in PRP-PCs and BC-PCs, is important in maintaining adenine nucleotide levels. It also upregulates glycolysis and consequently mandates more plasma carryover or addition of glucose to PAS. Magnesium and potassium both appear to decrease platelet activation and may downregulate glycolysis as well.<sup>44</sup> Studies with a number of platelet activation inhibitors (eg, prostaglandin E1, theophylline) suggest that these substances may enhance PAS efficacy, but safety concerns related to routine transfusion in varied patient populations significantly hinders commercial applicability.<sup>83</sup>

Robust clinical studies comparing platelets stored in plasma with the many PAS under investigation, are currently lacking. In studies to date examining corrected increments in patients, there appears to be somewhat better maintenance of platelet viability in 100% plasma early in storage, an effect that gradually disappears by Day 5.<sup>84</sup> Allergic reactions were markedly reduced with PAS platelets in several studies.<sup>84</sup> Although in-vitro data support slight advantages to PAS IIIM (Baxter S.A., Lachâtre, France) and Composol (Fresenius Kabi, Bad Homburg, Germany) over other PAS, the clinical arm of this comparison has not yet been carried out. Although there is much research still to be performed, PAS remains as an important future tool for reducing the concurrent infusion of plasma along with therapeutic doses of platelets.

---

## Component Modification

Several other PC modifications are occasionally required for various subsets of patients. Cellular products containing viable lymphocytes must be irradiated before transfusion to patients who are susceptible to graft-vs-host disease. An irradiation dose of 25 Gy (15 to 50 Gy) has no significant effect on common in-vitro parameters even after 7 days of storage following irradiation as early as Day 1.<sup>85</sup> Similarly, little or no effect of irradiation was seen on in-vitro storage parameters or in-vivo recovery and

survival after 5 days of storage of platelets irradiated with up to 30 Gy on Days 1 or 3.<sup>86,87</sup>

Patients with moderate to severe allergic reactions to plasma components or newborns with neonatal alloimmune thrombocytopenia receiving maternal platelets benefit from plasma removal by platelet washing. Some institutions also wash platelets to remove ABO-incompatible plasma.<sup>88</sup> Washing, however, leads to significant loss of platelets as well as a decrement in platelet function while also reducing the product shelf life to 4 hours. A standard saline wash procedure using the COBE 2991 instrument (CaridianBCT, Lakewood, CO) has been described.<sup>89</sup> Platelet losses range from 8% to 29%.<sup>90,91</sup> A study examining the effect of 0.9% saline or a 12.6% ACD-buffered saline wash fluid compared with unwashed platelets showed a 68% reduction in in-vivo recovery for saline-washed platelets and 28% reduction in recovery with ACD-buffered saline.<sup>92</sup> Thus, actual and functional losses may represent up to two-thirds of the pre-wash platelet content. For IgA-deficient patients, saline alone may not remove as much IgA as citrate-buffered saline because of the low isoelectric point of IgA and its coprecipitation with platelets in an acidic saline wash fluid.<sup>93</sup>

For transfusions in utero or for volume-sensitive neonates, additional concentration of platelet concentrates can be achieved by further volume reduction via plasma removal. This technique has also been used to minimize infusion of maternal antibodies or ABO-incompatible plasma, although washing removes more antibody. Procedures have been described for volume reduction that results in <15% loss of platelets and relatively preserved in-vivo viability.<sup>94</sup> PCs are centrifuged and excess plasma expressed from the unit followed by gentle resuspension by manual means or by use of an agitator. Volume-reduced PCs maintain acceptable in-vitro properties in plastic syringes at room temperature or in neonatal incubators (at 37°C).<sup>95</sup> PCs should be transfused as soon as possible after volume reduction in a closed system, employing sterile connection devices, and must be used within 4 hours if prepared in an open system, such as via spike entry.

Most apheresis platelets are leukocyte reduced during the separation process. Leukocyte reduction of WBD-PCs may be accomplished through bedside filtration or by using a more quality-controlled prestorage filtration process. An important benefit of pre- rather than poststorage filtration is the early removal of white cells that would otherwise produce cytokines throughout storage. Prestorage leukocyte reduction has resulted in a 75% to 90% reduction in febrile, nonhemolytic reactions after platelet transfusion.<sup>96,97</sup> Leukocyte reduction also reduces cytomegalovirus transmission and platelet alloimmunization.<sup>98,99</sup>

---

## Novel Storage Techniques

The short shelf life and significant infrastructure needed to maintain room-temperature, continuously agitated, liquid PCs have encouraged exploration of alternative storage approaches. Cold liquid storage clearly minimizes the impact of bacterial contamination and also promises to extend shelf life by further

slowing platelet metabolism. Unfortunately, while the function of refrigerated platelets is normal, they circulate poorly and despite success in mice, galactosylated clusters of GPIb $\alpha$  subunits still result in rapid reticuloendothelial clearance in humans.<sup>34-38</sup> Additional work to overcome the recognition of these clusters by hepatic  $\alpha_M\beta_2$  receptors is required. One group has reported stabilization of refrigerated platelet membranes with antifreeze glycoproteins derived from polar fish, but the safety and in-vivo activity of these platelets has not been described.<sup>100</sup>

Cryopreserved platelets can be prepared and stored for up to 10 years, but cost, inconvenience, procedure-related platelet loss, and functional decrements remain barriers to wider implementation. The most common method of freezing employs 5% to 6% dimethylsulfoxide (DMSO) as a cryoprotectant, and requires  $<-80^\circ\text{C}$  storage and postthaw washing to remove the DMSO.<sup>101,102</sup> The use of cryopreserved platelets results in corrected count increments that are 40% to 65% of the increments seen with liquid apheresis platelets transfused relatively early after storage.<sup>102,103</sup> The 50% to 66% loss of function in addition to the 15% to 20% platelet loss from transfers and washing may be mitigated by use of a commercial solution containing amiloride, adenosine, and sodium nitroprusside, which “stabilizes” platelets and allows reduction to a 2% DMSO content.<sup>104,105</sup> Studies have noted the superiority of controlled rate freezing over uncontrolled temperature reduction using both DMSO concentrations.<sup>106,107</sup> Frozen platelets are useful primarily for broadly alloimmunized patients who are refractory to allogeneic transfusion. Collected between successive rounds of high-dose chemotherapy, these units can support patients through short periods of severe thrombocytopenia.

Lyophilized platelets are attractive for use in forward-deployed military facilities where platelets are often unavailable. Animal studies in the 1950s showed no hemostatic effect of early preparations.<sup>108,109</sup> Bode and Read described a new technique using 1.8% paraformaldehyde to gently fix washed platelets, followed by freezing in 5% bovine albumin and lyophilization.<sup>110</sup> This preparation has been stored at  $-80^\circ\text{C}$  but may be stable at room temperature for shorter periods. Paraformaldehyde treatment appears to confer an additional benefit by killing bacteria and many viral pathogens. In-vitro studies show that these platelets, although reduced in surface glycoprotein content, are morphologically normal, support coagulation, and can be activated. In animal models, they participate in aggregates with normal platelets, shorten the bleeding time, and do not appear to induce disseminated coagulation.<sup>111</sup> In-vivo studies suggest, however, that the duration of action may be short following rehydration. Clinical studies in humans will be needed to define the product’s safety and efficacy, primarily in treatment of bleeding, rather than its prevention. An alternate method of lyophilization using trehalose instead of paraformaldehyde is still in preclinical testing.<sup>112</sup>

The role of platelet substitutes including platelet microvesicles, liposome-based hemostatic agents, fibrinogen-coated albumin microspheres, and red cells coated with fibrinogen or RGD

peptides is beyond the scope of this chapter and readers are referred to published reviews for additional information.<sup>111,113,114</sup>

## Acknowledgment

Scott Murphy, a platelet storage pioneer, authored this chapter for the three previous editions of this book. Platelet transfusion therapy originated from his seminal work. Scott’s intellectual curiosity, wit, and wisdom are sincerely missed. His spirit and words are woven into the fabric of this chapter.

## Disclaimer

The author has disclosed a financial relationship with Fenwal, Inc.

# 13 Thrombocytopenia and Platelet Transfusion

**Peter W. Marks**

Associate Professor of Medicine, Section of Hematology, Yale University School of Medicine, New Haven, Connecticut, USA

Thrombocytopenia is caused by disorders impairing platelet production, causing platelet destruction or leading to platelet sequestration. In addition, there are both congenital and acquired disorders of platelet function. These conditions may lead to the functional equivalent of thrombocytopenia, often despite the presence of a normal platelet count. Platelet transfusion represents an important therapeutic option for most of these disorders. However, under certain circumstances platelet transfusion is contraindicated. Therefore, correct diagnosis of the underlying etiology of thrombocytopenia is important.

Products for platelet transfusion include platelet pools derived from whole blood donation from multiple donors and apheresis units from individual donors. These components may be further manipulated depending on the requirements of the recipient. Allergic reactions to platelets can often be addressed by the administration of appropriate medications before transfusion. Platelet refractoriness represents a significant problem that develops in some patients who require repeated infusions of platelet products. Several therapeutic options exist to address platelet refractoriness, depending on the severity of the situation. These include the transfusion of crossmatched or HLA-matched platelets, the continuous infusion of platelets, and the administration of immune globulin, antifibrinolytic agents, or recombinant Factor VIIa. The development of platelet substitutes and the administration of thrombopoiesis-stimulating agents represent alternatives to platelet transfusion that are in various stages of clinical development and may ultimately reduce the need for donor-derived platelets.

## Thrombocytopenia

Thrombocytopenia refers to any reduction in platelet number below the lower limit of the normal range, which is about 150,000/ $\mu\text{L}$  in most laboratories. In the absence of other factors, however, the risk of bleeding is considered to be relatively modest until the

platelet count is less than 50,000/ $\mu\text{L}$ , and is not considered to be severe until the platelet count is less than 25,000/ $\mu\text{L}$ .<sup>1</sup> However, congenital or acquired abnormalities in platelet function may be associated with bleeding even when the platelet count is in the normal range.<sup>2,3</sup> A systematic diagnostic approach facilitates the correct diagnosis and appropriate management of thrombocytopenia and platelet dysfunction. Careful assessment of the medical history is imperative. In particular, review of concomitant medications is often revealing. The peripheral blood smear should be reviewed for morphologic abnormalities in any of the three lineages (myeloid, erythroid, megakaryocytic), which may provide important insight in to the underlying diagnosis, be it congenital or acquired. An overview of management options is presented in Table 13-1.

## Impaired Platelet Production

Disorders of platelet production may be congenital or acquired. Congenital disorders are relatively rare, whereas acquired disorders are more commonly encountered in clinical practice. In the absence of an apparent etiology, distinguishing decreased platelet production from increased platelet destruction or from splenic sequestration can sometimes be challenging. Decreased platelet production is generally characterized by normal platelet size on the peripheral blood smear and a normal mean platelet volume (MPV). In addition, the reticulated platelet count as measured by flow cytometry is low.<sup>4</sup> Although additional laboratory testing such as serology for platelet antibodies can be useful in specific instances, a marrow aspirate and biopsy may be required in order to determine the underlying disorder associated with thrombocytopenia.

Hematologic and nonhematologic malignancies are associated with replacement of the marrow space (myelophthisis). Alternatively, the marrow may be replaced with fibrosis. In general, these conditions usually present with pancytopenia. However, sometimes reduction in the platelet count is the first indication of these abnormalities. Platelet transfusions may be used appropriately for supportive care as needed while the underlying disorder is addressed.

## Platelet Sequestration

About one-third of the platelet mass is normally sequestered in the spleen.<sup>5</sup> Splenomegaly from any cause tends to increase

**Table 13-1.** Management Options for Disorders Affecting Platelets

| Disorder                               | Therapeutic Options                                                                                                                                                                                                           |
|----------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Impaired platelet production           | <ul style="list-style-type: none"> <li>• Platelet transfusion</li> </ul>                                                                                                                                                      |

splenic platelet pooling. Hematologic malignancies including the myeloproliferative disorders may result in marked splenomegaly. In particular, myelofibrosis may be associated with thrombocytopenia.<sup>6</sup> Portal hypertension from liver disease may also be associated with marked splenomegaly leading to thrombocytopenia or even pancytopenia. Cytokine-mediated mechanisms also contribute to the thrombocytopenia observed in liver disease.<sup>7</sup> The thrombocytopenia associated with splenic sequestration alone is generally moderate enough so as not to be associated with bleeding. However, concomitant conditions, such as the coagulopathy of liver disease or dysfibrinogenemia can exacerbate the tendency to bleed in this setting. Depending on the nature of the defect present, the use of Fresh Frozen Plasma to replace clotting factors and Cryoprecipitated AHF to provide fibrinogen may be important adjuncts to the use of platelet transfusion. Individuals with alcoholic cirrhosis and portal hypertension who continue

to consume alcohol may also have exacerbated thrombocytopenia resulting from suppression of platelet production from the megakaryocyte.<sup>8</sup>

Aside from splenomegaly, another potential cause of platelet sequestration is a cavernous hemangioma (Kasabach-Merritt syndrome). However, it is controversial whether platelet sequestration or platelet consumption is the primary defect leading to thrombocytopenia in this setting.<sup>9</sup>

### Congenital Platelet Disorders

Hereditary disorders may affect platelet number, platelet function, or both. Some congenital disorders leading to severe thrombocytopenia or markedly abnormal platelet function are identified early in life, but others are identified only after excessive bleeding is encountered in adulthood at the time of trauma or surgery.

### Congenital Megakaryocytic Hypoplasia

A markedly reduced platelet count early in life is seen with congenital megakaryocytic hypoplasia. This represents a group of disorders that include thrombocytopenia with absent radii syndrome.<sup>10</sup> These cases progress to include pancytopenia. Various mutations in the c-Mpl gene encoding the thrombopoietin receptor have been found.<sup>11</sup> Platelet transfusion is sometimes required in the event of bleeding because other therapeutic options such as corticosteroids, immune globulin, and splenectomy are ineffective. Ultimately, the definitive therapy to facilitate long-term survival appears to be hematopoietic stem cell transplantation.<sup>12</sup> An acquired form of megakaryocytic hypoplasia has been described that sometimes responds to immunosuppressive therapy.

### Platelet Receptor Defects

Glanzmann's thrombasthenia is an autosomal recessive condition associated with bleeding caused by absence, reduction, or impaired function of the glycoprotein (GP) IIb/IIIa receptor, which serves to bind fibrinogen and other cell adhesion molecules.<sup>13</sup> This receptor is also critical for sustained platelet activation in response to various agonists including epinephrine and adenosine diphosphate (ADP). The severity of bleeding in this disorder is quite variable, depending on the individual mutation present. Diagnosis is facilitated by platelet aggregation studies demonstrating a marked reduction or absence in platelet response to all standard agonists (ADP, epinephrine, collagen, arachadonic acid) except ristocetin.

Bernard-Soulier syndrome is an autosomal recessive condition associated with a variable reduction in platelet number and with the presence of large platelets.<sup>14</sup> It results from defects in the GPIb/IX/V complex that normally binds von Willebrand factor (vWF), resulting in platelet adhesion and activation. Similar to Glanzmann's thrombasthenia, the severity of bleeding is quite variable, depending on the exact mutation present. Diagnosis in this case is facilitated by the reduced platelet number, large platelets present on peripheral blood smear, and platelet aggregation assays demonstrating a response to all agonists except for ristocetin.

The platelet aggregation results in this disorder are thus complementary to the findings seen in Glanzmann's thrombasthenia.

### Other Congenital Defects Affecting Platelet Number or Function

Type 2B von Willebrand disease (vWD) is associated with an activating mutation in the von Willebrand protein that causes it to bind to platelets without the usual stimuli.<sup>15</sup> It is phenotypically indistinguishable from an activating mutation of the GPIb/IX/V receptor. This platelet-type vWD, or pseudo vWD, leads to binding of the platelet to vWF in the absence of activation of the usual signaling pathway. Both of these disorders result in reduction in platelet number because of clearance of activated or vWF-coated platelets in the spleen. Both are accompanied by a moderate bleeding tendency. Platelet aggregation assays performed using ristocetin demonstrate either spontaneous aggregation or heightened responsiveness to this agonist. Distinction between type 2B vWD and pseudo-vWD requires highly specialized laboratory testing.<sup>16</sup> Platelet transfusion must be administered very cautiously in patients with these disorders. In addition, use of desmopressin (DDAVP) is relatively contraindicated, as it may exacerbate thrombocytopenia. For bleeding in patients with type 2B vWD, use of a plasma-derived intermediate purity Factor VIII concentrate, such as Humate-P (CSL Behring, King of Prussia, PA) or Alphanate (Grifols, Barcelona, Spain) is recommended.

### Platelet Granule Defects

In addition to the surface receptors, platelets contain several types of granules that play important roles in aggregation, activation of coagulation, and wound healing. Hereditary defects in granule content, or abnormalities in the intracellular cyclooxygenase signaling mechanism may lead to impaired platelet function. These disorders include alpha granule deficiency (gray platelet syndrome is also associated with the Hermansky-Pudlak syndrome), dense granule deficiency, and combined deficiency.<sup>3,17</sup> Hereditary abnormalities in the cyclooxygenase signaling system are exceedingly rare. In these cases, platelet aggregation in response to many standard agonists is abnormal or abrogated, with the exception of aggregation to ristocetin, which is preserved.

### Therapy for Congenital Platelet Disorders

Although platelet transfusion is effective in the treatment of bleeding in congenital platelet disorders, it can lead to the production of platelet autoantibodies and thus should be reserved for serious bleeding episodes. Recombinant Factor VIIa (NovoSeven, Novo Nordisk, Bagsvaerd, Denmark) has been used effectively for Glanzmann's thrombasthenia in the setting of more severe bleeding, although it is not specifically approved for this indication.<sup>18</sup> Epsilon-aminocaproic acid (EACA) or DDAVP may be useful for minor bleeding or for perioperative management of minor procedures, depending on the severity of the underlying disorder. In the absence of any bleeding, patients should be counseled to avoid aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs),

and to take appropriate prophylactic measures before procedures (eg, use of EACA before minor dental procedures).<sup>19</sup>

### Acquired Platelet Disorders

Thrombocytopenia may be the primary manifestation of several different hematologic disorders. These include immune thrombocytopenic purpura (ITP) and the microangiopathic hemolytic anemias.

#### Immune Thrombocytopenic Purpura

Immune thrombocytopenic purpura (covered in more detail in Chapter 23) presents as an isolated reduction in the platelet count in the absence of abnormalities in the remaining cell lineages. In particular, red cell morphology is normal, and large platelets are often seen. In children, this condition is typically acute, is associated with an antecedent viral illness, and resolves spontaneously. In adults, chronic presentation is much more common.<sup>20</sup> Conditions associated with the development of ITP include human immunodeficiency virus infection, hepatitis C, and antiphospholipid antibodies.<sup>21</sup> The autoantibodies in ITP are most commonly directed against GPIIb/IIIa; however, they rarely affect platelet function.<sup>22</sup> In cases of severe or life-threatening bleeding, platelet transfusion is indicated. Although survival of transfused platelets is greatly reduced, they are likely to have some beneficial effect on active bleeding. Individuals with more moderate bleeding may be treated with immune globulin at doses of either 1 g/kg/day for 1 or 2 days or 0.4 g/kg/day for up to 5 days. In the absence of significant bleeding, corticosteroids represent first-line therapy in adult patients with ITP and platelet counts less than 30,000 to 50,000/ $\mu$ L. Corticosteroids may be administered either as 1 mg/kg of prednisone daily or dexamethasone 40 mg daily for 4 days.<sup>23</sup> Unfortunately, adult patients often relapse and require rescue therapies such as splenectomy or treatment with alternative immunosuppressive agents.

#### Microangiopathic Hemolytic Anemia

Several different conditions can cause a similar appearance on the blood smear: thrombocytopenia and the presence of red cell fragmentation (schistocytes).<sup>24</sup> However, clinical distinction between thrombotic thrombocytopenic purpura (TTP)/hemolytic uremic syndrome (HUS) and disseminated intravascular coagulation (DIC) is critical. In addition, malignant hypertension and valvular hemolysis may result in a similarly appearing smear.

TTP represents a medical emergency. Although the diagnostic pentad consists of fever, microangiopathic hemolytic anemia, thrombocytopenia, renal failure, and neurologic abnormalities, only microangiopathic hemolytic anemia and thrombocytopenia are required for the diagnosis.<sup>25</sup> Coagulation tests are almost always normal. The pathophysiology of this disorder has become elucidated as resulting from reduction or inhibition in function of the vWF-cleaving protease ADAMTS13.<sup>26</sup>

Platelets are activated in TTP, leading to a hypercoagulable state. Therefore, transfusion with platelets should be reserved for individuals with thrombocytopenia and life-threatening hemorrhage.

The therapy of choice is plasma exchange, although plasma infusion may be used as a temporizing measure. The use of antiplatelet agents and steroids is controversial. Relapsing TTP has been treated successfully with the CD20 monoclonal antibody rituximab.<sup>27</sup>

HUS in children is associated with diarrheal illness with shiga-toxin-producing bacteria such as *Escherichia coli* H:0157.<sup>28</sup> Supportive care is usually all that is required, because spontaneous recovery is the rule. In adults, however, HUS is additionally associated with use of various medications including cyclosporin A, gemcitabine, and mitomycin-C, among others. Use of potentially offending medications should be discontinued. Platelet transfusions are generally contraindicated in the absence of life-threatening bleeding as they are for TTP. However, the utility of plasmapheresis is less clear in this setting than for TTP, although successes have been reported, particularly in adults.

DIC is most commonly associated with infection or malignancy, although it can also be observed in the setting of vascular lesions such as hemangiomas and intravascular dissections. In contrast to TTP and HUS, the consumptive coagulopathy that occurs is not exacerbated by the administration of platelets and other blood components.<sup>29</sup> Although primary therapy should address the underlying condition, transfusions of platelets and other blood components may be safely administered in the interim.

### **Malignancy**

Thrombocytopenia is also a side effect of the cytotoxic chemotherapy administered for many different hematologic and nonhematologic malignancies. However, in addition, several hematologic malignancies are associated with inherent impairment in platelet function. Both the myelodysplastic and myeloproliferative syndromes are potentially associated with impaired platelet function out of proportion to any reduction in platelet number that is present. In this setting, platelet dysfunction results from ultrastructural abnormalities and impaired signaling, and may be manifest in platelet aggregation assays.<sup>30,31</sup> Platelet transfusions are sometimes indicated in the bleeding patient despite apparently acceptable platelet numbers. It should be noted, however, that myeloproliferative syndromes are also associated in some situations with platelet activation and thrombosis. Because of the latter, agents such as EACA should be used cautiously in these disorders and reserved for situations with reduced platelet function or severe thrombocytopenia.

### **Uremia**

Several nonmalignant acquired conditions are associated with platelet dysfunction. Of these, uremia is most commonly encountered in clinical practice. Elevated levels of metabolites, such as guanidinosuccinic acid, lead to impaired signaling from the surface receptors on the platelet through to cyclooxygenase.<sup>32</sup> Guanidinosuccinic acid also leads to inhibition of platelet aggregation by facilitating excess nitric oxide production.<sup>33</sup> Treatment of uremia with dialysis restores platelet function toward normal. For the patient with acute bleeding in the setting of uremia, several therapies have potential benefit.<sup>34</sup> DDAVP is administered

to release additional vWF from endothelial stores and to try to restore platelet signaling. It is reasonably safe and effective in this setting. Alternatively, administration of cryoprecipitate facilitates the same end. Recombinant Factor VIIa has been used off label in a small number of patients with severe bleeding in this setting, but its safety is still not well documented. For less acute bleeding, high doses of conjugated estrogens (several milligrams daily) may be effective. The mechanism of action is not well understood, and it usually takes several days to observe a beneficial effect.

### **Dialysis**

Although dialysis improves platelet function in uremia, it is also associated with the development of thrombocytopenia. In particular, continuous venovenous dialysis or hemofiltration has been associated with a reduction in platelet number in some patients.<sup>35</sup> It is important to distinguish thrombocytopenia caused by the dialysis procedure from heparin-induced thrombocytopenia, because patients are often treated with this anticoagulant in the intensive care setting.

### **Cardiac Interventions**

Cardiac procedures, use of ventricular assist devices, and cardiopulmonary bypass may all be associated with thrombocytopenia and/or defects in platelet function. Thrombocytopenia in cardiac catheterization is associated with the use of agents that inhibit GPIIb/IIIa function.<sup>36</sup> A hemorrhagic diathesis is exacerbated by the concomitant use of antiplatelet agents. Ventricular assist devices and cardiopulmonary bypass are also associated with platelet consumption.<sup>37</sup> As in the dialysis setting, the distinction of heparin-induced thrombocytopenia from other causes is critical. Platelet transfusion is indicated if simple platelet consumption is suspected, whereas it is relatively contraindicated when heparin-associated thrombocytopenia is present.

### **Medications and Supplements**

A number of medications, herbal remedies, and nutritional substances result in disorders of platelet function or number.<sup>38,39</sup> Aspirin and NSAIDs are among the most commonly used over-the-counter medications. In the case of aspirin, irreversible acetylation of cyclooxygenase in the platelet results in loss of function for the 5- to 7-day life span of the platelet. Conversely, NSAIDs are reversible inhibitors. This distinction is important in the bleeding patient. If a patient with life-threatening bleeding has consumed aspirin during the past several days, platelet transfusion may be indicated. However, in the case of NSAIDs, once at least four to five half-lives have elapsed, there is generally little utility in platelet transfusion unless a concomitant condition is present.

Immune-mediated thrombocytopenia (see Chapter 23) has been associated with the use of many different drugs. Most notably quinine, quinidine, sulfonamides, sulfonamide derivatives such as furosemide, and vancomycin have been associated with autoantibody formation.<sup>40,41</sup> Although platelet transfusion may

be necessary in patients with active bleeding, treatment consists primarily of discontinuation of the agent and observation. If necessary, treatment with immune globulin or corticosteroids may be initiated to hasten recovery of the platelet count.

Heparin-induced thrombocytopenia is a special class of immune-mediated thrombocytopenia in which antibodies form to the combination of heparin and platelet factor 4.<sup>42</sup> These antibodies bind to the platelet surface, resulting in activation and platelet clearance. The result of platelet activation is the presence of a highly hypercoagulable state that is not infrequently associated with either venous or arterial thrombosis. Although perhaps more commonly associated with unfractionated heparin, this syndrome is also associated with use of low-molecular-weight heparins. The diagnosis is suggested when the platelet count decreases by 50% or to less than 100,000/ $\mu$ L in a patient receiving one of these drugs. Although laboratory testing confirms the presence of antibodies, the diagnosis in the acute setting remains a clinical one. Because of the challenges inherent in distinguishing the cause of thrombocytopenia in critically ill patients, a relatively simple scoring system has been proposed.<sup>43</sup> When heparin-induced thrombocytopenia is suspected, treatment consists of immediate discontinuation of any heparin-containing product and institution of an alternative anticoagulant, such as lepirudin or the direct thrombin inhibitor argatroban. Use of warfarin alone is contraindicated, because it decreases protein C levels and can lead to catastrophic thrombosis.<sup>44</sup> Platelet transfusion is contraindicated even in patients with low counts on anticoagulation, except in the circumstance of life-threatening bleeding.

Many other commonly encountered classes of drugs are associated with qualitative or quantitative changes in platelets. These include traditional anticonvulsants such as valproic acid, which has also been associated with immune-mediated thrombocytopenia, and more recently approved agents such as gabapentin.<sup>45,46</sup> Simple discontinuation of these agents is generally all that is required in order to facilitate resolution of the defects. Drugs that affect both platelet number and function include heparin (mentioned above).

### Posttransfusion Purpura

The development of severe thrombocytopenia (platelet count often less than 10,000/ $\mu$ L) within approximately 1 week after blood transfusion should lead to suspicion of posttransfusion purpura (PTP). The pathophysiology of this disorder is poorly understood, but appears to involve autoantibody formation initiated by exposure to transfused antigens.<sup>47</sup> The most well-described cases involve autoantibodies to the platelet antigen HPA-1a ( $PI^{A1}$ ). Although the thrombocytopenia usually resolves spontaneously within a few weeks, there is a relatively high rate of bleeding associated with PTP, so that treatment should be considered. Platelet transfusion is generally ineffective. Administration of immune globulin (0.4 g/kg for 5 days or the equivalent) or plasmapheresis have been shown to have some efficacy in this setting, and represent reasonable therapeutic alternatives.<sup>48</sup>

### Neonatal Alloimmune Thrombocytopenia

About 1% to 2% of women have platelets of the HPA-1b ( $PI^{A2}$ ) phenotype. When they become pregnant with a fetus that has HPA-1a platelets, some of these women develop antibodies to HPA-1a. These antibodies cross the placenta and lead to fetal thrombocytopenia even during the first pregnancy, unlike the situation with Rh-negative individuals in which prior sensitization is required. Such fetal thrombocytopenia has been associated with intrauterine intracranial hemorrhage that usually occurs after about 30 weeks of gestation, as well as at the time of parturition. Most women come to attention after delivering a thrombocytopenic infant. Referral to specialists in high-risk obstetric practice is required. The administration of immune globulin after 20 weeks of gestation has sometimes been successful in preventing thrombocytopenia during further pregnancies.<sup>49</sup> In addition, use of intrauterine platelet transfusions may be considered (see Chapters 23 and 26).

---

## Platelet Transfusion

### Platelet Products

In the United States, whole-blood-derived platelet units (also called random-donor units) are prepared as platelet-rich plasma (see Chapter 12).<sup>50,51</sup> First, red cells and platelet-containing plasma are separated. Then the platelet-containing plasma is spun at higher centrifugal force to generate platelet-poor plasma and a platelet pellet, which is resuspended in about 50 mL of plasma. Outside of the United States, the buffy coat method is often used for platelet preparation.<sup>52</sup> In this case, after centrifugation analogous to that used to separate plasma from the red cell pellet, the buffy coat layer atop the red cells is harvested. Both platelet preparation methods involve the pooling of four to six units, result in a similar quality product. Each unit contain at least  $5.5 \times 10^{10}$  platelets.<sup>53</sup> Thus, a 6-unit pool would contain  $3.3 \times 10^{11}$  platelets. This platelet dose generally leads to a platelet increment of 30,000 to 60,000/ $\mu$ L in the platelet-naïve patient when measured 1 hour after administration.

Apheresis platelets (often called single-donor platelets) are harvested from an individual through use of an apheresis device.<sup>54</sup> This procedure results in a platelet concentrate prepared from one donor that generally contains more than  $3 \times 10^{11}$  platelets. The potential advantage of this method of collection is that it reduces donor exposure. However, studies comparing apheresis platelets to leukocyte-reduced pooled whole-blood-derived platelets have not demonstrated any reduction in alloimmunization.<sup>55</sup> In addition, because of the highly sensitive nature of transmissible agent testing of units that is currently in place, any reduction in infectious risk is likely modest at best. In some areas of the United States, apheresis collection is significantly more expensive than whole-blood donation. Therefore, although the products may be considered interchangeable, use of whole-blood-derived platelets in some settings is preferred to use of apheresis platelets in the absence of special circumstances such as the need for HLA matching.<sup>56</sup>

## Platelet Storage and Processing

Platelets concentrates are stored at room temperature (22°C) because chilling activates them and results in a poor recovery after transfusion.<sup>57</sup> Storage at room temperature presents the challenge of bacterial contamination and growth. For these reasons concentrates are stored for up to 5 days. Storage for up to 7 days using current techniques and testing methodologies has generally shown similar product safety.<sup>58</sup> However, controversy over use of 7-day platelet storage still exists. Indeed, in early 2008 additional concerns over the possibility of bacterial contamination in 7-day stored platelets led to cessation of a Food and Drug Administration (FDA) Phase IV trial for production of 7-day stored platelets. As of this writing, the future of 7-day stored platelets is uncertain. Attempts to develop methods for refrigerating or freezing platelets have been made. However, to date none has been sufficiently successful to replace the current storage methods. The FDA has licensed a platelet system for prestorage pooling of whole-blood-derived platelets for storage up to 5 days. This system permits the same bacterial monitoring as is performed for apheresis platelets. See Chapters 12 and 49 for more details.

Following collection, platelet products can undergo leukocyte reduction (see Chapter 16). Although leukocyte reduction is associated with loss of up to 25% of the platelets in a concentrate, beneficial effects include reduction in cytomegalovirus (CMV) infection, febrile transfusion reactions, and platelet alloimmunization.<sup>59,60</sup> Gamma-irradiation that is used to prevent transfusion-associated graft-vs-host disease (GVHD) may decrease the platelet increment somewhat. However, it is certainly indicated in transplant recipients and other immunocompromised patients, including individuals with leukemia or lymphoma. (See Chapter 54 for more details.) Washing of platelet concentrates is time-consuming and may result in a decrease in platelet number.<sup>61</sup> Therefore, washing should be reserved for patients with severe allergic reactions who cannot be managed with appropriate medications.

## Platelet Dose

As noted above, a unit of whole-blood-derived platelets generally contains at least  $5$  to  $7 \times 10^{10}$  platelets and apheresis units contain more than  $3 \times 10^{11}$  platelets. In the absence of a consumptive coagulopathy, the platelet-naïve patient is expected to have a 1-hour platelet increment of 30,000 to 60,000/ $\mu$ L. Multitransfused patients have more modest increments. Both immune and nonimmune mechanisms are responsible for this phenomenon, although the latter appear predominant. In patients with acute myeloid leukemia who have received 25 platelet transfusions, the mean 1-hour platelet increment is reduced by about one-third and the 18- to 24-hour platelet increment is reduced by more than half in comparison to that observed after the first platelet transfusion.<sup>62</sup> Therefore, reduction in the number of unnecessary platelet transfusions is of significant benefit. However, the optimal platelet dose for each transfusion still remains to be determined.

Prophylactic transfusion refers to maintenance of the platelet count above a certain threshold in patients who are neither bleeding nor actively consuming platelets because of immune destruction or infection. Several recent studies have indicated that a patient platelet transfusion threshold of 10,000/ $\mu$ L is acceptable in the setting of stable patients with thrombocytopenia, including individuals with leukemia.<sup>63-65</sup> This is in relative agreement with older data estimating the fixed daily platelet production requirement for hemostasis to be about 7500/ $\mu$ L.<sup>66</sup> Potential benefits of the use of a threshold of 10,000/ $\mu$ L compared to higher platelet counts include a reduction in the incidence of platelet refractoriness and decrease in the incidence of transfusion-associated reactions.

Platelet transfusion is indicated in individuals with thrombocytopenia who are bleeding or who require invasive therapeutic interventions. The platelet transfusion threshold in such instances is dependent on the individual circumstances, including the presence of concomitant infection, coagulopathy, or a history of platelet refractoriness. Data from well-conducted clinical trials in this area are lacking, and in their absence only general guidelines can be provided.<sup>67</sup>

For mild bleeding, such as oozing from the gums or epistaxis, it is reasonable to maintain the platelet count above 20,000/ $\mu$ L. For more severe hemorrhage, such as gastrointestinal bleeding with a decrease in hemoglobin of at least 2 g/dL, maintenance of the platelet count above 30,000 to 50,000/ $\mu$ L is indicated. For intracranial hemorrhage, maintenance of the platelet count above 70,000 to 100,000/ $\mu$ L is recommended. Platelet counts of at least 50,000/ $\mu$ L are generally considered safe for general surgery. However, lower counts are accepted by some. Platelet counts of 70,000 to 100,000/ $\mu$ L are considered appropriate for neurosurgery.

## Platelet Administration

Platelets contain ABO antigens on their surface. Transfusion of ABO-mismatched platelets, however, is not associated with a major reaction. Nonetheless, there are data to support the use of ABO-matched platelet products whenever possible.<sup>68</sup> ABO matching appears to result in reduced immune destruction, and may have further implications as well. When the supply allows, ABO-matched platelets should be transfused.

In contrast to ABO, Rh blood group antigens are not expressed on the surface of the platelet. However, red cells with these antigens are invariably contained in platelet products. Therefore, transfusion of platelets from Rh-positive donors to Rh-negative recipients can lead to alloimmunization to the D antigen. Because of immune suppression, this is uncommonly encountered in patients with hematologic malignancies receiving Rh-mismatched platelets. The resolution to this issue is to administer matched products whenever available or to administer intravenous (IV) Rh Immune Globulin. A dose of 100 IU is generally protective for a transfused bag of platelets.<sup>69</sup>

Specific platelet transfusion indications, such as for patients with acute leukemia, lend themselves to the use of leukocyte-reduced, irradiated platelet products (see Chapters 16 and 54).

Because of the potential reduction in the number of platelets, washing of platelets should be reserved for individuals with severe allergic reactions that cannot otherwise be overcome by appropriate medications.

Although acetaminophen 650 to 1000 mg and diphenhydramine 25 to 50 mg are frequently administered before platelet transfusion as primary prophylaxis against febrile and allergic reactions, few data exist to support this as routine practice.<sup>70,71</sup> However, once an allergic reaction has been observed (hives, wheezing, dyspnea), diphenhydramine is the drug of choice to prevent additional reactions in the future. If a moderate allergic reaction recurs in an adult despite administration of these premedications, hydrocortisone 100 mg IV, is often effective. Additional agents that might be of benefit include H<sub>2</sub>-antagonists such as cimetidine or ranitidine and doxepin. Recurrence of severe allergic reactions despite premedication is an indication for the use of washed platelets.

Platelet concentrates must be administered to adults through a blood filter. Generally a standard blood set with a 170- or 260-micron filter, or a platelet leukocyte reduction filter is used, with an infusion time of about 30 minutes to 1 hour. Slower administration, such as a continuous platelet drip, may be desirable in some settings. However, once the bag is entered the contents must be administered within 4 hours. Use of a mechanical pump has the advantage of a more controlled rate of platelet infusion and should be considered if a continuous platelet drip is employed.<sup>72</sup>

Platelet transfusion is not without risk. Aside from the development of platelet refractoriness and allergic reactions that can be observed with any blood component, platelets are the component most commonly associated with the transmission of bacterial infection.<sup>73</sup> In the past it has been estimated that about 1 in 5000 platelet units are contaminated with bacteria. Newer standards for bacterial testing should help reduce the incidence of bacteremia associated with platelet transfusion. Nonetheless, there is a heightened sense of awareness for the possibility of bacterial transmission in those receiving platelet transfusions, particularly if individuals are neutropenic and become febrile during or shortly after a platelet transfusion.

## Platelet Refractoriness

### Determination

Platelet refractoriness is often defined as failure to achieve the expected increment in the platelet count after two consecutive transfusions.<sup>74</sup> A poor response to a given platelet unit is common.

Determination of platelet refractoriness requires a platelet count between 10 and 60 minutes following completion of the transfusion. Lack of a response at a later time following transfusion can be caused by underlying clinical problems, whereas the absence of a response at this immediate point after transfusion usually indicates refractoriness from immunologic causes.

Two methods that are often used in the setting of clinical research are calculation of the corrected count increment

(CCI) and the 1-hour posttransfusion percent platelet recovery (PPR).<sup>75</sup> The formulas for these are as follows:

$$CCI = \frac{(\text{post-tx plt count}/\mu\text{L} - \text{pre-tx plt count}/\mu\text{L}) \times \text{BSA in m}^2}{(\text{number of plts transfused}) \times 10^{-11}}$$

$$PPR = \frac{(\text{post-tx plt count}/\mu\text{L} - \text{pre-tx plt count}/\mu\text{L}) \times \text{weight in kg} \times 75 \text{ mL}}{\text{plt count of product transfused}/\mu\text{L} \times \text{volume of plts in mL}}$$

where BSA is the body surface area, plt is platelet, and tx is transfusion. Although the number of platelets or platelet count of the product transfused is generally not known, approximations may be used. As noted earlier, a unit of whole-blood-derived platelets generally contains at least  $5.5 \times 10^{10}$  platelets. Thus a 6 unit pool contain  $3.3 \times 10^{11}$  platelets and units collected by apheresis contain at least  $3 \times 10^{11}$  platelets. These values can be used in the calculation. In a 75-kg individual a CCI of 10,000 to 20,000/ $\mu\text{L}$  is expected. Lower values than these are consistent with refractoriness.

An alternative calculation used in daily clinical practice is the platelet increment (posttransfusion platelet count/ $\mu\text{L}$  – pretransfusion platelet count/ $\mu\text{L}$ ). Assuming a platelet recovery of 60% in this setting, a whole-blood-derived platelet pool or an apheresis unit administered to a thrombocytopenic patient should increase the platelet count on average by about 20,000 to 40,000/ $\mu\text{L}$ .<sup>76</sup>

### Causes

Lack of response to platelet transfusion may be the result of an underlying acute illness, such as infection, or may result from a more chronic condition, such as splenomegaly. Fever, sepsis, DIC, hemorrhage, and conditions associated with marrow transplantation such as veno-occlusive disease and GVHD all contribute to platelet refractoriness.<sup>77</sup> Treatment of the underlying illness is indicated. Independent of other nonimmune and immune causes of decreased recovery, for reasons that are poorly understood, repeated platelet transfusion may be associated with decreased platelet recovery in certain populations, such as individuals with acute myeloid leukemia. Nonimmune causes generally have their greatest impact on the response to platelet transfusion beyond the 60 minutes and reduce, but do not eliminate, responsiveness.

Because platelets contain a variety of surface antigens, including ABO antigens, HLA antigens, and platelet-specific antigens, exposure to allogeneic transfusions can result in the formation of antibodies. Platelet refractoriness is, therefore, more commonly observed in patients who have received multiple transfusions and/or been pregnant.<sup>78</sup>

The most commonly encountered antibodies are those to HLA antigens (about 45%) and not to other platelet-specific antigens. However, compelling randomized data from patients undergoing treatment for acute leukemia or autologous transplantation for Hodgkin lymphoma have suggested that transfusion of

ABO-incompatible platelets increases the incidence of platelet alloimmunization. ABO incompatibility is defined in this case as the presence of A or B antibodies in the recipient to donor A or B antigens. Nine of 13 patients (69%) receiving ABO-incompatible platelets became platelet refractory with a median onset at Day 15 compared with only one of 13 patients (8%) treated with compatible platelets ( $p < 0.001$ ).<sup>79</sup> Mechanisms proposed include development of antibodies to the mismatched antigen and nonspecific stimulation of the immune system. Additional retrospective data in the literature support this finding. Use of ABO-matched platelets is recommended when possible, particularly for patients with hematologic malignancies who are likely to receive numerous platelet transfusions over time.

## Management of Platelet Refractoriness

### Platelet Crossmatching and HLA Matching

Platelet crossmatching and HLA matching may be used effectively to overcome platelet refractoriness (Fig 13-1). Each strategy has its advantages and disadvantages (see Chapters 11 and 31 for more detail).<sup>80</sup> Platelet crossmatching allows for screening of the transfused platelet product against HLA antigens and platelet glycoprotein antibodies. Because it does not rely on HLA typing of the recipient or specific donor procurement, it is potentially more rapid and less expensive than HLA typing. However, the number of units available for testing is often limited.

HLA matching of platelets uses databases of HLA-typed platelet donors who can then be asked to donate by apheresis. This requires logistic coordination, with a time lag of approximately 48 hours to facilitate appropriate transmissible agent testing, and is not effective in the 5% to 10% of patients who have antibodies to other platelet glycoproteins.

Despite use of crossmatched or HLA-matched platelet units, certain individuals remain platelet refractory. In some of these cases, resolution of concomitant conditions such as sepsis or hemorrhage results in a return of platelet responsiveness. In others, the underlying mechanism involves nonimmune mechanisms facilitating rapid platelet clearance.

### Continuous Infusion

For the patient who is actively bleeding or at high risk of bleeding because of severe refractory thrombocytopenia (platelet count less than 5,000 to 10,000/ $\mu\text{L}$ ), the use of a continuous infusion of a low dose of platelets may be employed. The equivalent of about three whole-blood-derived platelet units is administered over 4 hours, ideally with use of a mechanical pump. Even in the absence of a measurable increase in the platelet count this approach may be effective in facilitating hemostasis. Another advantage to this approach over repetitive bolus administration used in an attempt to achieve a measurable platelet increment is that it provides the blood bank with reasonable inventory

**Figure 13-1.** Evaluation and management algorithm used for individuals who appear to be refractory to platelet transfusion.  
DIC = disseminated intravascular coagulation;  
EACA = epsilon-aminocaproic acid.

expectations. Because of the significant blood bank and nursing resources involved, the use of a continuous infusion of platelets should be reserved for appropriate refractory cases in which alternatives have been thoroughly evaluated.

### Other Modalities

The administration of immune globulin has been reported in certain cases to be successful in overcoming platelet refractoriness.<sup>81</sup> Doses used have often been similar to those used in ITP (0.4 g/kg daily for 5 days or its equivalent). However, there are no data more systematically examining this modality.

EACA and tranexamic acid are effective adjuncts to platelet transfusion in patients with severe thrombocytopenia and bleeding (tranexamic acid is not available in the United States). Even at relatively low doses of 1 g every 6 hours, EACA appears to be effective in this setting. In one retrospective study of thrombocytopenic patients who were bleeding, 51 of 77 patients (66%) achieved a complete response to EACA administration, resulting in a reduction in platelet and red cell transfusion requirements.<sup>82</sup> Although antifibrinolytic agents should not be used in patients with DIC or upper urinary tract bleeding, their safety and efficacy profile in other thrombocytopenic patients with hemorrhage is favorable.

Sometimes touted as a universal hemostatic agent, recombinant Factor VIIa has been used in the setting of severe thrombocytopenia with bleeding in order to achieve hemostasis.<sup>83</sup> At this time, it is reasonable to consider the use of recombinant Factor VIIa at a dose of approximately 90 µg/kg for the thrombocytopenic individual who is refractory to platelet transfusion and has life-threatening bleeding. Aside from this setting, the most systematic data for use of this agent in platelet disorders exists for those with Glanzmann's thrombasthenia. It has been suggested that 90 µg/kg given to these individuals every 2 hours for three or more doses is effective in controlling bleeding.<sup>84</sup> Although observed to be effective in some cases, clinical trials are required to better define the use of this agent in those with thrombocytopenia or platelet function disorders.

### Alternatives to Platelet Transfusion

Current storage constraints on platelet concentrates often result in shortages of this product. Attempts have been made to develop platelet substitutes and novel storage technologies.<sup>85</sup> Although some promising approaches have been used, such products are not yet available for routine clinical use. Conversely, one cytokine [interleukin 11 (IL-11)] has received regulatory approval for use in the management of thrombocytopenia and several other agents are likely to be approved in the near future.

### Platelet Substitutes and Storage Technologies

Platelet substitutes are in relatively early stages of development. Among other approaches, ongoing efforts are being made to develop human platelet fragments that could be stored for lengthy periods and platelet cell surface molecules that are coupled to nanoparticles.<sup>86</sup>

The lesion that leads to the clearance of platelets that have been stored in the cold (below 12°C) has been investigated extensively. In vitro, it appears that glycosylation (in particular, galactosylation) can prevent the clearance of refrigerated human platelets that are otherwise recognized by macrophage complement type 3 (CR3) receptors.<sup>87,88</sup> Whether modification of platelets in this manner will facilitate the effective transfusion of platelets in humans remains to be seen.

### Cytokines and Thrombopoietin Analogs

Recombinant IL-11 is a growth factor produced by DNA technology that stimulates proliferation of hematopoietic stem cells (including megakaryocytes), induces megakaryocyte maturation, and increases platelet production. IL-11 was found to be moderately effective in reducing the need for platelet transfusions when administered subcutaneously at a dose of 50 µg/kg daily in patients receiving cancer chemotherapy that caused severe thrombocytopenia.<sup>89</sup> However, these trials were relatively small. IL-11 has been associated in some individuals with allergic reactions, and it has also been associated with cardiovascular adverse events including atrial arrhythmias and tachycardia.

Because of the promise of more specific and potent stimuli for platelet production, the investigation of thrombopoietin analogs has overshadowed the development of IL-11. Thrombopoietin was identified as the 332 amino acid glycoprotein ligand for the c-Mpl receptor.<sup>90</sup> Although it has effects on other stem cells, it has been shown to stimulate platelet production through the proliferation of marrow stem cells and the maturation of megakaryocytes. Thrombopoietin is regulated through a feedback loop. It is synthesized primarily in the liver and binds to the surface of circulating platelets and to megakaryocytes. When thrombocytopenia is present, more thrombopoietin is available to bind to the c-Mpl receptor and stimulate platelet production. Initial attempts at the development of a thrombopoietin analog for therapeutic use (pegylated recombinant megakaryocyte growth and development factor) were associated with antibody formation in healthy volunteer platelet donors. Thus, further development was halted. However, more recently a recombinant thrombopoietin analog has been developed in which part of the molecule has been fused to an immunoglobulin Fc peptide. This molecule, AMG531, has been termed a peptibody. Studies conducted in patients with chronic ITP demonstrated that when administered subcutaneously, this agent was safe and effective, producing platelet responses in the range of 50,000 to 450,000/µL in more than half of the patients treated with an acceptable safety profile.<sup>91,92</sup> The FDA granted regulatory approval of this agent in 2008.

Other approaches to stimulating platelet production have involved developing nonpeptide molecules that stimulate the c-Mpl receptor. Several of these compounds are currently in development. The most advanced of these is eltrombopag. This oral agent has been evaluated in patients with ITP and in patients with thrombocytopenia resulting from cirrhosis and hepatitis C virus infection. In both settings it was highly effective in a

dose-dependent manner when compared with placebo in increasing the platelet count to the target range. At a dose of 75 mg daily, 81% of patients with ITP achieved a platelet count of greater than 50,000/ $\mu$ L and 65% of patients with cirrhosis and hepatitis C infection achieved a platelet count of greater than 100,000/ $\mu$ L.<sup>93,94</sup> Additional studies with AMG531, eltrombopag, and other novel investigational agents are ongoing.

Although efficacy in settings such as hematopoietic stem cell transplant is unlikely given the above-noted experience, other applications are possible. For example, AMG531 has been reported to result in improvement in platelet counts in patients with myelodysplastic syndromes.<sup>95</sup> However, given the emerging safety data regarding another hematopoietic growth factor, erythropoietin, use of thrombopoietin-mimetics in the setting of malignancy will likely proceed in a cautious manner.<sup>96</sup>

## Summary

A variety of diverse congenital and acquired conditions are associated with thrombocytopenia or its functional equivalent. Congenital causes are rare, but acquired causes are relatively common. In particular, thrombocytopenia or platelet dysfunction associated with the administration of chemotherapy or with surgical procedures are leading indications for platelet transfusion. The availability of a variety of platelet products for transfusion facilitates the supportive care of individuals receiving chemotherapy and the treatment of bleeding individuals with thrombocytopenia or its functional equivalent. Leukocyte-reduced whole-blood-derived platelets and apheresis platelets are associated with similar rates of infection and alloimmunization, and can be used interchangeably in most settings. A prophylactic platelet transfusion threshold of 10,000/ $\mu$ L is generally acceptable for afebrile patients receiving cancer chemotherapy. Maintenance of a higher platelet count is indicated in a number of situations, including the settings of sepsis, DIC, hemorrhage, trauma, and surgery. Febrile and allergic reactions to platelet transfusion can often be managed conservatively with the administration of acetaminophen and diphenhydramine. Platelet refractoriness based on nonimmune and immune mechanisms remains a major issue when repeated transfusions are required. After platelet refractoriness following two transfusions has been documented, ABO matching, platelet crossmatching, and HLA matching may be used as initial strategies to address the situation. Antifibrinolytic agents and recombinant Factor VIIa are useful adjuncts to platelet transfusion in the bleeding or platelet refractory patient. Because of the limitations of current storage techniques, research and development continue on platelet storage and substitutes. Thrombopoiesis-stimulating agents should provide additional therapeutic alternatives for the management of thrombocytopenia in specific settings. However, much additional research and development will be necessary in order to establish their safety and efficacy in patients receiving cancer chemotherapy.

## 14

# Neutrophil Production and Kinetics: Neutropenia and Neutrophilia

**Thomas H. Price**

Executive Vice-President and Medical Director, Puget Sound Blood Center, and Professor of Medicine, University of Washington, Seattle, Washington, USA

The neutrophil is the body's principal defense against bacterial infection and is especially equipped to locate, phagocytose, and kill invading microorganisms. The system of neutrophil production in the marrow and distribution in the blood and tissues serves both to maintain a baseline supply of these cells and to ensure the rapid delivery of increased numbers of neutrophils to areas of infection or inflammation.

## Production in Marrow

The pluripotent stem cell may give rise to any type of hematopoietic cell. With differentiation, a fraction of these cells becomes committed to the neutrophil line. Development beyond this committed progenitor stage proceeds sequentially from the myeloblast, the earliest recognizable neutrophil precursor, to the promyelocyte, the myelocyte, the metamyelocyte, the band forms, and the mature segmented neutrophil, at which time cells are released into the circulation—a process that normally takes 10 to 12 days. There are two important features to marrow neutrophil production: cell proliferation and cell maturation. Cell division is limited to the myeloblast, promyelocyte, and myelocyte compartments.<sup>1</sup> Most cells probably undergo four or five divisions between the myeloblast and myelocyte stage, each division taking approximately 1 day.<sup>2</sup> Cell maturation occurs continuously from the myeloblast to the mature neutrophil. An essential feature of this process is the ordered development of the neutrophil's characteristic four types of cytoplasmic granules. Primary granules containing myeloperoxidase and serine proteases appear during the promyelocyte stage; secondary granules containing lactoferrin and collagenase and tertiary granules containing gelatinase appear at the myelocyte stage; and secretory vesicles appear at the stage of the mature cell. This cytokine-driven chronology is based on the transcriptional regulation of sequentially expressed genes coding

the various granular proteins.<sup>3</sup> Additional changes during maturation include increased adherence abilities, increased deformability, increased responsiveness to chemoattractants, and the development of the neutrophil's characteristic segmented nucleus. Under normal circumstances the transit time for the postmitotic pool is approximately 7 days,<sup>4</sup> a value that can be shortened by 2 to 3 days under situations of stress.<sup>5</sup> Normal baseline neutrophil production, based on the transit time and the size of the postmitotic compartment, is approximately  $0.85 \times 10^9$  cells/kg/day.<sup>4</sup>

An important requirement of the neutrophil defense system is that it be able to deliver large numbers of mature neutrophils to a site of infection or inflammation. To this end, approximately two-thirds of the marrow postmitotic pool, composed of segmented neutrophils and band forms, can be shifted rapidly from the marrow into the circulation under situations of stress or of increased tissue neutrophil demand.<sup>6</sup> Mobilization also occurs as a response to stimuli such as exercise, corticosteroids, endotoxin, cytokines such as granulocyte colony-stimulating factor (G-CSF), chemokines, or bacterial products.<sup>7,8</sup> The time course varies with the stimulus from a few minutes (chemokines) to a few hours (G-CSF, corticosteroids, infection). For G-CSF-mediated mobilization, the interaction of the chemokine stromal-derived factor-1 (SDF-1) and its receptor (CXCR4) appear to be key.<sup>8</sup> SDF-1 is constitutively produced by osteoblasts and marrow stromal cells. CXCR4 is expressed on neutrophils, and retention in the marrow may depend on this SDF-1/CXCR4 interaction. With G-CSF administration, marrow SDF-1 levels and neutrophil CXCR4 levels both fall dramatically. Treatment with AMD3100, an inhibitor of CXCR4, results in neutrophil mobilization. Regardless of the mechanism, the extent of the storage pool shift depends on the intensity of the stimulus and will be reflected in the magnitude of the neutrophilia and in the degree to which immature forms are seen in the blood.

## Regulation of Neutrophil Production

The commitment of a pluripotent progenitor to myeloid development is incompletely understood but is strongly influenced by

both cytokines and transcription factors. The cytokines G-CSF, granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin (IL)-3, and IL-6 all stimulate granulopoiesis, but G-CSF appears to be pivotal.<sup>8</sup> In addition to inducing commitment to the myeloid line, G-CSF stimulates myeloid proliferation, reduces transit time through the marrow, and causes release of neutrophils from the marrow. Knockout mice for either G-CSF or the G-CSF receptor exhibit severe neutropenia,<sup>9,10</sup> as do animals treated with antibody to G-CSF.<sup>11</sup> In vivo, G-CSF causes a dramatic increase in neutrophil production with marked neutrophilia.<sup>5,12</sup> Cell development along the neutrophil line is also dependent on more than a dozen transcription factors, molecules that bind to DNA and regulate gene expression.<sup>13</sup> Two of the critical factors are PU.1 and CCAAT/enhancer-binding protein  $\alpha$  (C/EBP $\alpha$ ). PU.1 binds to promoter sequences and is essential for maturation of cells in the myeloid lines. C/EBP $\alpha$  is important in early myeloid development. C/EBP $\alpha$  null mice lack mature neutrophils, and the cells do not express the G-CSF receptor. Presumably there is a negative feedback system in which inflammatory stimuli or a paucity of mature neutrophils stimulates neutrophil production. Stark et al<sup>14</sup> have recently described such a system in mice in which tissue phagocytosis of apoptotic neutrophils reduced IL-23 production by macrophages/dendritic cells. IL-23 normally stimulates T cells to produce IL-17 which, in turn, stimulates production of G-CSF. Thus, adequate numbers of tissue neutrophils would decrease G-CSF levels, whereas a relative lack of tissue neutrophils would increase G-CSF levels, and stimulate neutrophil production.

## Blood Kinetics

Neutrophils leave the circulation by first-order kinetics, implying random loss rather than loss caused by senescence, a finding consistent with the fact that these cells perform their primary function after they leave the bloodstream. The blood half-disappearance time is normally 6 to 8 hours.<sup>4,15</sup> Blood neutrophils are distributed between two freely exchangeable pools of approximately equal size, the circulating pool and the marginal pool.<sup>16</sup> Cells in the circulating pool are those readily sampled by drawing blood. Conventionally, the cells in the marginal pool have been considered to be loosely adherent to the endothelium of the small venules. This notion has arisen from direct observation of the microcirculation in animals, which has shown neutrophils slowly rolling along the endothelial surfaces outside the main axial stream of the blood flow<sup>17,18</sup> as well as from the observation that cells in the marginal and circulating pools are in rapid equilibrium.<sup>16</sup> However, other information suggests that the marginal pool is not diffusely distributed throughout the vasculature but is largely localized to the liver, the spleen, or the pulmonary vasculature.<sup>19-25</sup>

## Migration into Tissues

The process of migrating from the blood to a site of inflammation is complex.<sup>24-26</sup> The initial stage of neutrophil capture and

rolling along the endothelial surface is mediated by the interaction of selectins and their ligands. L-selectin on the neutrophil surface interacts with a sialomucin oligosaccharide on the endothelial cell surface.<sup>24-27</sup> The ligand for P-selectin and E-selectin on the endothelial cells is platelet sialoglycoprotein ligand-1 (PSGL-1). The slow rolling of the neutrophils, in concert with local inflammatory signals, initiates firm adhesion, mediated by the interaction of neutrophil  $\beta 2$  integrin CD11/18 with intercellular adhesion molecule 1 (ICAM-1) on the endothelial cells.<sup>24-27</sup> Neutrophils migrate between endothelial cells into the tissues; they home to these migration points via an IgG-type molecule, platelet-endothelial cell adhesion molecule 1 (PECAM-1). The importance of these adhesion molecules for neutrophil emigration from the blood has been demonstrated by the effects of antibodies to these proteins<sup>25,28,29</sup> and by the identification of patients who lack these molecules or their ligands.<sup>30-33</sup> Patients with leukocyte adhesion deficiency types I and II are deficient in the  $\beta 2$  integrin and in a selectin ligand (SLeX), respectively, on the neutrophil surface. Both disorders are characterized by severe neutrophil dysfunction, neutrophilia, an inability to deliver neutrophils to sites of infection, and recurrent bacterial infection.

The nature and mechanisms of neutrophil margination and emigration appear to be different in the pulmonary vasculature than in the systemic vasculature. Neutrophil sequestration and migration in the lungs occurs principally in the capillary bed rather than in the post-capillary venules.<sup>25</sup> The degree of neutrophil sequestration in the pulmonary capillary bed, 35 to 100 times that of the larger systemic vessels, may be more related to cell size and deformability than to the influence of adhesion proteins.<sup>34-36</sup> The role of the adhesion proteins in neutrophil migration to the alveolar space may depend on the particular inflammatory stimulus. Recent evidence has indicated that emigration after infection with gram-positive organisms is independent of selectin/integrin, whereas that seen after infection with gram-negative organisms requires the involvement of these adhesion proteins.<sup>25,35,37</sup>

Neutrophil survival in both the blood and the tissues depends upon the rate of cellular apoptosis, the regulation of which is poorly understood. Pro-inflammatory stimuli such as G-CSF inhibit apoptosis, prolonging cell survival both in vitro and in vivo.<sup>5,38</sup> Pro-apoptotic factors, which serve to dampen the inflammatory response, have been identified in certain tissue inflammatory sites. Regulation of neutrophil apoptosis thus appears to be an important determinant of the intensity of the inflammatory process.<sup>39</sup>

## Response to Infection

The kinetic features of the inflammatory response are shown in Fig 14-1. The first phase is characterized by a rapid shift of bands and segmented neutrophils from the marrow into the blood, typically associated with an increase in the degree of margination. At the same time, expansion of cell production in the mitotic pool occurs by an increased rate of division of promyelocytes and myelocytes. It then takes 2 to 4 days for the leading edge of this wave of proliferation to proceed through the maturational pool

**Figure 14-1.** Marrow response to inflammation and/or infection. Pool size is represented by height of the box. Time spent in each pool is represented by width of the box. Rate of cell flow between compartments is represented by size of the arrows. Mitotic pool consists of myeloblasts, promyelocytes, and myelocytes. Maturation pool consists of metamyelocytes, bands, and segmented neutrophils. Early response is characterized by shift of marrow storage pool into circulation and increased margination of blood neutrophils. Late response is characterized by proliferation of mitotic pool and reduced transit time through the marrow pools. CP = circulatory pool; MP = marginal pool.

and reach the blood, resulting in a steady increased supply of neutrophils for delivery to the tissues. The degree to which marrow neutrophil production can increase during a serious infection has never been determined. However, if one assumes that, as with other cell lines, production might be able to increase five-fold, one might expect peak to neutrophil marrow output to be as much as  $5 \times 10^9$  cells/kg/day. When the infection clears or the inflammatory process runs its course, the marrow proliferative activity returns to baseline over the period of a few days.

## Blood Neutrophil Count

Although blood is merely the vehicle for transporting neutrophils from the marrow to the tissues, the blood neutrophil count remains the physician's most convenient measure of the status of the neutrophil defense system. Abnormalities of the neutrophil count are caused by alterations in the rate of effective marrow production, shifts from the marrow reserve into the circulation, or changes in the distribution or survival of blood neutrophils.

## Neutropenia

### Classification

Neutropenia is defined as a blood neutrophil count less than  $1500/\mu\text{L}$ . Neutropenia is important not only because it is an

indicator of an underlying abnormality but also because it can be associated, if severe (less than  $500/\mu\text{L}$ ), with an increased incidence of bacterial or fungal infection. It occurs in a variety of infectious, inflammatory, nutritional, malignant, and hematologic diseases, and as a consequence of many chemotherapeutic agents. In most of these disorders neutropenia is accompanied by significant degrees of anemia and/or thrombocytopenia. The following discussion focuses on the selective neutropenias, those conditions in which neutropenia is the dominant hematologic abnormality (Table 14-1).

The most common cause of isolated neutropenia is drug related. Cytotoxic drugs used for treatment of malignancy or for immunosuppression regularly cause neutropenia and, if given in large enough doses, will do so in all patients. These treatment-induced neutropenic states are further discussed in Chapters 15 and 31. Neutropenia can also result from an idiosyncratic reaction to a drug that, in most patients, does not cause neutropenia. In severe cases, the onset is sudden, and patients present with high fever, malaise, and perhaps evidence of localized infection. Blood neutrophils are few or absent; marrow examination reveals depletion of mature neutrophils and, in severe cases, absence of all myeloid cells. Many drugs have been reported to be responsible for these reactions.<sup>40-42</sup> These drug reactions are thought to occur by one of two mechanisms. The first is dose-related inhibition of neutrophil development, either by direct suppression of precursors (eg, ticlopidine, chlorpromazine) or by induction of apoptosis (eg, clozapine). The second is an immunologic

Table 14-1. Selective Neutropenias

reaction (eg, aminopyrine, propylthiouracil), the patient having developed an antibody to the drug or a drug metabolite. The two mechanisms are not distinguishable on the basis of the original clinical presentation. In either case, the offending drug should be considered permanently contraindicated.

The congenital neutropenias comprise a diverse collection of syndromes characterized by decreased marrow neutrophil production.<sup>43-46</sup> The pathophysiologic mechanisms are incompletely understood, but a common feature appears to be increased apoptosis of marrow neutrophil precursors. The best-studied syndrome has been that of severe congenital neutropenia. This disorder presents in infancy and is characterized by severe neutropenia (<500 cells/ $\mu$ L) and repeated episodes of infection. Examination of the marrow reveals few cells beyond the promyelocyte stage. Before the availability of G-CSF treatment, most patients did not survive childhood. Plasma G-CSF levels are normal or elevated, and G-CSF receptor expression is normal. Inheritance may follow an autosomal dominant or recessive pattern, the latter comprising about one-third of the cases. Mutations in the gene for neutrophil elastase (ELA2) are present in about two-thirds of the autosomal dominant or sporadic cases, but elastase RNA and protein levels are decreased in all patients, whether or not an ELA2 mutation is present. Mutations in the *HAX1* gene have been detected in the autosomal recessive

variety.<sup>47</sup> To date, all patients studied have exhibited downregulation of the downstream transcription factor lymphoid enhancer-binding factor 1 (LEF-1). LEF-1 interacts with both C/EBP $\alpha$  and the ELA2 promoter and is required for the maturation of myeloid precursors.

Myelokathexis is a disorder in which severe neutropenia is accompanied by a hypercellular marrow containing neutrophils with hypersegmentation and degenerative changes. The underlying pathology appears to be accelerated neutrophil apoptosis with resultant ineffective marrow neutrophil production. The genetic basis for this disorder is a mutation of the gene coding for the chemokine receptor CXCR4.<sup>45</sup> The disorder may be part of the WHIM syndrome, characterized by warts, hypogammaglobulinemia, infection, and myelokathexis.

Shwachman-Diamond syndrome is an autosomal recessive disorder characterized by short stature, pancreatic exocrine deficiency, and moderate neutropenia.<sup>48,49</sup> Anemia and thrombocytopenia occur in about half of the patients. Over 90% of patients have mutations in the Shwachman-Bodian-Diamond syndrome (*SBDS*) gene. The *SBDS* gene, located in the 7q11 region of chromosome 7, encodes a protein thought to be involved in RNA metabolism. Cytogenetic abnormalities may develop, particularly involving chromosome 7. Approximately 20% of patients can be expected to develop leukemia/myelodysplasia over the course of 20 years.<sup>49</sup>

Patients with Chediak-Higashi syndrome have cutaneous and ocular hypopigmentation, the presence of large abnormal granules in all granule-containing cells, frequent pyogenic infections, and the propensity to develop a late lymphoma-like accelerated phase. Neutropenia is usually mild, and the neutrophils are dysfunctional.<sup>50</sup> Mutations occur in the lysosomal tracking regulator gene, probably associated with protein transport to and from the lysosome.<sup>51</sup>

The p14 deficiency syndrome is characterized by severe neutropenia, partial albinism, short stature, and recurrent infections. The defect is a mutation in the gene encoding p14, an adaptor protein involved in mitogen-activated protein kinase signaling.<sup>52</sup>

Cyclic neutropenia is an autosomal dominant or sporadically occurring disorder characterized by regular oscillations of leukocytes, platelets, and reticulocytes, with predictable severe neutropenia occurring every 21 days.<sup>53</sup> These patients all have mutations in ELA2,<sup>54</sup> the likely mechanism being alterations in the rate of neutrophil apoptosis.

Neutropenia can also be seen in a number of broader metabolic or immunologic syndromes, some examples of which are listed in Table 14-1. Severe neutropenia and neutrophil dysfunction frequently accompany type 1b glycogen storage disease, an autosomal recessive disorder attributable to mutations in the glucose-6-phosphate-translocase gene.<sup>55</sup> Reticular dysgenesis is a neonatal disorder characterized by thymic aplasia and lack of lymphoid or myeloid development.<sup>56</sup> Patients are prone to serious bacterial and viral infection, and death occurs in early infancy. Dyskeratosis congenita is a rare disorder with dystrophic abnormalities in nails, skin, and mucous membranes, neutropenia, and an increased incidence of malignancy. Inheritance

can be X-linked or autosomal dominant or recessive. The gene involved in the X-linked variety has been mapped to Xq28 and is thought to be involved in cell cycle function.<sup>57</sup> Barth syndrome is X-linked and characterized by neutropenia, short stature, and cardiac and skeletal muscle myopathies. The genetic defect is a mutation in the gene that encodes tafazzin, a protein expressed in cardiac and skeletal muscle.<sup>58</sup> Griscelli syndrome is characterized by immune deficiency, partial albinism, neurologic abnormalities, lymphohistiocytosis, thrombocytopenia, and neutropenia. Various subtypes exist; the one related to hematologic abnormalities is associated with mutations in the *Rab27a* gene, which encodes a guanosine triphosphate (GTP)-binding protein.<sup>59</sup>

Chronic idiopathic neutropenia may be congenital or acquired and is characterized by absence of other hematologic findings, splenomegaly, or chromosomal abnormalities.<sup>60</sup> The marrow appears normal except for reduced mature neutrophils in certain patients. Clinical problems with infection tend to be more severe in patients with the lowest neutrophil counts and the fewest neutrophil precursors in the marrow. However, susceptibility to infection is best judged by the patient's experience, because some patients with very low counts have little clinical difficulty. Progression to malignancy or more serious hematologic disease is unusual.

Isolated neutropenia can be seen with deficiencies of folic acid, vitamin B<sub>12</sub>, or copper, although these disorders are more often accompanied by other hematologic abnormalities. Pure white cell aplasia is a rare disorder characterized by absence of myeloid cells in the marrow, attributed to autoimmune suppression of neutrophil production.<sup>61</sup>

Immune neutropenia and some neutropenias associated with splenomegaly are probably kinetically attributable to increased neutrophil turnover. Alloimmune neutropenia is a well described but uncommon disorder caused by the transplacental transfer of maternal antibody to neonatal HNA antigens. The clinical course is usually benign, and the disorder is transient, resolving after maternal antibody is metabolized. Autoimmune neutropenia is a poorly characterized syndrome, usually defined by the ability to detect an antibody directed toward a neutrophil antigen, often in the HNA system. In most cases, the clinical picture is similar to that of chronic idiopathic neutropenia.<sup>62</sup> Neutropenia is also occasionally a feature of immune-mediated diseases such as systemic lupus erythematosus and Sjögren syndrome.<sup>63,64</sup> The neutropenia of Felty syndrome (rheumatoid arthritis, splenomegaly, and neutropenia) is most likely attributable to a marrow proliferative defect in concert with reduced blood neutrophil survival caused by immune complexes produced in the spleen.<sup>65</sup>

Increased margination may be seen in patients with splenomegaly or inflammation<sup>21,66-68</sup> and mild neutropenia may result. Whether the increased margination seen with inflammation is a generalized phenomenon or occurs only in the small vessels in the area of inflammation is not known.

Mild to moderate neutropenia can occur in association with a variety of bacterial, viral, parasitic, or rickettsial infections. The mechanisms are poorly understood but probably involve a

combination of marrow suppression, increased adherence to endothelial cells, increased utilization, and splenic sequestration. In the face of overwhelming sepsis, neutropenia may be severe, reflecting increased utilization and exhaustion of the marrow reserves.

### Management of Neutropenia

The principal complication of moderate to severe neutropenia is the increased incidence of infection. Febrile neutropenic patients should be carefully evaluated to identify infection and treated initially with broad-spectrum antibiotics. Once an offending organism is identified, the antibiotic regimen can be adjusted accordingly. Prophylactic use of antibiotics may be associated with the emergence of resistant organisms, gastrointestinal complaints, and allergic reactions; nevertheless, their use may be appropriate in patients with frequent infections.

G-CSF therapy is often administered for severe neutropenia caused by an idiosyncratic drug reaction, even though most studies have not been able to demonstrate a survival advantage. Recent studies have suggested that treatment with G-CSF is effective in reducing the rate of infectious morbidity and mortality only in patients with neutrophil counts of less than 100/ $\mu$ L.<sup>41</sup>

G-CSF has proven very successful in treatment of the congenital neutropenias. Dale et al<sup>69</sup> reported a randomized controlled trial of daily G-CSF treatment in 123 patients with recurrent infections and severe chronic neutropenia (absolute neutrophil count less than 500/ $\mu$ L). Patients were randomly assigned to G-CSF treatment or 4 months of observation; those in the observation arm were subsequently treated with G-CSF. Ninety-three percent of patients responded. On therapy the mean blood neutrophil count was 1500/ $\mu$ L, marrow examination revealed an increased proportion of mature neutrophils, the incidence and duration of infectious episodes were decreased 50%, and the duration of antibiotic use decreased 70%. More recently, the Severe Chronic Neutropenia International Registry reported data on 853 patients followed since 1994, most of whom were treated with daily or every-other-day G-CSF.<sup>45,47,70</sup> Over 95% of patients responded to therapy; success was defined as achieving a blood neutrophil count in excess of 1000/ $\mu$ L. Mean blood neutrophil counts increased from 300/ $\mu$ L to 3700/ $\mu$ L over the course of the first year; these responses were for the most part long lasting with continued drug treatment. G-CSF has also been shown to be effective in patients with Shwachman-Diamond syndrome,<sup>49</sup> myelokathexis,<sup>71</sup> Felty syndrome,<sup>72</sup> autoimmune neutropenia,<sup>73</sup> and glycogen storage disease type 1b.<sup>74</sup> Myelodysplasia and acute leukemia have developed in 11.5% of patients with severe congenital neutropenia or Shwachman-Diamond syndrome (but not in other disorders listed in Table 14-1) followed over 5 to 6 years on G-CSF therapy.<sup>45</sup> The annual incidence increases with the duration of therapy and with higher doses of G-CSF. Leukemic conversion is associated with the development of other genetic abnormalities such as monosomy 7, ras mutation, or mutation of the G-CSF receptor (resulting in a truncated C-terminal cytoplasmic region). Because genetic instability and leukemic transformation were known to be part of these disorders before the

Table 14-2. Mechanisms and Causes of Neutrophilia

| Mechanism                      | Causes                                                                                                                                                                                                                                                                                     |                                                                                                                                                  |

advent of G-CSF therapy, it is not clear whether the increased incidence seen with therapy is an effect of G-CSF or merely reflects the fact that the patients live longer on therapy.<sup>45</sup>

Patients with febrile neutropenia may also benefit from G-CSF therapy. A randomized controlled study compared G-CSF/antibiotic therapy with that of antibiotics alone and demonstrated that patients receiving G-CSF had shorter duration of neutropenia and fever and a reduced likelihood of prolonged hospitalization.<sup>75</sup> The greatest benefit appeared to be for patients with documented infection and very severe neutropenia (neutrophil counts less than 100/ $\mu$ L).

Neutrophilia

Neutrophilia, defined as a blood neutrophil count in excess of 7500/ $\mu$ L, may be either acute or chronic (Table 14-2). Unlike the case with neutropenia, an elevated level of mature blood neutrophils usually has no clinical implications in itself; rather, it serves to alert the clinician to underlying events.

A shift of cells from the marginal pool to the circulating pool, resulting in neutrophilia, may be seen as an effect of epinephrine, in situations of acute stress, or with vigorous exercise. The effect is a rapid one, usually occurring within minutes, and is short lived, the neutrophil count rapidly returning to baseline when

the stimulus is removed. The neutrophil count usually will no more than double, and immature neutrophils are not seen.

Acute neutrophilia may also occur with mobilization of the marrow neutrophil reserves, most commonly as a result of infection or inflammation. The extent of the storage pool shift under these conditions depends on the intensity of the stimulus and will be reflected in the magnitude of the neutrophilia and in the degree to which immature forms are seen in the blood.

Chronic neutrophilia most commonly represents the marrow’s normal reaction to infection or inflammation. The marrow proliferative pool expands, increasing marrow neutrophil production several times over baseline. Chronic neutrophilia is also a feature of the myeloproliferative diseases, where marrow neutrophil production is autonomous.<sup>76</sup> These disorders can usually be distinguished from the more common benign reactive neutrophilias by the presence of additional features such as erythrocytosis, thrombocytosis, eosinophilia, basophilia, a more pronounced shift to the left (more immaturity), splenomegaly, a low leukocyte alkaline phosphatase (in chronic myelocytic leukemia), chromosomal abnormalities, or the presence of the *BCR* gene rearrangement.

Chronic neutrophilia is also caused by reduced migration of neutrophils from the blood to the tissues. This mechanism is responsible for the mild to moderate neutrophilia seen with chronic corticosteroid therapy.<sup>77,78</sup>

Patients with reactive leukocytosis occasionally present with leukocyte profiles that are indistinguishable from that of leukemia—so-called leukemoid reactions. Usually there is marked leukocytosis (more than 50,000 cells/ $\mu$ L) with immature forms present, and the confusion is with the myeloproliferative syndromes (most commonly chronic myelocytic leukemia), although acute leukemias may be simulated. The absence of the characteristic features of the myeloproliferative disorders listed above (eg, basophilia, chromosomal markers) is often helpful in the differential diagnosis. However, the diagnosis of a leukemoid reaction can be considered certain only if the leukocyte profile returns to normal when the underlying infectious or inflammatory disorder resolves.

# 15 Neutrophil Collection and Transfusion

**Ronald G. Strauss**

Professor Emeritus, Pathology and Pediatrics, University of Iowa College of Medicine, Iowa City, Iowa, USA

Life-threatening infections with bacteria, yeast, and fungus continue to be a consequence of severe neutropenia (fewer than 500/ $\mu$ L blood neutrophils) and disorders of neutrophil (PMN) dysfunction. The most frequent situation is neutropenic fever and infection with yeast or fungus during either hematopoietic progenitor cell (HPC) transplantation or intense chemotherapy for hematologic malignant disease. Neutropenic infections cause considerable morbidity, occasionally are fatal, and add considerable cost to the treatment of these patients.

Previous attempts to prevent infection in severely neutropenic patients by transfusing PMN concentrates—commonly called prophylactic granulocyte transfusions (GTXs)—achieved only questionable success. Although rates of certain infections were significantly reduced with prophylactic GTX compared to antibiotics only, many adverse effects including pulmonary infiltrates and cytomegalovirus infection were reported, and GTXs were expensive. Similarly, use of therapeutic GTX to resolve existing infections has not gained broad acceptance, despite many reports documenting benefit.<sup>1,2</sup> This lack of enthusiasm for GTX can be explained by the continuing development of effective antimicrobial drugs to prevent and manage infection, by the availability of recombinant hematopoietic growth factors to quicken PMN recovery, by preference for peripheral blood HPC (HPC-A) transfusions over marrow-derived HPC (HPC-M) transplantation to hasten patient recovery from myelotoxic therapy and shorten the period of severe neutropenia, and by lack of familiarity by some physicians with the markedly improved PMN concentrates now available for transfusion.

Historically, PMN concentrates, collected for transfusion from unstimulated donors or those stimulated only with corticosteroids, contained woefully inadequate numbers of PMNs. Currently, much larger numbers of PMNs can be collected from healthy donors by means of granulocyte colony-stimulating

factor (G-CSF) plus corticosteroid marrow stimulation followed by large-volume leukapheresis.<sup>2</sup> This chapter discusses the current technology of PMN collection and provides a critical assessment of the potential for use of therapeutic and prophylactic GTX.

---

## Collection of Neutrophils for Transfusion

### Donor Marrow Stimulation

A limitation of GTX has been the inability to transfuse satisfactory numbers of adequately functioning neutrophils. To ensure adequate numbers and quality of PMNs for transfusion, PMNs must be collected from optimally stimulated donors by automated leukapheresis using an erythrocyte sedimenting agent, such as hydroxyethyl starch (HES).<sup>2</sup> Under the stress of a severe bacterial infection, the marrow of an otherwise healthy adult will produce between  $10^{11}$  and  $10^{12}$  PMNs in 24 hours. Granulocyte (PMN) concentrates collected from healthy donors who are not stimulated with corticosteroids or G-CSF will contain between 0.2 and  $0.8 \times 10^{10}$  PMNs—about 1% of a healthy marrow's output. Hence, donor stimulation to increase the blood PMN count is mandatory to achieve even a hope of a reasonable PMN dose per GTX.

Donor stimulation with properly timed corticosteroids ( $\geq 4$  hours before leukapheresis) will increase the yield to about  $2 \times 10^{10}$  PMNs.<sup>3</sup> Stimulation with G-CSF, alone or in combination with corticosteroids, will produce higher but variable PMN yields that vary with G-CSF dose and schedule of administration. Currently, PMN donors are optimally stimulated using 300 to 480  $\mu$ g G-CSF given subcutaneously, plus 8 mg dexamethasone taken orally, approximately 12 hours before beginning leukapheresis.<sup>4</sup> Yields of 4 to  $8 \times 10^{10}$  PMNs are achieved regularly, and posttransfusion blood PMN counts in the patient frequently increase to 1000 to 3000/ $\mu$ L, with PMNs detected in the bloodstream for several hours after GTX (often  $>24$  hours).

Adverse effects following G-CSF and dexamethasone are frequent. Most donors experience minor pain in muscle, bone, or head that is readily relieved with acetaminophen or ibuprofen.<sup>5</sup> Donors given G-CSF for PMN collection have no long-term adverse

effects, and it is unusual that they refuse to donate again.<sup>6</sup> A recent report suggested that adrenal corticosteroids might cause posterior subcapsular cataracts in PMN donors.<sup>7</sup> Although this report appeared not to be confirmed by statistically significant findings in a study of larger numbers of PMN donors,<sup>8</sup> many trends—all suggesting possible adverse effects of corticosteroids—were worrisome in the results.<sup>9</sup> Thus, questions of potential donor risk still remain, and it seems logical to include this cautionary information in donor consent forms or to stimulate PMN donors using G-CSF without corticosteroids—accepting that PMN yields will be decreased by about 25%—until the issue is resolved.

Although they are known to alter PMN function, G-CSF and corticosteroids such as dexamethasone have relatively minor effects at the doses administered to donors for PMN collection.<sup>5</sup> The functional properties of PMNs collected from donors stimulated with G-CSF do not deviate greatly from those of normal PMNs and cause no unusual reactions in recipients when transfused. After transfusion, PMNs from G-CSF-stimulated donors have long intravascular survival times explained by multiple factors, including shift of young PMNs from the storage compartment of donor marrow into the bloodstream for collection, an alteration in expression of several membrane proteins on donor PMNs associated with neutrophil adherence to vascular endothelium and egress from the circulation into the tissues, and possibly by specific anti-apoptotic effects of G-CSF on PMNs.<sup>5</sup> Although it has been suggested that G-CSF-mobilized PMNs might exhibit decreased migration into tissue sites because of their prolonged intravascular circulation, studies with transfused PMNs indicate that they migrate satisfactorily into areas of inflammation and infection.<sup>6,10</sup>

The ability to collect and store PMNs differs when donors are stimulated only once during a course of GTX therapy compared with when they serve as a dedicated donor for the recipient and are stimulated repeatedly on a daily or every-other-day schedule for GTX. PMNs collected after several days of G-CSF stimulation are qualitatively different from PMNs collected after a single dose of G-CSF.<sup>5</sup> They are younger, exhibit increased metabolic activity and different surface markers, may possess enhanced antifungal properties, and do not have the same separation characteristics during centrifugation leukapheresis. Because the functional properties and possibly the efficacy and toxicity of PMNs may differ when collected under conditions of single vs repeated G-CSF and corticosteroid stimulation, additional studies are needed to define optimal donor stimulation and GTX therapy.

### Hydroxyethyl Starch

Use of an erythrocyte-sedimenting agent, such as HES, during centrifugation leukapheresis is mandatory. The optimal formulation of HES to be used for PMN collection is controversial. In an uncontrolled multicenter trial, pentastarch appeared to be an efficacious and safe erythrocyte-sedimenting agent for use during centrifugation leukapheresis because PMN concentrates, prepared by centrifugation leukapheresis techniques with pentastarch in four cytopheresis centers, were found to contain quantities of PMNs comparable with concentrates prepared previously

with hetastarch at participating centers.<sup>3</sup> Later, the efficacy of pentastarch for PMN collection was challenged by a study<sup>11</sup> in which steroid-stimulated donors underwent paired PMN collections, separated by 2 weeks to 7 months, during which they received 500 mL of either 10% pentastarch or 6% hetastarch during centrifugation leukapheresis (7 L donor blood processed at a 1:13 starch:donor blood ratio). In 92% of the donors, hetastarch procedures were more efficient. The PMN yield per collection was  $2.3 \pm 0.7 \times 10^{10}$  with hetastarch vs  $1.4 \pm 0.076 \times 10^{10}$  with pentastarch.

It is unclear why pentastarch performed so poorly in the later study<sup>11</sup> compared with its performance in the initial multicenter trial.<sup>3</sup> Until the issue is resolved, it is prudent for each center preparing PMN concentrates to perform continuing quality assessment of its own leukapheresis program. The average PMN yield obtained by means of processing 10 L of donor blood after corticosteroid stimulation *alone* and use either of pentastarch or a hetastarch at a 1:13 starch:donor blood ratio should be between  $1.5$  and  $2.5 \times 10^{10}$ . After G-CSF stimulation plus dexamethasone, the PMN yield should be between  $4$  and  $8 \times 10^{10}$ . If these yields are achieved equally with pentastarch or hetastarch, it seems reasonable to select pentastarch because of its better safety profile—particularly if donors experience repeated leukapheresis at short intervals. Pentastarch is more rapidly eliminated from the bloodstream than is hetastarch and avoids the problem, with repeated leukapheresis, in which hetastarch blood levels accumulate and increase in a staircase manner.<sup>12</sup> Pentastarch exerts lesser effects on coagulation than does hetastarch.<sup>13</sup> If PMN yields are not satisfactory with pentastarch, as is often the case, pentastarch should be replaced by hetastarch.

---

## Neutrophil Transfusion in Clinical Medicine

### Historical Overview of Therapeutic Granulocyte Transfusion

To obtain a historical perspective regarding the efficacy of therapeutic GTX (ie, collected without donor G-CSF), seven controlled studies are analyzed briefly.<sup>14-20</sup> In these seven studies, the response of infected neutropenic patients to treatment with GTX plus antibiotics (study group) was compared with that of comparable patients given antibiotics alone (control group) evaluated concurrently. The design, size, and results of these seven studies are presented in Tables 15-1 and 15-2. Three of the seven studies reported a significant overall benefit for GTX.<sup>17-19</sup> In two additional studies,<sup>14,16</sup> overall success was not demonstrated for GTX, but certain subgroups of patients were found to benefit significantly. Thus, some measure of success for GTX was evident in five of the seven controlled studies (Table 15-1). However, this success was counterbalanced by four studies that reported negative results in some respect—two with negative overall results<sup>15,20</sup> and two with negative results for some types of patients.<sup>14,16</sup>

An explanation for these inconsistent results is evident on critical analysis of the adequacy of GTX support (Table 15-2).

Patients in the three successful trials received relatively high doses of PMNs (generally  $\geq 1.7 \times 10^{10}$ /day), and donors were selected to be both erythrocyte and leukocyte compatible.<sup>17,19</sup> By contrast, the four controlled studies reporting overall or partial negative results can legitimately be criticized. Two of the four studies with negative findings used PMNs collected by filtration leukapheresis for some patients.<sup>14,16</sup> It is now established that such PMNs are defective, and they are no longer transfused. In the negative studies using PMNs collected by centrifugation leukapheresis,<sup>14,16,20</sup> the dose was extremely low ( $0.41$  to  $0.56 \times 10^{10}$  per GTX). As another factor, investigators in two of the four negative studies<sup>14,20</sup> made no provision for the possibility of leukocyte alloimmunization, as donors were selected solely on the basis of erythrocyte compatibility. Finally, control subjects responded particularly well to antibiotics alone in three of the four negative studies,<sup>14,15,20</sup> suggesting that these patients fared relatively well with conventional treatment alone, and it was not possible to document additional benefit by adding GTX.

The results of the seven controlled GTX trials have been analyzed by formal meta-analysis,<sup>21</sup> and conclusions were that the low doses of PMNs transfused and the relatively high survival rate of the nontransfused control subjects were primarily responsible for the differing success rates of these studies. In clinical

settings in which the survival rate of nontransfused control subjects was low,<sup>16-19</sup> study subjects benefited from receiving adequate doses of GTX—prompting the authors to suggest that severely neutropenic patients with life-threatening infections should be considered for GTX given in high doses.<sup>21</sup>

### Historical Overview of Prophylactic Granulocyte Transfusion

Based on historical reports, prophylactic GTXs were of marginal value. Some measure of success was found in seven of 12 studies.<sup>22-28</sup> Five studies failed to show a benefit for prophylactic GTXs.<sup>29-33</sup> In none of these five negative studies were large numbers of PMNs obtained from matched donors and transfused daily. In a situation analogous to that for the negative therapeutic GTX trials, the failure of prophylactic GTX might be explained, as least in part, by inadequate transfusions.

In 1997, data from eight of the 12 controlled trials of prophylactic GTX were analyzed quantitatively by means of formal meta-analysis.<sup>34</sup> The findings of the meta-analysis confirmed that variability in the dose of PMNs transfused, inconsistent attempts to provide leukocyte-compatible GTX, and the varying duration of severe neutropenia in different patient groups were primarily responsible for the differing success rates in the reported controlled trials. It was recommended that high doses of compatible PMNs be transfused, if future trials are conducted.<sup>34</sup>

### Assessment of Modern Granulocyte Transfusion Therapeutic Granulocyte Transfusions

A modern therapeutic GTX is defined as a transfusion in which PMNs are obtained from donors stimulated with G-CSF with or without corticosteroids and collected by means of centrifugation leukapheresis with an erythrocyte-sedimenting agent during the processing of relatively large volumes of donor blood. Specifically, the requirements of an ideal PMN collection should include 1) at least 300  $\mu$ g G-CSF given subcutaneously plus 8 mg dexamethasone given orally to the donor approximately 12 hours before leukapheresis is begun, 2) pentastarch or, preferably, hetastarch infused throughout the leukapheresis procedure at a ratio

\*Donors selected to be compatible with recipient by HLA typing (A and B loci matched, at least in part) and/or by leukocyte crossmatching. WBC = white cell.

of 1 part starch to 12 to 14 parts donor blood, and 3) processing of 8 to 10 L of donor blood. The goal should be to transfuse 6 to  $8 \times 10^{10}$  neutrophils per GTX, with a lower limit of  $4 \times 10^{10}$ .

At this time, no randomized clinical trials of modern therapeutic GTX collected after G-CSF and dexamethasone donor stimulation have been reported to establish either the efficacy or the potential toxicity of modern GTX. However, many case reports suggest success. For example, Clark et al<sup>35</sup> and Catalano et al<sup>36</sup> each reported single patients with aplastic anemia, undergoing progenitor cell transplantation, with fungus infections that responded favorably. Ozsahin et al<sup>37</sup> and Bielora et al<sup>38</sup> each reported single patients with chronic granulomatous disease and fungal infections that responded favorably to GTX during the transplantation period. Bielora et al<sup>39</sup> reported a single patient with acute leukemia and sepsis with vancomycin-resistant *Enterococcus* that cleared slowly with GTX. Similarly, Lin et al<sup>40</sup> reported a single patient with multidrug-resistant *Pseudomonas* sepsis who underwent a successful HPC-A transplantation supported by GTX. It is impossible, in these single reports of very complicated patients, to firmly ascribe the good outcome to the GTX.

Studies of larger numbers of infected, neutropenic patients given GTX from G-CSF-stimulated donors are listed by Table 15-3. Even with investigation of larger numbers of patients, the benefits of GTX are unclear because of the lack of concurrent control patients treated with antibiotics alone. Hester et al<sup>41</sup> transfused 15 patients

with hematologic malignancies and infections. PMNs were collected from donors stimulated only with G-CSF and selected without regard for leukocyte compatibility. Although GTXs were successful in most patients, it was not possible to distinguish responses of fungus vs yeast infections. Grigg et al<sup>42</sup> transfused 11 patients. Eight patients had hematologic malignancies and progressive infections—five of the eight undergoing HPC transplantation and three receiving chemotherapy. Three additional patients who were undergoing HPC transplantation had stable fungus infections. PMNs were collected from donors stimulated only with G-CSF and selected without regard for leukocyte compatibility. Success was excellent for bacterial and stable fungus infections, but was quite poor for progressive fungus infections with organ dysfunction—a troubling pattern reported later by others.<sup>6,43</sup> Peters et al<sup>44</sup> transfused 30 patients with hematologic disorders—18 undergoing HPC transplantation. PMNs were collected from donors stimulated with G-CSF or prednisolone and selected without regard for leukocyte compatibility. The exact PMN dose transfused is uncertain, but values from  $0.9 \times 10^{10}$  to  $14.4 \times 10^{10}$  were estimated from data reported. It was impossible to distinguish the success of GTX from G-CSF-stimulated vs prednisolone-stimulated donors. However, the outcome of bacterial infections overall appeared to be superior to that of fungus infections.

Price et al<sup>6</sup> transfused 19 patients (Table 15-3) with hematologic malignancies, 16 of whom had received HPC transplants

**Table 15-3.** Neutropenic Patients Treated with GTX Collected from G-CSF-Stimulated Donors

\*Assumptions made as PMN dose expressed  $\times 10^{10}$  unclear in these reports. PMN dose calculated using values for the total number and differential count of leukocytes collected, and the volume of units collected (Grigg et al). Dose calculated that would be given to a 70-kg recipient for Peters et al. GTX = granulocyte transfusion; G-CSF = granulocyte colony-stimulating factor; PMNs = granulocytes.

and three who were scheduled for transplantation. PMNs were collected from donors stimulated with G-CSF and dexamethasone. Although donors were selected without regard for leukocyte compatibility, recipients were documented not to exhibit evidence of leukocyte alloimmunization at study entry. Bacterial infections responded well and yeast infections responded modestly. Despite very high PMN doses, success for invasive fungus infections was dismal. Hübel et al<sup>43</sup> expanded the study of Price et al<sup>6</sup> to a total of 74 patients receiving HPC transplants. Comparisons were made to historical control patients ( $n = 74$ ) who did not receive GTX. PMNs were collected either from unrelated donors given G-CSF alone or in combination with dexamethasone, or from family members given G-CSF only. Hetastarch was used for single leukapheresis procedures, and pentastarch was used when donors experienced repeated leukapheresis procedures. Comparative success in nontransfused historical control patients was approximately 90% for bacterial, 40% for yeast, and 30% for fungal/mold infections—values similar to those achieved by GTX recipients. Nontransfused controls actually had better success than PMN recipients for bacterial infections ( $p = 0.04$ ). As a potential adverse effect, allogeneic transplant recipients given GTX from unrelated donors experienced significantly more ( $p = 0.04$ ) Grade IV graft-vs-host disease (GVHD) than controls who were not given GTX. However, relatively few patients were assessed for this endpoint, and firm conclusions are not warranted.

Lee et al<sup>45</sup> transfused 25 patients with hematologic malignancies, many of whom were infected with multiple organisms. Thus, the outcome of infections with specific types of individual organisms could not be determined. PMNs were collected from donors stimulated with G-CSF alone (66% of donors), G-CSF plus dexamethasone (25% of donors), or dexamethasone alone (8% of donors). Of patients with sepsis, 50% (two of four) responded favorably, and 38% (8 of 21) of patients with progressive localized infections responded favorably.

Two studies reported results in ways that did not lend themselves to tabulation, and they will be briefly described. Illerhaus et al<sup>46</sup> transfused 42 neutropenic patients with GTX collected from donors stimulated with  $5\mu\text{g/kg}$  G-CSF. Eighteen of the patients had severe infections with a variety of organisms and each received a median of three GTX each containing a median of  $2.6 \times 10^{10}$  leukocytes. Of these 18 patients, eight (44%) improved, four (22%) stabilized, and six (33%) deteriorated—with four of these last six dying of pulmonary aspergillosis. Rutella et al<sup>47</sup> transfused 20 patients with hematologic malignancies and neutropenic infections. Donors were HLA-identical siblings and each received  $5\mu\text{g/kg}$  G-CSF. Favorable responses were seen in 54% of patients with bacterial and 57% of fungal infections. Underlying cancer status (ie, complete or partial remission achieved) and recovery of blood PMN counts to  $500/\mu\text{L}$  or more were significantly correlated with a favorable response to GTX.

No firm conclusions can be drawn from these larger, but still somewhat anecdotal reports of modern therapeutic GTX for several reasons: 1) no concurrent control subjects were included (ie, randomly assigned to receive antimicrobial drugs, but no

GTX); 2) the number of patients reported, generally, was quite small; and 3) PMN collection methods were variable with a broad range of PMN doses transfused. Based on these preliminary findings, bacterial infections appeared to respond quite well to modern GTX, and relatively mild fungus and yeast infections responded modestly well. However, serious fungus infections with tissue invasion often resisted even the large doses of PMNs transfused with modern GTX.<sup>6,42-46</sup> The precise role of modern therapeutic GTX, collected from donors stimulated with G-CSF plus corticosteroids, in the management of infected, neutropenic, oncology/transplant patients awaits definition by randomized clinical trials.

### Prophylactic Granulocyte Transfusions

The role of modern prophylactic GTX (ie, from G-CSF-stimulated donors) has not been established by definitive clinical trials. However, two factors suggest possible success: 1) rapid recovery from myeloablation, hastened by HPC-A transfusions and treatment of patients with recombinant growth factors, has shortened the period of severe neutropenia to as brief as 1 week; and 2) this relatively brief period of severe neutropenia might literally be eliminated by transfusing large doses of PMNs collected from donors stimulated with G-CSF plus corticosteroids. A few studies have begun to explore this possibility (Table 15-4).

Bensing et al<sup>48</sup> transfused seven allogeneic marrow recipients with PMNs collected from their HLA-identical or syngeneic marrow donors after G-CSF stimulation. Because donors experienced leukapheresis on consecutive days, collection techniques were quite variable in terms of quantities of HES infused and liters of donor blood processed, and the number of PMNs per GTX varied from 0.3 to  $14.4 \times 10^{10}$ . Recipients received an average of 7.6 GTXs while awaiting marrow recovery, and recipients were given  $5\mu\text{g/kg}$  G-CSF daily to maintain a mean blood PMN count of  $950/\mu\text{L}$ , measured 24 hours after transfusion. The goals of this study were to evaluate the feasibility and safety of collecting and transfusing PMNs from G-CSF stimulated donors; patient outcomes were not reported.

Adkins et al<sup>49</sup> transfused 10 allogeneic marrow recipients with PMNs collected from their HLA-matched sibling marrow donors. Leukapheresis was performed on Days 1, 3, and 5 after transplantation, and GTXs were administered on these days. Recipients were given  $7.5\mu\text{g/kg}$  G-CSF every 12 hours until blood PMNs were greater than or equal to  $1500/\mu\text{L}$ . Recipient blood PMNs were maintained at greater than  $500/\mu\text{L}$  throughout the 5 days of posttransplant GTX. By comparison, a historical group of control recipients treated with G-CSF, but no GTX, exhibited mean blood PMN counts less than  $500/\mu\text{L}$  following transplantation. Prophylactic GTX seemed promising in this setting and, perhaps, would have been even more effective (ie, higher recipient blood PMN counts and fewer infections) if given daily. In another study, Adkins et al<sup>50</sup> transfused 23 autologous HPC-A recipients with PMNs collected from first-degree relative donors. Leukapheresis was performed on posttransplant Days 2, 4, 6, and 8, and GTXs were given on those days.

GTX = granulocyte transfusion; PMNs = granulocytes; F-CSF = granulocyte colony-stimulating factor.

Recipients were given 5 μg/kg G-CSF daily until the blood PMN count was greater than or equal to 1500/μL. Recipients were studied for the effects of lymphocytotoxic antibodies (ie, leukocyte alloimmunization) on GTX effectiveness. The 15 recipients who did not exhibit lymphocytotoxic antibodies during the 10-day study period experienced a mean of 4.1 febrile days and required 7.3 days of antibiotics. Values for the eight recipients with lymphocytotoxic antibodies were less desirable—6.3 febrile days and 10.5 days of antibiotics. Rates of documented infections were not reported.

In a later report from the same group,<sup>51</sup> 151 donor-recipient pairs, consisting of HLA-matched sibling donors of peripheral blood progenitor cells and the recipients of their progenitor cells, were initially allocated to either a GTX group or a non-GTX group based on ABO matching of red cells. For several reasons, the final allocation was 53 ABO-matched donor-recipient pairs assigned to GTX and 98 pairs assigned to the non-GTX group. PMNs were collected for GTX on either Days 3 and 6 or on Days 5 and 7 after transplantation (different days due to enrollment into two different studies). Thus, recipients received two GTXs on an every-other-day schedule. Recipients also received G-CSF (10 μg/kg/day) beginning 1 day after transplantation and continuing until a blood PMN count was equal to or greater than 1500/μL for 3 days. The percentage of recipients with posttransplant fever was 64% with GTX vs 83% without GTX (*p* = 0.03). The median number of days that intravenous antibiotics were given was 9 with GTX vs 11 without GTX (*p* = 0.03). No significant differences were found for length of hospital stay, 100-day survival, or rates of acute GVHD (Table 15-4).

No firm conclusions can be drawn from these reports of modern prophylactic GTX because few nontransfused control subjects were included (none randomly assigned before the studies); relatively few patients were studied; and most patients were given GTXs every other day, rather than daily—possibly

providing a less than optimal dose of PMNs. Modern prophylactic GTXs appear promising, but their efficacy, potential adverse effects, and economic analysis await definition by randomized clinical trials of sufficient numbers of patients.

**Pediatric Granulocyte Transfusion**

Therapeutic GTXs are prescribed for children with marrow failure and severe neutropenic infections using the same criteria as for adults. In a study by Sachs et al,<sup>52</sup> 27 children with hematologic/oncologic disorders and neutropenic infections received GTXs every other day. PMNs were collected from crossmatch-compatible donors stimulated with G-CSF only. The average dose of PMNs per each GTX was 8 × 10<sup>8</sup> PMN/kg recipient body weight. This corresponds to 5.6 × 10<sup>10</sup> PMNs for a 70-kg adult. GTXs were very successful with 93% of patients able to clear infections—including all with invasive pulmonary aspergillosis infections—and with an 82% survival 1 month later.

Most patients with congenital disorders of PMN dysfunction have adequate numbers of blood PMNs, but they are susceptible to serious infections because their PMNs fail to kill pathogenic microorganisms. Patients with severe forms of PMN dysfunction are relatively rare, and no randomized clinical trials have been reported to establish the efficacy of therapeutic GTX in their management. Firm recommendations about the use of GTX to treat patients cannot be made. However, several patients with chronic granulomatous disease, complicated by progressive life-threatening fungal infections, have been reported to benefit.<sup>53-61</sup> Because of the possibility of alloimmunization to leukocyte and red cell antigens, particularly to the Kell blood group, plus the risk of transfusion-transmitted infections, therapeutic GTXs are recommended only for progressive infections that cannot be controlled with antimicrobial drugs. Because of lifetime problems with infections, prophylactic GTXs are impractical.

Neonates (infants within the first month of life) are another group of patients who may suffer life-threatening bacterial infections caused, at least in part, by PMN dysfunction and neutropenia. Neutropenia must be viewed differently in neonates than in older patients, because in the latter, GTXs are considered usually when the blood PMN count falls to less than 500/ $\mu$ L. By contrast, because normal neonates exhibit a physiologic neutrophilia, absolute blood PMN counts as high as 3000/ $\mu$ L (ie, relative neutropenia due to age) might prompt consideration of GTX in neonates. Six controlled trials (reviewed in Strauss<sup>62</sup>) have assessed the role of GTX in treating neonatal infections. Although four of the six found a significant benefit for GTX, the controlled studies, when assessed by meta-analysis, were insufficiently homogeneous to permit clear recommendations regarding the efficacy of GTX.<sup>21</sup> Thus, the role of therapeutic GTX for neonatal infections is unclear at present and, because they are transfused only rarely at this time, they will not be discussed further.

## Summary and Recommendations

The use of G-CSF with glucocorticoids to stimulate PMN donors has brought GTX therapy into a new era. It is now possible to collect relatively large numbers of PMNs by modern leukapheresis techniques. Because GTXs were successful historically in the management of bacterial infections, even when PMNs were given in low doses, it is prudent to reassess both therapeutic and prophylactic GTX.

To determine whether a need exists for therapeutic GTX, physicians should survey the outcome of neutropenic infections at their own institutions. If these infections respond promptly to antibiotics alone and the survival rate approaches 100%, therapeutic GTX is unnecessary and should not be used, because possible benefits are small and would not outweigh the risks and expense. In contrast, if patients with infection and neutropenia (fewer than 500 PMN/ $\mu$ L) do not respond quickly and completely to antibiotics alone, the addition of therapeutic GTX should be considered along with other modifications of therapy, such as selection of different antibiotics, closer monitoring of antibiotic blood levels, intravenous  $\gamma$ -globulin therapy, and treatment with recombinant myeloid growth factors.

Prophylactic GTX is most likely to be useful in the setting of HPC transplantation. Both autologous and allogeneic HPC-M transplantation have been largely supplanted by HPC-A transfusion—a technique that is convenient and economical, and leads to relatively rapid PMN engraftment. Recovery to a blood PMN count of at least 500/ $\mu$ L occurs usually within 7 to 14 days after HPC-A transfusion. Future HPC-A donors may be stimulated with recombinant cytokines other than G-CSF alone, such as AMD3100 (antagonist of the receptor for stromal-cell-derived factor 1), stem cell factor, or interleukin-7; the period of severe neutropenia may be shortened even more by transfusing these PMNs. Thus, complete elimination of severe neutropenia with a

strategy of transplanting HPC-A followed by prophylactic GTX is a distinct possibility that deserves more study.

Once the decision has been made to provide either therapeutic or prophylactic GTX, PMNs must be collected and transfused optimally as follows:

1. Collect PMNs from allogeneic donors with a goal to transfuse 6 to 8  $\times 10^{10}$  PMNs per GTX with an absolute lower limit of 4  $\times 10^{10}$ . The need to select donors of who are leukocyte compatible with recipients has not been established for modern (high PMN dose) GTX, despite the historical importance of doing so when lower doses of PMNs were transfused. In studies of modern GTX, Price et al<sup>6</sup> found no apparent adverse effects of several leukocyte antibodies (granulocyte agglutinating, granulocyte immunofluorescent, lymphocytotoxic, and lymphocyte immunofluorescent) that became detectable in the recipient's blood during GTX therapy. Adkins et al,<sup>50</sup> however, found the presence of lymphocytotoxic antibodies to be a poor prognostic factor, in general, even though actual donor-recipient incompatibility for individual GTX was rare. Until more data are available, it seems prudent to select donors who are leukocyte compatible (eg, by means of HLA matching or leukocyte crossmatching) whenever easily feasible, but never to delay or deny GTX therapy if selecting donors by these methods is not readily accomplished.
2. Stimulate donor neutrophilia by giving 300 to 600  $\mu$ g G-CSF subcutaneously plus dexamethasone orally 12 hours before beginning leukapheresis. A regimen reported to produce high PMN yields with reasonable adverse effects on the donor is 450  $\mu$ g G-CSF given subcutaneously plus 8 mg dexamethasone given orally 12 hours before leukapheresis.<sup>4</sup>
3. Process 8 to 10 L of donor blood using a continuous-flow, centrifugation blood separator with citrated HES (hetastarch preferred) solution infused throughout the entire collection at a starch:donor blood ratio of 1:13.
4. Transfuse PMNs as soon as possible after collection to minimize storage damage. Data suggest deterioration of PMN function begins within a few hours of storage. Until the efficacy of stored neutrophils from G-CSF-stimulated leukapheresis donors is documented, it seems wise to transfuse within 6 hours or so of collection. This timing may require agreement by the patient's physician to perform infectious disease testing on the donor before actual PMN collection (eg, at the time G-CSF is administered before leukapheresis) or accept a donor who has been tested recently for a previous donation (eg, within approximately 10 days), but has not been tested for the PMN collection in question.
5. Give GTX daily as prophylactic GTX in an attempt to prevent infection during the period of severe neutropenia or as therapeutic GTX either to resolve a documented infection—as evidenced by clearing of tissue lesions, negative cultures, or resolution of fever—or until marrow function recovers to produce adequate numbers of endogenous PMNs. Determining marrow recovery may be difficult because PMNs collected from G-CSF-stimulated and dexamethasone-stimulated donors and transfused at doses of 6 to 8  $\times 10^{10}$  PMNs may elevate the recipient's blood PMN count to more than 1000/ $\mu$ L for more than 24 hours. Accurate

differentiation of transfused PMNs from those produced endogenously is challenging, and marrow recovery must be based on a sustained increase in blood PMN count after GTX is discontinued.

## Leukocyte-Reduced Blood Components: Laboratory and Clinical Aspects

**Darrell J. Triulzi<sup>1</sup> & Walter H. Dzik<sup>2</sup>**

<sup>1</sup> Director, Division of Transfusion Medicine, and Professor, Department of Pathology, University of Pittsburgh, Pittsburgh, Pennsylvania, USA

<sup>2</sup> Co-Director, Blood Transfusion Service, Massachusetts General Hospital, and Associate Professor of Pathology, Harvard Medical School, Boston, Massachusetts, USA

Donor leukocytes present in cellular blood components have been linked to a wide range of complications in transfusion recipients. Both acute and long-term complications can result directly from exposure to donor leukocytes, prompting the adoption of leukocyte reduction as a highly effective and widely practiced prevention strategy. For other complications, the association with donor leukocytes is less certain, and more research is needed before specific transfusion practice can be established. This chapter reviews the current technologies for leukocyte reduction, the scientific basis for adverse effects of exposure to donor leukocytes, and the evidence for leukocyte reduction of cellular components. The reader is also referred to recent reviews of this topic.<sup>1,2</sup>

### Laboratory Aspects

Fresh cellular blood components contain considerable quantities of residual donor leukocytes (Table 16-1). However, during refrigerated storage of Red Blood Cells (RBCs), a substantial proportion of donor leukocytes undergo cellular degeneration and apoptosis, and surface antigens on residual cells change. Thus, refrigerated storage itself may help prevent complications from transfused donor leukocytes to a degree not completely appreciated. In the 1980s, washed or frozen deglycerolized RBCs were used to prevent complications resulting from transfusion of donor leukocytes. During the 1990s, several technologies were introduced to remove or inactivate residual donor leukocytes in blood components. High-performance leukocyte reduction filters are used for either RBCs or whole-blood-derived platelet concentrates. Apheresis platelets can be leukocyte reduced (LR) at the time of collection without the use of filters. Chemical pathogen reduction systems designed specifically for RBCs, platelet concentrates, or plasma are undergoing clinical trials. These chemicals inactivate residual donor leukocytes. The potential

**Table 16-1.** Approximate Residual Number of Leukocytes in Cellular Blood Components

| Component                        | No. of Leukocytes   |
|----------------------------------|---------------------|
| Fresh Whole Blood                | $10^9$              |
| Red Blood Cells (RBCs)           | $10^8$ - $10^9$     |
| Buffy-coat-depleted RBCs         | $10^8$              |
| Washed RBCs                      | $10^7$              |
| Frozen deglycerolized RBCs       | $10^6$ - $10^7$     |
| Whole-blood-derived platelets    | $10^7$ - $10^8$     |
| Apheresis platelets              | $10^6$ - $10^8$     |
| Leukocyte-reduced (LR) RBCs      | $<5 \times 10^6$    |
| LR whole-blood-derived platelets | $<0.83 \times 10^5$ |
| LR apheresis platelets           | $<5 \times 10^6$    |
| Fresh Frozen Plasma              | $<10^4$             |

of these diverse technologies to affect known complications of recipient exposure to donor leukocytes is shown in Table 16-2.

### Technologies for Leukocyte Reduction

#### Centrifugation

Removal of the buffy coat from whole blood during initial component preparation is widely practiced in Canada, Europe, and Japan. In one technique, called the *top-and-bottom method*, whole blood is subjected to centrifugation at relatively high gravity force to compress both platelets and leukocytes into the buffy coat (Fig 16-1). Preparation of the buffy coat component is sensitive to minor changes in centrifugation and separation conditions. Automated devices have been developed to render the process more reproducible. Buffy-coat-reduced RBCs contain approximately 70% to 80% fewer leukocytes than do unmodified RBCs. This advantage is offset to some degree by the loss of platelets and red cells that occurs during the procedure. Buffy coat depletion is sufficient to prevent many febrile nonhemolytic transfusion reactions (FNHTRs) to blood but is not considered sufficient to prevent HLA alloimmunization or cytomegalovirus (CMV) transmission.

**Table 16-2.** Potential Use of Technologies Designed to Reduce the Risk of Complications Attributed to Residual Donor Leukocytes

| Use                                                       | Leukocyte-Reduced Blood | $\gamma$ Irradiation | Ultraviolet-B Irradiation | Chemical Inactivation |
|-----------------------------------------------------------|-------------------------|----------------------|---------------------------|-----------------------|
| Reduce rate of HLA antibody formation                     | Yes                     | No                   | Yes                       | Uncertain             |
| Reduce risk of transmission of leukotropic viruses        | Yes                     | No                   | No                        | Yes                   |
| Reduce risk of FNHTRs due to donor cytokine               | Yes, if prestorage      | Unproven             | Probable                  | Probable              |
| Reduce risk of FNHTRs due to reaction against donor cells | Yes                     | No                   | No                        | Uncertain             |
| Reduce risk of TA-GVHD                                    | Unproven                | Yes                  | Animal studies only       | Animal studies only   |

FNHTR = febrile nonhemolytic transfusion reaction; TA-GVHD = transfusion-associated graft-vs-host disease.

**Figure 16-1.** Preparation of buffy-coat-depleted blood components from whole blood by means of the top-and-bottom method. The primary bag (left) has undergone centrifugation at a high-gravity force. The buffy-coat-containing leukocytes and platelets are between the plasma (open area) and red cells (hatched area). The supernatant plasma is expressed out the top of the primary bag into a satellite bag while the red cells are expressed out the bottom into another satellite bag. The buffy-coat-containing donor white cells and platelets are then pooled with other buffy coats, and the pool is subjected to centrifugation at a lower gravity force than used previously. After this centrifugation, the pooled platelet-rich plasma is expressed out the top of the pooling bag, and the residual cellular elements are discarded. FFP = fresh frozen plasma; RBC = red cells; Add Sol = additive solution.

## Filtration

Filtration has emerged as the most commonly used method of leukocyte reduction. Because of rapid product development and enhancement in this area, the results of earlier clinical studies underestimate the potential clinical efficacy of current filters. Early leukocyte reduction achieved only 90% to 99% (1 to 2  $\log_{10}$ ) leukocyte reduction. Current high-performance leukocyte removal filters can reduce the residual white cell (WBC) content at least 3 logs and typically achieve 4 log or greater removal. As a result, the proportion of filtered units with less than  $10^6$  residual leukocytes has steadily increased to 99% or greater. Until recently, component-specific filters were required for red cell components and platelet components. The filters designed for red cells removed unacceptable numbers of platelets. A whole blood filter has been developed that provides a LR red cell, platelet, and plasma component using a single filter. Whole blood filter

performance appears comparable to existing single component filters and was recently approved in the United States.<sup>3</sup>

## Mechanisms of Filtration

High-performance filters have been specifically designed to remove leukocytes.<sup>4,5</sup> The plastic housing that contains the filtration medium is designed so that blood encounters a large surface area of medium; the volume of blood retained by the filter (hold-up volume) is minimal; and the medium fits tightly enough within the housing so that blood entering the device cannot bypass the filtration medium. Depletion of leukocytes results primarily from barrier retention in which the pore size of the filter medium is large enough to allow passage of red cells and platelets but small enough to impede passage of leukocytes. To achieve the small pore sizes required, manufacturers have used three different fabrication strategies. In one method, polyester is melted and extruded through fine nozzles into a turbulent gas stream at high velocity. In the process, akin to the formation of cotton candy, the polyester is stretched and cooled to form fine threads of microfibers. These fibers are matted together (like teased hair) and compressed to a controlled fiber density. A variation of this technique is used in products made by Pall Corporation (East Hills, NY), Asahi Kasei Medical Company (Tokyo, Japan), and Fresenius AG (Bad Homburg, Germany). An alternative approach (used by Terumo Corporation, Tokyo, Japan) produces coral-reef-like structures of porous polyurethane with an open-cell geometric configuration containing interconnecting channels that necessitate a circuitous path of flow (Fig 16-2).

Polyester fiber filters consist of a series of layers of fiber material. At the upstream end of the filter, the fiber diameter and effective pore size are large (Fig 16-3). As blood passes through the layers of medium, the fiber diameter becomes smaller, and the pore size decreases to approximately 4 microns (Fig 16-4). Red cells, which are more deformable than leukocyte nuclei, can traverse these small pores. Differences in the viscoelastic properties of red cells and leukocytes are particularly pronounced at low temperatures. This accounts for the better performance of red cell leukocyte reduction filters used at refrigerated temperatures. Because synthetic materials are naturally hydrophobic, they do not become “wet” easily in aqueous solutions. As a result, surface tension would prevent blood from flowing through

**Figure 16-2.** Electron micrograph of a Terumo filter showing coral-reef-like structures of porous polyurethane with an open-cell geometric configuration containing interconnecting channels that necessitate a circuitous path of flow. (Courtesy Terumo Medical Corporation)

**Figure 16-3.** Electron photomicrograph shows fibers in the coarse filter (upstream layer) of a leukocyte reduction filter designed for RBCs. A microaggregate is present in the center of the figure. The diameter of the pore and the caliber of the fibers relative to individual cells are evident. (Used with permission from Nishimura et al.<sup>6</sup>)

very fine pore spaces under gravity. To overcome this obstacle, manufacturers have modified the surface of the filter medium fibers to increase their “wetability.” The polyurethane matrix in the Terumo filter mechanically traps leukocytes with minimal interaction between the cells or proteins and the filter material.

**Factors Affecting Filter Performance**

Because of the complex physical and biologic forces involved in leukocyte retention by the filter medium, it is not surprising that several factors have been shown to affect the degree of leukocyte reduction obtained (Table 16-3). A primary factor is the capacity of the filter itself. The input load of WBCs to be filtered has a direct relation to the postfiltration WBC content. The temperature of filtration has a dominant effect on the performance

**Figure 16-4.** Electron micrograph shows fibers from the fine filter (downstream layer) of a leukocyte reduction filter designed for RBCs. The caliber of the fibers relative to that of individual cells is evident. (Used with permission from Nishimura et al.<sup>6</sup>)

**Table 16-3.** Factors Affecting Filter Performance

of leukocyte filtration of RBCs. Nearly all studies have found that the efficiency of filtration improves when the procedure is conducted at refrigerated temperatures. Beaujean et al<sup>7</sup> and Sirchia et al<sup>8</sup> showed that when RBCs were filtered under conditions that mimicked bedside filtration at room temperature, filtration became less efficient such that most units filtered under bedside conditions over 3 to 4 hours did not meet minimum standards for LR RBCs. Improved performance of filtration at refrigerated temperatures has been observed by other investigators<sup>9,10</sup> and is associated with lower rates of hemolysis of stored RBCs.<sup>11</sup> The dominant effect of temperature on the performance of early filters designed for use with RBCs may have had a subtle effect on the results of the CMV prevention trial conducted by Bowden et al,<sup>12</sup> which was conducted before the temperature effect was realized.

The cellular composition of the blood also affects retention of leukocytes. Blood from donors with sickle cell trait often does not become adequately leukocyte reduced when filtered. Results of studies suggest that approximately 50% of units from donors with hemoglobin AS clog the filter and do not flow. Of the remaining 50%, approximately half of these flow normally but do not undergo adequate leukocyte reduction.<sup>13,14</sup> Preliminary investigation suggests that citrate anticoagulant and low oxygen tension contribute to Hb S polymerization<sup>15</sup> and that sickle trait

**Figure 16-5.** Electron micrograph demonstrating adherent “sticky” sickle red cells to fibers in a leukocyte reduction filter. (Used with permission from Gorlin and Gudino.<sup>16</sup>)

red cells are far more adhesive to the filter medium<sup>16</sup> (Fig 16-5). As the filter medium is progressively coated with erythrocytes, there is less effective medium area for leukocyte trapping. Other factors that affect the performance of filtration include the protein content of the cell suspension. For example, as little as 5 to 10 mL of plasma added to RBCs suspended in SAG-M additive solution improved the leukocyte removal efficiency of an RC50 filter (Pall Corporation) 10-fold.<sup>17</sup> This observation suggests that adhesive proteins present in plasma contribute to leukocyte retention in some filters. The speed of filtration also has been shown to affect leukocyte reduction. If temperature is held constant, faster flow rates result in decreased performance.<sup>8</sup> This is presumed to result from high shear rates and decreased contact time with the medium. Performing filtration in a controlled laboratory or blood center environment according to the manufacturer’s instructions optimizes the quality of the LR component compared with bedside filtration.

### Low-Leukocyte Apheresis Devices

Red cells collected on apheresis devices cleared by the Food and Drug Administration (FDA) require filtration to achieve the requisite level of leukocyte removal to label the product as leukocyte reduced. However, manufacturers of apheresis devices have modified the instrument to collect platelets with low levels of residual donor leukocytes that require no further filtration to meet standards as LR platelet concentrates. In the United States, three devices—the Spectra LRS (CaridianBCT, Lakewood, CO), Trima

(CaridianBCT), and the Amicus (Fenwal, Lake Zurich, IL)—are approved for collection of LR platelet concentrates without filtration (process leukocyte reduction). These devices achieve a high degree of separation between the donor platelets and the donor leukocytes as a result of several design principles. Flow path geometry, counterflow centrifugation, elutriation, and fluid particle bed separation all are used to separate platelets from leukocytes on the basis of differences in cell mass. Despite advanced design, apheresis systems can fail to collect platelet concentrates that meet standards for being considered leukocyte reduced. Failed collections may result from sudden changes in the donor bleed rate, paused collections that disturb centrifugal separation, or characteristics of the donor blood that interfere with optical sensors on the devices. As in the case of filtration-based systems, some form of process control is required to document that the collected products are leukocyte reduced.

### Process Control of Leukocyte-Reduced Components

To achieve the expected clinical benefits of providing LR blood, facilities need to control the process by which such products are prepared. Process control of leukocyte reduction seeks to establish with a specified statistical confidence that a specified proportion of units conform to the standards for leukocyte reduction. Selecting an appropriate degree of confidence and conformance depend on the expected use of the technology. For example, a greater degree of process control might be applied by facilities that use leukocyte reduction technology as the sole means to prevent transmission of CMV. In contrast, because FNHTRs are not serious events and because prevention of HLA alloimmunization has not been shown to result in improved clinical outcomes, a lower degree of process control may be appropriate if leukocyte reduction is to be used to achieve these two goals. Process control of leukocyte reduction also should document that the prepared products retain an adequate amount of the therapeutic blood cells intended for transfusion. Guidelines for statistical process control of LR blood have been published<sup>18</sup> and draft guidance documents have been issued by the FDA.<sup>19,20</sup>

The concentration of WBCs in a 300-mL LR blood component with  $10^6$  WBCs per unit is only 3.3 WBCs/ $\mu$ L. Because traditional automated cell counters are not accurate at leukocyte concentrations less than 100 WBCs/ $\mu$ L, special techniques are required to accurately count residual WBCs in LR components. The challenges of counting such low levels of leukocytes have been reviewed.<sup>21</sup> All methods depend on counting the cells present in a large volume of blood. Sampling errors and the precision of different methods affect the confidence of the measured result. Several different methods have been published, including cytopspin methods, Nageotte chamber counting, flow cytometry, and counting based on the polymerase chain reaction (PCR). Leukocytes can be stained with either a crystal violet nuclear stain (Turk’s solution), fluorescent dye (propidium iodide), or other vital stains (eg, Plaxan solution). Nageotte chamber counting with crystal violet stain is the most commonly used technique, requires only a light microscope, and has been used for

both RBCs and platelet concentrates. The Nageotte counting chamber has a 50- $\mu$ L bed volume. The sample to be counted is mixed with a red cell or platelet lysing agent and a nuclear stain, allowed to settle undisturbed in the counting chamber, and then examined under 200 $\times$  magnification. The Nageotte counting method has been shown in multicenter evaluations to be accurate to approximately 1 WBC/ $\mu$ L.<sup>22</sup> Because of its simplicity, low cost, and low limit of detection, it is adequate for routine quality control programs. With concentration of a larger volume of blood sample before staining, the lower limit of accurate detection by means of Nageotte counting can be reduced by as much as 100-fold.<sup>23</sup>

Flow cytometry can be used to achieve a lower limit of accurate detection (approximately 0.1 WBC/ $\mu$ L) because a larger volume of sample can be processed. The method requires an expensive instrument and relies on a fluorescent dye that is taken up by leukocyte DNA and emits light when struck by the cytometer laser. With adjustment of the conditions of data acquisition of the cytometer, signals from fluorescent residual leukocytes can be discriminated from those of residual red cells or platelets. Techniques are available for counting WBCs in RBCs and platelet concentrates.<sup>21</sup> Within the range detectable by means of Nageotte counting, the two methods show good correlation.

### **Prestorage, Poststorage, or Bedside Leukocyte Reduction**

Leukocyte reduction by means of filtration can be performed at three different points in time—before storage, after storage but before issue from the blood bank, and at the bedside. Bedside filtration was the first approach to leukocyte reduction and has been shown in clinical studies to be highly effective for the prevention of febrile reactions to RBCs. Although bedside filtration is probably effective for prevention of CMV transmission,<sup>12</sup> one study concluded that it was not effective for prevention of HLA alloimmunization.<sup>24</sup> Bedside filtration has several disadvantages compared with laboratory filtration. These include reduced performance and poor quality control. In addition, there is evidence that febrile reactions to platelet concentrates may be more effectively prevented if leukocytes are removed before storage. Moreover, for some recipients taking angiotensin-converting enzyme (ACE) inhibitors, bedside filtration has been associated with hypotensive transfusion reactions.<sup>25</sup> For these reasons bedside leukocyte reduction is not generally recommended.

Poststorage leukocyte reduction is filtration of components before issue from the blood bank. This approach allows development of an inventory of LR blood. Poststorage filtration is easy to standardize, can be incorporated into the laboratory procedure in a manner similar to that for other manipulations of blood components, and is easily adapted into a program of process control. For whole-blood-derived platelet concentrates, poststorage leukocyte reduction has the disadvantage that cytokines that accumulate during storage are not removed by filtration. For RBCs there is no known disadvantage to poststorage leukocyte reduction.

Prestorage leukocyte reduction during or soon after component preparation is becoming the preferred method of leukocyte reduction and is ideally suited to process control. Opinions differ as to the definition of prestorage leukocyte reduction, but the FDA has suggested that 72 hours be used as the time from collection to filtration. For platelet concentrates, numerous investigators have documented that inflammatory cytokines including interleukin-1 (IL-1), tumor necrosis factor (TNF), and IL-6 can accumulate during storage in some units. The extent of cytokine accumulation correlates with the leukocyte content of the unit and the duration of room temperature storage. For some transfusion recipients, the passively transferred cytokines result in FNHTRs (see later). Prestorage leukocyte reduction of platelet concentrates prevents accumulation of these cytokines. There is speculation that prestorage leukocyte reduction would have additional advantages by preventing transfusion of leukocyte fragments that would otherwise develop during storage. Results of laboratory studies and preclinical animal studies have suggested that leukocyte breakdown may contribute to HLA alloimmunization,<sup>26</sup> release of intracellular viruses,<sup>27</sup> and immunosuppression.<sup>28</sup> However, none of these effects has been documented in clinical trials. Results of a large, randomized, controlled study conducted in Europe with patients undergoing cardiac surgery showed no advantage of prestorage LR RBCs over poststorage LR RBCs for the prevention of postoperative infection, multiple organ failure, or death.<sup>29</sup> Nevertheless, prestorage leukocyte reduction is evolving as the standard method.

---

## **Clinical Indications for Leukocyte Reduction**

The clinical indications for the use of LR blood components continue to evolve. New higher-performance filters, the perception of clinical benefit, and the decreasing availability of non-LR blood in many countries have resulted in greater use of LR components. According to a nationwide survey of 2006 data,<sup>30</sup> 72% of RBCs collected in the United States were leukocyte reduced, of which 98% were prestorage leukocyte reduced. Among platelet components, leukocyte reduction was performed on nearly all apheresis platelets and 40% of whole-blood-derived platelets. There has been considerable debate concerning whether all cellular blood components should undergo leukocyte reduction (discussed at the end of the chapter). Evidence-based clinical indications for the use of LR blood have been proposed<sup>1</sup> and are listed in Table 16-4.

### **Reduction in Febrile Nonhemolytic Transfusion Reactions**

Reduction in the rate of recurrent FNHTRs to RBCs was among the earliest applications of leukocyte reduction. Washed RBCs, frozen deglycerolized RBCs, and RBCs filtered through micro-aggregate blood filters all were effective at preventing FNHTRs. This success was based in large part on the fact that FNHTRs may be prevented with blood containing fewer than  $5 \times 10^8$  WBCs

**Table 16-4.** Clinical Indications for Leukocyte-Reduced Blood Components**Established Indications**

- Reduce frequency of recurrent febrile nonhemolytic transfusion reactions to Red Blood Cells (RBCs)
- Reduce rate of alloimmunization to leukocyte antigens for patients with hematologic malignant disease
- Reduce risk of transmission of cytomegalovirus among persons at risk of infection by transfusion

**Emerging Indications**

- Improved outcomes in cardiac surgery

**Indications under Investigation\***

- Reduce risk of bleeding due to platelet refractoriness
- Reduce risk of postoperative bacterial infection
- Reduce risk of immune modulation leading to tumor recurrence
- Reduce risk of bacterial overgrowth of *Yersinia enterocolitica* in stored RBCs
- Reduced risk of white-cell-associated viruses (Epstein-Barr virus, human T-cell lymphotropic virus)
- Reduce, but not eliminate risk of transfusion-associated graft-vs-host disease (GVHD)

**Contraindications†**

- Prevention of GVHD
- Prevention of transfusion-related acute lung injury caused by passive infusion of leukocyte antibody
- Prevention of the red cell or platelet storage lesion
- Prevention of virus reactivation among patients with human immunodeficiency virus infection
- Prevention of vCJD transmission

\* Inadequate evidence to suggest benefit from leukocyte reduction.

† Evidence demonstrates no benefit of leukocyte reduction.

per transfusion. This value represents 100-fold more leukocytes than a widely used benchmark for prevention of HLA alloimmunization or CMV transmission— $<5 \times 10^6$  per transfusion.

**Mechanisms**

At least three mechanisms may account for the development of FNHTRs (Fig 16-6) (see Chapter 53). The final pathway for all three mechanisms is the elaboration of inflammatory cytokines such as IL-1, IL-6, or TNF. IL-1 and TNF react with cell surface receptors in the hypothalamus and stimulate prostaglandin and leukotriene-mediated pathways that reset the thermoregulatory center of the brain. IL-6 stimulates energy mobilization in muscle and fatty tissue, which leads to increased body temperature.

One mechanism of FNHTRs involves recipient antibodies reacting with donor leukocytes and stimulating the release of endogenous pyrogens (cytokines) from the donor cells. This mechanism is consistent with the prevention of FNHTRs by leukocyte reduction of donor blood and with the results of studies by Perkins et al<sup>31</sup> and Brubaker<sup>32</sup> that documented the high prevalence of lymphocyte or granulocyte antibodies in the sera of patients who experienced FNHTRs. The mechanism does not explain all FNHTRs,

**Figure 16-6.** Three mechanisms for the development of febrile nonhemolytic transfusion reactions. (A) Donor cells react with recipient leukocyte antibody and cause a release of interleukin of donor origin. (B) Donor cells react with recipient antibody and form antigen-antibody complexes that react with recipient monocytes to result in the release of recipient interleukin. (C) Residual donor leukocytes present in platelet concentrates during storage release interleukin passively transfused to the recipient.

however. Patients with antibodies to platelet-specific antigens may have febrile reactions when they receive LR platelet concentrates.

A second proposed mechanism for FNHTRs suggests that inflammatory cytokines are released by recipient cells in response to antigen-antibody complexes formed when incompatible donor cells are transfused to patients with reacting antibodies.<sup>33</sup> This mechanism is consistent with the role of recipient antibodies, the ease of preventing FNHTRs to RBCs, and the difficulty of preventing these reactions among alloimmunized patients receiving platelet concentrates. This mechanism also accounts for the fever and chills accompanying hemolytic transfusion reactions.

A third mechanism of FNHTRs is based on the passive transfer of inflammatory cytokines that accumulate in whole-blood-derived platelet concentrates during storage. Several investigators have found detectable levels of IL-1, TNF, and IL-6 in platelet concentrates after several days of storage.<sup>34</sup> These substances do not accumulate in platelet concentrates that have undergone prestorage leukocyte reduction or in platelet concentrates prepared from buffy coats. Of note, the accumulation of IL-1 and TNF in platelet concentrates does not occur if platelet concentrates are stored at refrigerated temperatures.<sup>35</sup> This may explain why IL-1 does not accumulate in RBC units and may account for the relative ease of preventing FNHTRs to RBCs.

Clinical evidence that FNHTRs to platelet concentrates result from passive transfer of cytokines was presented by Heddle et al.<sup>36</sup> They showed that the large majority of FNHTRs were to the plasma supernatant from stored whole-blood-derived platelets vs the cellular (platelet fraction). Furthermore, the severity of the reactions to the plasma supernatant correlated with the level of IL-1 $\beta$  and IL-6 present in the plasma. The passive transfer of cytokines accumulated during storage of platelet concentrates may explain FNHTRs that occur in the absence of detectable

leukocyte or platelet antibodies or the absence of a history of transfusions or pregnancies. It is also consistent with the observation that the incidence of FNHTRs to platelet concentrates increases with increasing duration of storage.<sup>37,38</sup>

Clinical Studies

Several recent clinical trials have confirmed that prestorage leukocyte reduction is effective in reducing the rate of FNHTRs to red cells by approximately 50% with residual rates well below 1% (Table 16-5).<sup>39-41</sup> In contrast to the experience with RBCs, leukocyte reduction has had mixed results regarding the prevention of FNHTRs to platelet concentrates. Consistent with the role of passively transferred cytokines as mediators of reactions to platelet concentrates, Mangano et al,<sup>42</sup> Goodnough et al,<sup>43</sup> and Mintz<sup>44</sup> found that bedside leukocyte reduction of platelet concentrates did not substantially reduce the rate of FNHTRs. In contrast, prestorage leukocyte reduction of platelet concentrates has resulted in a major reduction in the rate of FNHTRs to less than 1%.<sup>39,40</sup>

Reduction in HLA Alloimmunization

Leukocyte reduction is commonly used in an attempt to prevent alloimmunization to donor HLA antigens. Prevention of alloimmunization is of clear clinical value for patients undergoing renal, heart, or lung transplantation<sup>45</sup> and those with aplastic anemia awaiting stem cell transplantation.<sup>46</sup> In addition, much attention has been given to the prevention of alloimmunization among patients undergoing chemotherapy. In 33 studies involving more than 3000 patients, the median reported incidence of HLA alloimmunization when unmodified components were used was 39% (range, 20% to 71%). The use of LR components was shown to reduce the incidence of HLA alloimmunization and subsequent platelet refractoriness. Reduced refractoriness is expected to decrease morbidity or mortality caused by bleeding, but this has not yet been documented in any clinical trials.

The threshold level of leukocytes needed to provoke primary HLA alloimmunization is generally regarded to be 1 to 5 × 10<sup>6</sup> per transfusion. Fisher et al<sup>47</sup> administered transfusions of small doses of platelet concentrate to two groups of 12 patients

undergoing dialysis on three occasions at 14-day intervals. Five of 12 patients given a mean of 15 × 10<sup>6</sup> WBCs per transfusion made HLA antibodies, and none of 12 given fewer than 5 × 10<sup>6</sup> WBCs per transfusion made HLA antibodies. Although this study had numerous serious design flaws, results of a subsequent study by van Marwijk-Kooy et al<sup>48</sup> also suggested that 5 × 10<sup>6</sup> represented a threshold dose for alloimmunization. In a prospective trial, patients with leukemia received filtered buffy-coat-depleted RBCs and were then randomly assigned to receive either centrifuged platelet concentrates (mean WBC content, 35 × 10<sup>6</sup>) or filtered platelet concentrates (mean WBC content 5 × 10<sup>6</sup>). Clinical refractoriness occurred in 46% of those given centrifuged platelet concentrates but in only 11% of those given filtered platelet concentrates. Although significant individual variation is likely, 5 × 10<sup>6</sup> WBCs per transfusion was adopted during the 1990s as the standard for LR blood components. However, the threshold level was set at 1 × 10<sup>6</sup> WBCs per transfusion in Europe.

Mechanism

Decades of research provide unequivocal evidence that passenger leukocytes, which express donor HLA antigens, are a prime cause of recipient sensitization to HLA alloantigens. Experiments by Claas et al<sup>49</sup> with a rodent transfusion model showed that residual donor leukocytes provoked major histocompatibility complex (MHC) alloimmunization and that leukocyte reduction could decrease the incidence of primary sensitization to MHC antigens. These investigators further documented that even very low numbers of donor leukocytes in previously sensitized animals induced secondary immunization, suggesting that leukocyte reduction would be less effective in the previously sensitized patient. The importance of donor leukocytes was confirmed in experiments by Kao<sup>50</sup> and Blajchman et al,<sup>26</sup> who also provided evidence for the possible role of antigens on microparticles in plasma.<sup>51</sup>

Alloimmunization can occur by means of both direct and indirect immune recognition.<sup>52</sup> Direct allorecognition is the process by which recipient immune cells respond directly to donor HLA antigens without the processing of donor antigens by recipient antigen-presenting cells (APCs). The mixed lymphocyte reaction is an in-vitro example of direct T-cell recognition. Direct allosensitization requires at least three fundamental elements—binding of the antigen to the antigen receptor, binding of costimulatory molecules mediating cell-cell contact, and local elaboration of cytokines and appropriate cytokine receptors. Recipients may recognize intact Class I structures on the surface of donor leukocytes (Fig 16-7). Alternatively, Class-II-positive donor APCs may carry, within the peptide-binding groove, oligopeptides that represent the cell's own HLA Class I antigen (Fig 16-8). In either case, depletion of Class-II-positive donor APCs would reduce the chance of direct HLA immunization to Class I antigens. The failure of the recipient to recognize donor Class I antigens on platelets may reflect the fact that platelets lack critical costimulatory molecules required for direct allostimulation.

Indirect allorecognition is the process by which recipient APCs first engulf donor cells and then process donor antigen

**Figure 16-7.** Direct HLA alloimmunization to Class I antigen. The recipient cell directly recognizes foreign Class I provided that a second costimulatory molecule also is expressed and provided that the appropriate cytokine is locally present. Ag = antigen; IL = interleukin.

**Figure 16-8.** Direct HLA alloimmunization to Class I antigen. The donor cell carries a fragment of its Class I molecule within the peptide-binding groove of its own Class II molecule. This model, suggested by Dzik, provides one hypothesis to explain the frequency with which transfusion of unmodified cellular components results in antibodies to HLA Class I. Ag = antigen.

for redisplay to the recipient immune system. Donor cells, cell fragments, or soluble donor antigens are engulfed and degraded within lysozymes of the recipient APCs. Small peptide fragments corresponding to the alloantigenic region of donor HLA are then deposited in the peptide-binding groove of Class II structures on recipient APCs (Fig 16-9).<sup>53</sup> Recipient T and B cells then interact with recipient APCs in an MHC-restricted manner and respond to the donor peptide antigens displayed by the APCs. Recipient helper T-cell receptor-mediated recognition of this complex results in elaboration of cytokines by the donor APC (IL-1, IL-12), which in turn results in APC surface expression of CD80 and CD86. These molecules bind to CD28, the

**Figure 16-9.** Indirect HLA alloimmunization to Class I antigen. Recipient antigen-presenting cells (APCs) have digested donor cells or cell fragments and deposited a fragment of donor Class I antigen in the peptide-binding groove of the recipient Class II molecule.

central co-stimulatory molecule on helper T cells. T cells are further activated and elaborate cytokines such as CD40 ligand, IL-4, IL-5, and IL-10, which provide the critical help to B lymphocytes for their proliferation and antibody production.<sup>52</sup> Ultraviolet (UV) B irradiation of APCs disrupts costimulatory signals<sup>54</sup> and thus may account for the effectiveness of this method for reducing the rate of HLA alloimmunization observed in a large clinical trial.<sup>55</sup> Indirect immune recognition is unlikely to account for the initial response in an in-vitro mixed leukocyte reaction. However, the indirect pathway may be particularly relevant for alloimmune responses observed in vivo after transfusion.<sup>52</sup> In addition, the indirect pathway may account for experimental evidence in favor of alloimmunization by donor cell microparticles.

### Clinical Trials

Several clinical trials have investigated the usefulness of leukocyte reduction for the prevention of HLA alloimmunization and refractoriness. These studies have been reviewed by Heddle<sup>56</sup> and by Vamvakas.<sup>57</sup> Twelve randomized, controlled trials (RCTs) have been published (Table 16-6). Typically, in these trials patients with hematologic malignant disease were randomly assigned to receive either filtered or unfiltered blood components. Filters have ranged from early devices that achieved only 1- to 1.5-log reduction in residual leukocytes to current filters that are capable of at least 3-log reduction. Some investigators measured the residual WBC content after filtration, whereas others assumed that patients in the filtration arm received components that had been adequately leukocyte reduced. Some investigators used in-laboratory leukocyte reduction, whereas others used bedside leukocyte filtration. Patients were followed with periodic measurement of HLA antibodies. The details of HLA antibody detection and the criteria for labeling a patient as alloimmunized varied among different clinical trials. Once a patient met

†Numbers are the proportion (%) of patients demonstrating HLA antibodies.

LR = leukocyte reduced; RBCs = Red Blood Cells; PLTs = platelets; AML = acute myelogenous leukemia; ALL = acute lymphocytic leukemia; AA = aplastic anemia; BMT = bone marrow transplantation; CLL = chronic lymphocytic leukemia; CML = chronic myelogenous leukemia.

the study criteria for alloimmunization, some trials censored the patient from further analysis in the study, whereas others continued to collect data on the patient. Because of these differences in study design and execution, strict comparison of the current RCTs must be made cautiously. With these limitations, meta-analysis has identified a reduction in alloimmunization with leukocyte reduction for patients with hematologic malignant disease.<sup>56,57</sup> In support of these studies, a decrease in platelet alloimmunization and refractoriness was observed in a Canadian study of nearly 14,000 platelet transfusions with the adoption of universal leukocyte reduction.<sup>58</sup> Of particular note, RCTs of leukocyte reduction for the prevention of HLA alloimmunization among less immunosuppressed transfusion recipients are lacking. A retrospective study of leukocyte reduction for potential kidney transplant recipients found no effect on HLA alloimmunization rates among those who received LR (33%) vs non-LR (27%) blood components.<sup>59</sup>

The Trial to Reduce Alloimmunization to Platelets (TRAP) was the largest randomized trial to test the effect of leukocyte reduction for prevention of HLA alloimmunization.<sup>55</sup> The 530 patients undergoing initial therapy for acute leukemia were randomly assigned to one of four arms—whole-blood-derived platelets (control), LR whole-blood-derived platelets, LR apheresis platelets, and UVB-irradiated pooled platelets. All red cell components were leukocyte reduced. Patients were evaluated for 8 weeks. Blood components were leukocyte reduced in the laboratory under process control. Overall, 3% of transfusions were not of the assigned group. Alloimmunization was defined as cytotoxicity against one or more wells of a 30- to 60-cell target HLA antibody panel. During the 2 weeks before enrollment and assignment, 75% of patients had received transfusions (mostly

non-leukocyte-reduced). The results showed that platelet refractoriness was infrequent (10%) and was similar for all four treatment arms. Lymphocytotoxic antibodies developed in 45% of patients supported with non-LR pooled platelets compared with 21% in the UVB group, 18% in the group receiving LR pooled platelets, and 17% in the group receiving LR apheresis platelets. All three treatment groups had significantly lower rates of alloimmunization than did controls. The three treatment groups had similar results; that is, no advantage was observed for prestorage LR apheresis platelets compared with poststorage LR pooled platelets. It is also noteworthy that alloimmunization was defined as reactivity against a single target cell and so should not be confused with broad alloimmunization. Finally, the study was limited to 8 weeks; long-term rates of alloimmunization were not determined.

### Will Leukocyte Reduction Prevent Secondary Alloimmunization?

Because a secondary or anamnestic immune response requires a far smaller antigenic challenge than does a primary response, the secondary antibody recall to MHC antigens is difficult to prevent with LR blood components.<sup>49</sup> Most clinical studies of HLA alloimmunization have included patients with previous exposure to transfusion or pregnancy. Therefore, the issue of secondary alloimmunization seldom has been independently addressed. However, subgroup analysis of studies listed in Table 16-6 showed a higher rate of sensitization among pregnant patients or those who previously have received transfusions. The issue of secondary alloimmunization was directly addressed in the study by Sintnicolaas et al.<sup>60</sup> Female patients (n = 75) with hematologic malignant disease and a history of previous pregnancy were

randomly assigned to receive platelet concentrate support with either unmodified or LR apheresis platelet concentrates. Among the evaluable patients, HLA alloimmunization developed in 43% (9 of 21) of the standard platelet concentrate group and in 44% (11 of 25) of the filtration group. Refractoriness occurred in 41% (14 of 34) of women in the standard platelet concentrate group and in 29% (8 of 28) of the filtration group ( $p=0.52$ ). The time to development of refractoriness was similar in the two groups. The authors concluded that leukocyte reduction to fewer than  $5 \times 10^6$  WBCs per transfusion did not prevent alloimmunization and refractoriness among previously sensitized recipients.

In the TRAP study, however, analysis of patients who had been pregnant showed some benefit, albeit decreased, from the use of LR blood. In that study, 62% of patients with a history of pregnancy had HLA alloantibodies after transfusion of routine components; 33% did so after transfusion of LR components.<sup>55</sup> More recently, Seftel et al analyzed 106 women with hematologic malignancy and a history of pregnancy treated before and after the introduction of universal leukocyte reduction in Canada.<sup>58</sup> They found that leukocyte reduction did not significantly change the rate of alloimmunization (15% vs 10%) or platelet refractoriness (11% vs 9%), although the surprisingly low rate of alloimmunization in control patients may have accounted for the lack of observed benefit of leukocyte reduction. However, when previous transfusion was studied as an immunizing event, leukocyte reduction was highly effective in reducing the rate of alloimmunization (29% vs 2%).<sup>58</sup> Thus, it appears that patients with hematologic malignant disease and a history of exposure to foreign HLA antigens from a previous pregnancy derive diminished benefit from the use of LR components. This benefit may not extend to patients with diagnoses other than hematologic malignant disease.

#### **Will Prevention of Alloimmunization Decrease Bleeding Complications Caused by Platelet Refractoriness?**

Although the clinical trials conducted to date provide meaningful information on the prevention of HLA alloimmunization by means of leukocyte reduction, measurement of alloimmunization is a poor proxy for prevention of bleeding caused by immune-mediated refractoriness and is no proxy for bleeding resulting from nonimmune causes.<sup>56</sup> In addition, because bleeding is not limited to refractory patients, prevention of refractoriness will not prevent all bleeding complications. Finally, because serious bleeding complications are infrequent even when unmodified (non-LR) blood components are used, the potential gain resulting from the prevention of alloimmunization is small. These three factors make the clinical importance of leukocyte filtration technology difficult to assess. For example, in one prospective study, 502 patients undergoing marrow transplantation were randomly assigned to receive support with either filtered or unfiltered blood components to analyze the effect of filtration on transmission of CMV.<sup>12</sup> Even among patients who were at high risk of fatal bleeding complications, there was no difference in overall early mortality between the two treatment arms. Thus, leukocyte filtration was not likely to have substantially

affected the rate of fatal bleeding episodes. Similarly, the large TRAP study was unable to demonstrate that the use of LR blood conferred any advantage to prevent bleeding due to HLA refractoriness. Moreover, survival rates, remission rates, and blood component support all were unaffected by leukocyte reduction. Because of the low incidence of bleeding associated with platelet refractoriness, prevention of HLA alloimmunization by means of leukocyte reduction may not be cost-effective. Thus, leukocyte reduction has been shown to decrease the rate of HLA alloimmunization, but the effect on patient outcome has not been adequately assessed.

#### **Reduced Risk of Transmission of Cytomegalovirus and Other Leukotropic Agents**

The human leukotropic viruses—CMV, Epstein-Barr virus (EBV), and human T-cell lymphotropic virus (HTLV-I/II)—reside within the leukocytes of infected individuals. These viruses are found in such a low copy number outside of cells, that plasma from donors with established infections does not transmit infection. Unlike human immunodeficiency virus (HIV), these three viruses are not present in platelets. Thus, substantial leukocyte reduction of blood components would be expected to prevent transmission of CMV, EBV, and HTLV through blood transfusion. Leukocyte reduction does appear to reduce the content of EBV<sup>61</sup> and HTLV<sup>62</sup> in cellular components; however, EBV and HTLV are rarely clinically important transfusion-transmitted pathogens. In contrast, CMV is an important pathogen for immunosuppressed recipients and has been the subject of several clinical trials of LR blood components<sup>12,63</sup> (Table 16-7). In evaluating such trials, it is important to recognize that many patients, even if immunosuppressed, do not acquire primary CMV infection from unmodified blood transfusions. This may be attributed to the fact that among healthy blood donors only a small minority of leukocytes (estimated at less than 0.2%) carry CMV.<sup>64</sup> Sensitive PCR techniques are needed to demonstrate the CMV genome in the blood of seropositive healthy donors. Studies on blood from infected donors showed that the CMV PCR signal is lost or greatly reduced when blood was leukocyte reduced by means of filtration<sup>65-67</sup> or apheresis processing.<sup>66</sup>

Collection of blood from donors with negative test results for antibodies to CMV has been a traditional method to decrease the risk of transfusion-transmitted CMV. Although the use of CMV-seronegative blood has been shown to be an effective prevention strategy, it is not completely effective. Using an older PCR assay, Larsson et al<sup>68</sup> reported that CMV DNA could be detected in 55% of seronegative Swedish donors. A more recent study using a CMV nucleic acid amplification test with superior specificity found no positives among 514 seronegative donors, suggesting that the results reported in the Larsson study were false-positive results.<sup>64</sup> However, among high-risk recipients even the use of seronegative components is associated with a 1% to 1.5% failure rate. This may be caused by the presence of low level CMV viremia in recently seroconverting donors reported to be 1.6%.<sup>69</sup> Because the use of CMV-seronegative donors or

\*Data derived from Bowden<sup>12</sup> and Hillyer.<sup>63</sup>

<sup>†</sup>Values in parentheses are percentages.

LR = leukocyte reduced; RBCs = Red Blood Cells; PLTs = platelets; CMV = cytomegalovirus; BMT = bone marrow transplantation.

leukocyte reduction does not completely prevent CMV transmission, products prepared with either of these methods are better termed “reduced risk” for CMV.

### Transfusion-Transmitted Cytomegalovirus among Low-Birthweight Neonates

Term neonates of normal birthweight with normal immunity do not acquire serious CMV disease as a result of exposure to blood components. However, low-birthweight premature neonates, who frequently need small-volume blood transfusions, are at risk of contracting CMV disease (see Chapter 47). Consequently, all low-birthweight infants are appropriate candidates for strategies to prevent CMV transmission by means of transfusion. Because these infants are at times given fresh blood, protection against CMV resulting from leukocyte apoptosis during refrigerated storage is diminished. Early studies showed that the use of frozen deglycerolized RBCs decreased the rate of transmission of CMV among at-risk neonates. As high-performance leukocyte reduction filters replaced freezing technology, studies were performed to document the effectiveness of leukocyte depletion to prevent CMV transmission to at-risk neonates. Gilbert et al<sup>70</sup> conducted a prospective, randomized, blinded trial in which 515 newborns were randomly assigned to receive transfusion support with either unmodified RBCs or RBCs filtered through an IG500 (Terumo Corporation) filter capable of 1- to 1.5-log leukocyte removal. In the control arm, 29 infants weighed less than 1500 g, and CMV infection developed in nine (33%). In the filtration arm, among 24 neonates weighing less than 1500 g who were CMV seronegative and received CMV-seropositive filtered blood, none acquired CMV infection. In another study, Eisenfield et al<sup>71</sup> used less advanced filtration technology and documented prevention of CMV transmission to at-risk neonates. In contrast,

Ohto et al<sup>72</sup> performed a prospective randomized study of LR blood components in 52 newborn infants of whom 43 weighed <1500 g. There was no effect of leukocyte reduction on the rate of CMV infection; however, the geographic region in Japan where this study was conducted had a high rate of CMV among the mothers (89%) and the blood donors (89%). Because current filters are considerably more effective at leukocyte reduction than were those used in the published studies, it is likely that filtration technology is completely adequate to prevent CMV transmission to at-risk neonates. There are no data to support additional benefit by using a combination of CMV-seronegative blood donors and leukocyte reduction in low-birthweight neonates. The presence of a passively transferred antibody must be considered in interpretation of the results of CMV serologic testing after transfusion.

### Transfusion-Transmitted Cytomegalovirus after Hematopoietic Transplantation

Patients undergoing allogeneic hematopoietic transplantation are at great risk of CMV infection and disease because of the intense immunosuppression needed for stem cell engraftment, graft-vs-host disease (GVHD), and the persistent defects in cellular and humoral immunity resulting from the chimeric immune system present after transplantation. In this setting, uncontrolled CMV infection can represent a devastating illness with high mortality. As a result, CMV-seronegative recipients of CMV-seronegative stem cells should be protected from transfusion-transmitted CMV. When either the donor or the recipient is seropositive for CMV, the role of transfusion-transmitted CMV becomes much less important. In these latter cases, there is little evidence that the use of CMV-reduced-risk blood components has any substantial clinical benefit.

For CMV-seronegative donor-recipient pairs, the traditional approach has been to use seronegative donor blood. Early reports documented that leukocyte filtration was an alternative approach to prevent transfusion-transmitted CMV infection among patients undergoing allogeneic marrow transplantation. The results of these studies were consistent with those of studies conducted with neonates. They showed that prevention of CMV transmission with use of platelet concentrates does not require extensive leukocyte reduction. Bowden et al<sup>12</sup> conducted a large, randomized, prospective trial with CMV-negative patients who received transplants of CMV-negative marrow. The investigators compared support with CMV-seronegative blood with support with filtered blood from untested donors. They randomly assigned 502 CMV-seronegative patients undergoing autologous or allogeneic marrow transplantation to two treatment groups. Among 252 patients receiving CMV-seronegative blood components, two had CMV infection; none had CMV disease. Among 250 patients receiving filtered CMV-untreated components, three CMV infections (three with CMV disease) were observed. Two additional CMV infections in the seronegative group and three in the filtration group occurred within 21 days of entrance to the study and were considered the result of transfusions before enrollment. The survival rate was equal in the two study arms.

Several features of the study by Bowden et al<sup>12</sup> affect interpretation of the results. First, the filters used were not as effective as current filters. Second, filtration was conducted at the bedside under conditions now known to decrease filter performance. Third, patients could receive up to 6 units of blood to which they were not assigned (protocol violations) and still have the outcome included in the results. Fourth, the serostatus of four of the five patients who developed CMV infection within 3 weeks of being assigned to treatment groups was equivocal or discrepant. Although most observers interpreted this study to show no significant difference between the two strategies of CMV prevention, the results sparked controversy over the relative merits of the two methods. A subsequent nonrandomized “before and after” trial by Pamphilon et al<sup>73</sup> compared 114 recipients of CMV-seronegative components to 61 recipients of LR components. There were no cases of CMV infection observed in either group. However, a larger “before and after” study of 807 patients prospectively followed by Nichols et al<sup>74</sup> reported that CMV-infection rose from 1.7% when almost exclusively CMV-seronegative components were used to 4.0% when filtered components accounted for 1.5% of red cells and 15.8% of platelets transfused. Only a single case of CMV disease was observed because of CMV antigen monitoring and preemptive antiviral therapy. This study was not randomized and compared patients transfused in 1994 through 1996 to those transfused in 1996 through 2000. Observed differences may have been caused by confounders such as changes in treatment regimens or leukocyte reduction methods. In addition, the source of CMV was not identified and patients who received more transfusions were more likely to develop CMV infection and also more likely to receive a filtered component. There are no studies comparing the use of both methods of CMV prophylaxis

vs either method alone because of the large sample size required. The controversy regarding the equivalence of CMV-seronegative vs LR components was recently reviewed and a meta-analysis performed on the clinical studies in allogeneic stem cell recipients.<sup>75</sup> The meta-analysis indicates that CMV-seronegative components are associated with a 60% risk reduction for CMV infection compared with leukocyte reduction. This conclusion should be qualified in that the findings may have been biased by confounders in the observational studies by Nichols<sup>74</sup> and Pamphilon<sup>73</sup> and are applicable only to allogeneic stem cell recipients. With active CMV surveillance and preemptive antiviral therapy in this population, there is no evidence that clinical outcomes are worse with LR components.

### **Transfusion-Transmitted Cytomegalovirus among Recipients of Solid-Organ Transplants**

Although the morbidity and mortality associated with CMV among recipients of solid-organ transplants are not as severe as they are among recipients of allogeneic marrow, CMV still represents a serious infectious complication of solid-organ transplantation. In addition, CMV infection can promote rejection of the allograft. Because the graft is the most common site of post-transplantation CMV infection, the distinction between rejection and CMV infection can be difficult. Glomerulopathy, vanishing bile duct syndrome, accelerated atherosclerosis, and obliterative bronchiolitis may be the renal, hepatic, cardiac, and lung allograft expressions of CMV infection. The dominant factors controlling the development of CMV infection after transplantation are the serologic status of the organ donor and recipient and the degree of immunosuppression of the recipient. There is no evidence that patients who are CMV seropositive benefit from use of seronegative or LR blood components. Although infection with a second strain of CMV transmitted by blood transfusion is theoretically possible, there are no published reports of second-strain infections attributable to blood transfusion. Patients who are CMV seronegative and who receive organs from CMV-seropositive donors are at the greatest risk of postoperative CMV disease and acquire the infection from the allograft. Thus, prevention of transfusion-transmitted CMV is currently an appropriate consideration only for CMV-seronegative recipients of allografts from CMV-seronegative donors.<sup>45</sup>

No results of prospective, randomized trials document that leukocyte reduction prevents transfusion-transmitted CMV infection among seronegative recipients of seronegative solid organs. Experience with neonates, patients with hematologic malignant disease, and patients undergoing hematopoietic transplantation, however, suggests it is highly likely that use of CMV-seronegative or LR components are equivalent methods of reducing the risk of transfusion-transmitted CMV infection. Liver transplantation often requires massive transfusion support, but the attack rate for transfusion-transmitted CMV in liver transplantation is very low. In many cases it is not practical to restrict these patients to seronegative or LR blood components. For example, the deliberate use of CMV-untreated, non-LR

blood in the care of CMV-seronegative patients receiving CMV-seronegative liver allografts resulted in only a 10% incidence of CMV disease and no deaths attributed to CMV infection.

## Investigative Applications of Leukocyte Reduction

### Virus Reactivation

A number of preclinical studies suggested a role of donor leukocytes in CMV and HIV reactivation.<sup>76,77</sup> The clinical relevance of these observations was specifically addressed in a large, multicenter, RCT—the Viral Activation by Transfusion Study (VATS).<sup>78</sup> The study was conducted to evaluate the ability of LR blood to prevent either HIV or CMV activation among a cohort of patients with HIV infection undergoing therapy for the infection. The study showed no beneficial effect of leukocyte reduction for prevention of early death, virus activation, or time to first infection-related complication.

### Bacterial Overgrowth

It is unlikely that prestorage removal of leukocytes would have any measurable effect on the incidence of bacterial overgrowth in blood components. The mechanisms by which leukocyte reduction filters may deplete blood components of low levels of contaminating bacteria have been reviewed.<sup>79</sup> Because bacterial overgrowth is infrequent, a clinical study would require an enormous number of observations. The hemovigilance network in France reported an analysis of reported cases of bacterial sepsis before and after introduction of universal leukocyte reduction.<sup>80</sup> The study found that bacterial sepsis decreased from 3.8% to 1.7% ( $p < 0.001$ ) of all reported adverse events.<sup>80</sup> This observation does not prove that leukocyte reduction accounts for the reduced reports of bacterial sepsis. In the absence of a clinical trial, investigation of the potential role of prestorage filtration has entailed deliberate inoculation experiments. Units of blood are “spiked” with varying concentrations of bacteria and split into pairs, one of which is filtered. The paired units are stored and checked periodically for bacterial overgrowth. Many variables affect the results of such experiments. These include the strain of bacteria, the presence of bacterial plasmids, blood component characteristics, the filter selected, the inoculation dose, the holding time and temperature between inoculation and filtration, the method of assaying for bacterial overgrowth, the type of isolator used to culture bacteria, and the statistical power of the study.<sup>79</sup> Because of these numerous variables, caution must be used when interpreting the results of in-vitro experiments. It is expected that pathogen reduction systems will prove far more effective than leukocyte reduction for reducing the risk of bacterial overgrowth in stored blood components.

### Variant Creutzfeldt-Jakob Disease

Universal leukocyte reduction was adopted by several European countries to reduce the risk of variant Creutzfeldt-Jakob disease (vCJD) transmission based on experimental evidence of B-cell depletion in an animal model.<sup>81</sup> A subsequent study has shown

that prions can be found in both plasma and cellular elements of blood and that leukocyte reduction with current filters reduces infectivity by approximately 40%, but does not eliminate infectivity.<sup>82</sup> Novel blood filters currently under development are specifically designed for the removal of prion protein.<sup>83</sup> However, currently no claim can be made that leukocyte reduction has a clinical impact on transfusion-transmitted vCJD.

### Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is an acute, immune-mediated transfusion reaction characterized by dyspnea, hypoxia, pulmonary edema, low pulmonary capillary wedge pressure, and alveolar infiltrates on chest radiographs (see Chapter 56). Two different mechanisms may contribute to the development of TRALI. First, results of serologic investigations suggest that TRALI occurs when donor plasma contains antibodies reactive against the recipient's HLA type or against recipient non-HLA leukocyte antigens. Some have postulated that TRALI may result when recipient leukocyte antibodies react with residual donor leukocytes, although solid evidence is lacking. However, an FNHTR reaction is more common in this setting. A second mechanism proposes a two-hit model involving lipid agents in donor blood that prime recipient neutrophils in the presence of specific cytokine activation.<sup>84</sup> Currently, TRALI is best documented to result from the passive transfer of antibodies directed against recipient leukocyte antigens. Thus, leukocyte reduction is not expected to play an important role in the prevention of TRALI.

### Transfusion-Associated Graft-vs-Host Disease

Transfusion-associated GVHD (TA-GVHD) results from the unchecked clonal expansion of allogeneic donor leukocytes (see Chapter 54). Patients who experience TA-GVHD either do not eliminate donor leukocytes because of severe immunosuppression or do not recognize donor cells as foreign because of HLA similarity between the donor and recipient. The threshold number of donor leukocytes required to provoke human TA-GVHD cannot be determined and likely varies among different donor-recipient pairs. Because TA-GVHD depends on recipient exposure to viable allogeneic donor leukocytes, it might be anticipated that sufficient leukocyte reduction would reduce the risk of TA-GVHD. However, there are no conclusive clinical data to support this notion, and TA-GVHD has been reported among isolated patients who received transfusion of LR blood components.<sup>85,86</sup> Therefore,  $\gamma$ -irradiation remains the only acceptable current means to prevent TA-GVHD, although emerging pathogen-reduction technologies may prove to be effective. Nevertheless, there are data that suggest the risk of TA-GVHD may be related to the residual leukocyte content of blood components. In an in-vitro study in which the mixed lymphocyte reaction was used to model GVHD, a logarithmic decline in the number of cells available to respond resulted in a decline in lymphocyte reactivity similar to that after irradiation.<sup>87</sup> Of greater in-vivo relevance, the number of instances in which blood is

transfused from a donor who is HLA homozygous for a haplotype shared by the recipient far exceeds the observed incidence of TA-GVHD. This finding, coupled with the observation that TA-GVHD is more common after transfusion of fresh blood components containing large numbers of leukocytes, suggests that under normal transfusion circumstances the decline in donor cell viability that occurs during routine blood storage may provide some degree of protection against TA-GVHD. A recent report describing the Serious Hazards of Transfusion data from Britain stated that the number of reported cases of TA-GVHD decreased from 12 to 1 before and after the introduction of universal leukocyte reduction in 1999, with no cases reported since 2001.<sup>88</sup> It is not clear whether this decline is a result of leukocyte reduction or other factors that changed over the same time frame, such as the age of the transfused red cells and/or more widespread use of irradiated blood components. The authors noted that the mean age of red cells at issue increased from 8 days to 12 to 14 days. Of potential relevance are new data showing that leukocyte reduction does not affect the rate at which long-term persistence of donor leukocytes (microchimerism) is observed after transfusion in trauma patients.<sup>89</sup> The important message is that leukocyte reduction may decrease, but does not eliminate, the risk of TA-GVHD.

### Transfusion-Related Immunomodulation

Allogeneic transfusions have been associated with a variety of immune phenomena, including tolerance to subsequent solid-organ transplantation, increased susceptibility to viral or bacterial infection, and diminished immune surveillance against tumors (see Chapter 45).<sup>90</sup> This effect has not been unequivocally linked to transfusion, and a large body of research has investigated a number of possible mechanisms. Early hypotheses included patient selection bias, clonal deletion of primed cells by immunosuppressive drugs, the development of idiotype antibodies, and the development of suppressor T cells. Subsequent proposals have included central thymic tolerance, effects of microchimerism, persistence of donor veto cells, shifting of T-cell cytokine expression, inhibition of natural killer cell activity,

and infusion of soluble HLA proteins or soluble mediators of apoptosis.

Several lines of evidence have suggested that recipient exposure to donor WBCs can result in improved survival of subsequent renal transplants. For example, the original studies of Opelz and Terasaki<sup>91</sup> showed that the use of frozen-deglycerolized (and thus leukocyte-reduced) blood did not protect against rejection of renal transplants as well as did other RBC preparations. Okazaki et al<sup>92</sup> subsequently found that the beneficial effect of pretransplantation transfusion could be obtained by means of transfusion of the buffy coat alone. In 1993, a prospective, double-blind, randomized trial showed that patients given postoperative transfusions of non-LR fresh RBCs had better renal allograft survival than did patients given frozen deglycerolized RBCs.<sup>93</sup> Because cyclosporine and tacrolimus have become widely adopted as immunosuppressive agents for organ transplantation, the contribution of transfusion to graft survival has declined. A more recent three-arm prospective RCT in 144 naïve patients undergoing cadaveric renal transplantation compared graft survival in patients who received pretransplant leukocyte-rich transfusions that were HLA-DR mismatched, those who received transfusions that were one HLA-DR antigen matched, and those who received no transfusions.<sup>94</sup> There was no difference in graft survival at 1 year or 5 years, indicating that there is no longer a routine role for pretransplant transfusions to prolong graft survival. Because the risk of HLA alloimmunization associated with using leukocyte-rich blood components outweighs any benefit from potential immune tolerance, LR components are indicated for organ transplant candidates.

Recipient exposure to allogeneic leukocytes has been proposed to account for increased susceptibility to bacterial infections among persons receiving transfusions. Numerous studies with human subjects have shown that postoperative infection is more common among patients who undergo transfusion than among patients who do not. However, such studies are flawed in that these two groups do not have comparable infectious risk. Thus, the observations do not shed light on the role of donor leukocytes or the value of leukocyte reduction. Unlike these studies, nine

\*Data derived from Vamvakas.<sup>95</sup>

LR = leukocyte reduced; CI = confidence interval; S = single center; M = more than one center; RBCs = Red Blood Cells.

RCTs have been performed to examine postoperative infection rates among recipients of LR or non-LR blood (Table 16-8). These studies have provided conflicting results; some show benefit of leukocyte reduction and others do not. An “intention to treat” meta-analysis of eight studies (excluding the report of Van Hilten et al) indicated that there was no significant transfusion-related immunomodulation (TRIM) effect.<sup>95</sup> However when the three cardiac surgery studies were analyzed separately, a statistically significant TRIM effect was observed with a summary odds ratio (OR) of 1.39 (95% CI 1.08-1.80), indicating that cardiac surgery patients transfused with non-LR components had a 39% higher risk of postoperative infection. A subsequent meta-analysis of these eight studies and the additional RCT by van Hilten<sup>96</sup> included only those patients who were *actually transfused* and found a statistically significant ( $p=0.005$ ) OR of 0.52 across all studies, indicating a nearly 50% reduction in the risk of postoperative infection associated with the use of LR components.<sup>97</sup> Subset analysis indicated that the three studies in patients undergoing cardiac surgery were the primary contributors to the overall statistical significance. One limitation of these meta-analyses is that the studies differed in the type of component assigned to the non-LR control with some using standard red cells and others using buffy-coat-depleted red cells. Overall, however, these data increasingly suggest a beneficial role of LR blood in reducing the risk of postoperative infections, particularly in patients undergoing cardiac surgery.

Recipient exposure to donor leukocytes was previously considered possibly associated with an increased rate of relapse after resection of colorectal carcinoma. Preclinical studies with rodents demonstrated that the deliberate inoculation of tumor cells produced more pulmonary metastasis or tumor growth if followed by transfusion of blood that contained allogeneic leukocytes rather than transfusion of syngeneic or LR blood.<sup>98</sup> Although several clinical studies have shown that patients who undergo transfusion have a higher relapse rate than do patients who do not undergo transfusion, such studies cannot be used to draw conclusions about the effect of leukocyte reduction. In three RCTs with human subjects, investigators directly compared outcomes among patients receiving either LR or buffy-coat-depleted blood. These studies did not show a beneficial effect of leukocyte reduction.<sup>90</sup> In a 2001 randomized trial, investigators found no beneficial effect of leukocyte reduction on 5-year cancer recurrence rates among patients with colorectal carcinoma.<sup>99</sup> In light of current evidence, leukocyte reduction cannot be considered indicated for the prevention of a purported TRIM effect on cancer recurrence.

Leukocyte-reduced blood components have been reported to be associated with improved patient outcomes, specifically reduced mortality and/or hospital length of stay unrelated to postoperative infection. This effect has been primarily studied in cardiac surgery patients. A prospective study of three serial periods of transfusion strategies in cardiac surgery patients using non-LR components, LR components, and then non-LR components showed that hospital length of stay declined from 10.1 to 9.5 days with the use of LR components and then returned to 10.8 days with the reintroduction of non-LR components. There was no change in length of stay

in control patients who did not require transfusions.<sup>100</sup> A meta-analysis of three RCTs studying LR components in cardiac surgery showed that leukocyte reduction was associated with reduced mortality as well as a reduced risk of postoperative infection.<sup>101</sup> These data are supported by a recent prospective RCT of LR blood components in 562 patients undergoing cardiac surgery which found that those who received LR components had a significant reduction in mortality at 60 days (9.7 vs 4.9%,  $p = 0.029$ ) and at 1 year (11.7% vs 7.0%,  $p = 0.053$ ) compared to control patients.<sup>102,103</sup> The excess mortality was primarily caused by heart failure, because there was no difference in postoperative infection rates. Taken together these data provide convincing evidence in support of the use of LR components in patients undergoing cardiac surgery.

---

## Adverse Effects of Leukocyte Reduction

Little evidence suggests a serious clinical disadvantage of leukocyte reduction. The technology is expensive—estimated at more than \$1 billion every 2 years for the United States alone. Concern has been raised that this cost will divert resources from other initiatives of greater consequence to safe transfusion practice.<sup>1</sup> In addition to the cost, three disadvantages have been observed.

First, filtration results in a substantial loss of the therapeutic blood element intended for transfusion. The VATS<sup>78</sup> found that patients randomly assigned to the leukocyte reduction arm received a statistically smaller mass of red cells.<sup>104</sup> It is unclear whether this actually results in additional red cell transfusions. This problem may be particularly important if filtration is combined with other manipulations, such as preparation of RBCs by the buffy coat removal technique, preparation of washed platelet concentrates, or pathogen inactivation techniques.

Second, bedside leukocyte reduction has been associated with hypotensive reactions, especially among recipients treated with ACE inhibitors.<sup>25</sup> As blood passes through negatively charged filters, contact activation occurs. The activation, in turn, causes generation of short-lived vasoactive proteins such as bradykinin, leading to hypotension. For example, Takahashi et al<sup>105</sup> found that some filters were associated with the production of bradykinin during filtration of platelet concentrates. Bradykinin level increased from 37 pg/mL to 6794 pg/mL as a result of filtration. If an ACE inhibitor was added to the plasma, the level increased to 36,000 pg/mL because the ACE inhibitor also inhibits the kininases responsible for the breakdown of bradykinin. These reactions led to recommendations to use prestorage leukocyte reduced components to eliminate this complication.<sup>106</sup> Recently, these reactions were reported in a patient taking ACE inhibitors despite the fact that the blood was prestorage leukocyte reduced; an inherited defect in kinin metabolism was suspected.<sup>107</sup> Thus, patients taking ACE inhibitors and patients with inherited deficiencies of kininases are more susceptible to the hypotensive effects of administered bradykinin.

Third, reports of allergic reactions characterized by acute conjunctivitis, pain at the site of blood infusion,<sup>108</sup> or the sudden

onset of back pain and hypertension<sup>109</sup> have been observed in some patients undergoing transfusion of LR blood. Although these events appear to occur in a very small proportion of patients who undergo transfusion, the studies highlight that even low-frequency adverse consequences attributed to leukocyte filtration will affect growing numbers of patients as the technology becomes more widely used.

## Universal Leukocyte Reduction

Nearly all of Europe and Canada have implemented leukocyte reduction of all cellular blood components—termed “universal leukocyte reduction.” It has not been mandated by the FDA in the United States and the most recent survey data indicate that 72% of red cells, 40% of whole-blood-derived platelets, and nearly all apheresis platelets are leukocyte reduced.<sup>30</sup> These percentages may reflect availability more than clinical preference. In October 2000, the University Health Consortium concluded that the available evidence was insufficient to recommend universal leukocyte reduction. In contrast, the US Blood Safety and Availability Committee recommended in January 2001 that universal leukocyte reduction be implemented as “soon as is feasible.” Adoption of universal leukocyte reduction remains a hotly debated topic.<sup>110</sup> A prospective RCT of leukocyte reduction in a major academic medical center failed to demonstrate a difference in in-hospital mortality, hospital length of stay, or other secondary outcomes.<sup>111</sup> Other RCTs in HIV-infected patients<sup>78</sup> and trauma patients<sup>112</sup> failed to show a benefit in patient outcomes. A “before and after” study of the effects of adopting universal leukocyte reduction in Canada reported that the unadjusted hospital mortality rates declined from 7.03% to 6.19% ( $p < 0.04$ ).<sup>113</sup> There was no difference in serious nosocomial infections, although posttransfusion fevers and antibiotic use did decrease. A similar analysis of Canadian data in premature neonates found no difference in the primary outcomes: nosocomial bacteremia and neonatal intensive care unit mortality.<sup>114</sup> Improvement in some secondary clinical outcomes were reported. These two studies must be interpreted with caution, however, because of their retrospective design and potential bias from confounders. When viewed in the context of the negative RCTs noted above, adoption of universal leukocyte reduction cannot be justified on the basis of available scientific evidence. Other considerations such as logistics, public policy, public perception, and mechanisms for funding leukocyte reduction all play a role in making a final decision regarding adoption of universal leukocyte reduction.

## Summary

The use of LR cellular blood components has expanded dramatically in the last decade. The development of high-performance blood filters and low-leukocyte apheresis devices have made LR components available to all transfusion facilities.

The technology represents an important advance in the preparation of blood components. Several European nations and Canada have adopted universal leukocyte reduction of the blood supply. However, leukocyte reduction represents the largest incremental increase in the cost of producing blood components in history. Although billions of dollars in health-care resources would be needed to implement universal leukocyte reduction in the developed world, clinical trials have shown benefit for only limited patient populations.

## 17

# Composition and Mechanisms of Blood Coagulation and Fibrinolysis

**Peter Hellstern**

Director and Professor, Institute of Hemostaseology and Transfusion Medicine, Academic City Hospital, Ludwigshafen, Germany

The first part of this chapter describes the composition of plasma, focusing on those protein components that are important for treatment with plasma or its derivatives. The second part addresses individual factors influencing plasma levels of therapeutic plasma proteins. The regulation of blood coagulation and fibrinolysis and clinically useful blood coagulation and fibrinolysis screening tests are then discussed.

## Plasma Composition

Plasma is the cell-free part of blood composed of water, proteins, electrolytes, lipids, and carbohydrates. It is the transportation medium through which nutrients, hormones, waste products, and drugs are transported through the body. In vivo, the fluidity of plasma is maintained through complex interactions between its procoagulant and anticoagulant proteins and between these proteins, circulating blood cells, and the endothelium. Coagulation activation in plasma is prevented and its fluidity maintained in vitro by the addition of anticoagulants. Citrate is presently the only anticoagulant used for collecting therapeutic plasma and plasma for fractionation, the starting material for the manufacture of plasma protein concentrates. Although proteomics based on two-dimensional gel electrophoresis and mass spectrometry has revealed about 10,000 different human plasma proteins,<sup>1,2</sup> the number of constituents important for transfusion medicine is small, comprising albumin, immunoglobulins G (IgG) and M (IgM),  $\alpha_1$ -antitrypsin, C1 inhibitor, von Willebrand factor (vWF)-cleaving protease, blood coagulation factors, vWF, and the blood coagulation inhibitors antithrombin (AT) and protein C. The plasma levels and biological half-lives of these plasma proteins are subject to large interindividual

variation. Plasma is either prepared from citrate-phosphate-dextrose-anticoagulated whole blood units or collected by automated plasmapheresis. As a consequence of lower final citrate concentrations and lower dilution due to lower anticoagulant-to-blood ratios, apheresis plasma contains higher concentrations of clotting Factors V, VIII, IX, and XI than plasma from whole blood.<sup>3,4</sup> A dilution of 1:7 to 1:9 for plasma from whole blood and of 1:16 for apheresis plasma has to be considered when plasma protein concentrations are given that are related to circulating undiluted plasma. IgG levels in plasma from whole blood are significantly greater than in apheresis plasma because of a decrease in IgG when individuals donate apheresis plasma repeatedly at short intervals.<sup>4,5</sup>

## Albumin

Albumin is a 66.4-kD protein synthesized in the liver. Considering a total plasma volume of 3 L, about 120 to 140 g or 40% of the total body content of albumin circulates in the plasma at concentrations between 35 and 50 g/L (Table 17-1), which is more than 50% of the total plasma protein concentration, ranging from 64 to 88 g/L. The albumin concentration in the interstitial space of 10 to 12 L is about 14 g/L. The intravascular albumin compartment is responsible for 80% of plasma oncotic pressure, thus mainly contributing to maintaining blood volume. An intact liver synthesizes 12 g of albumin per day. In a steady state, the same amount of albumin is eliminated per day. The biological half-life of albumin in plasma is 17 to 20 days. Compensatory reduction of albumin metabolism occurs when plasma levels decrease because of reduced synthesis in the liver or capillary leakage.<sup>6</sup> A marked acquired hypoalbuminemia is a nonspecific marker of severe illness and strongly indicates poor prognosis.<sup>7,8</sup>

The functions of albumin are as follows:

- Maintenance of the intravascular oncotic pressure.
- Binding and transportation of drugs, vitamins, minerals, bilirubin, uric acid, hormones, amino acids, and fatty acids.
- Binding of toxic metabolites, among them free fatty acids, and radical scavenging.

**Table 17-1.** Therapeutic Plasma Proteins: Albumin, Immunoglobulins, Alpha-<sub>1</sub>-Antitrypsin, and C1 Inhibitor

| Plasma Protein                   | Plasma Concentration | Biological Half-Life | Main Functions                                                                           |
|----------------------------------|----------------------|----------------------|------------------------------------------------------------------------------------------|
| Albumin                          | 35-50 g/L            | 17-20 days           | Maintenance of intravascular oncotic pressure; transportation protein; radical scavenger |
| Immunoglobulin G                 | 6-17 g/L             | 23 days              | Humoral immunity                                                                         |
| Immunoglobulin M                 | 0.5-2.5 g/L          | 5 days               | Humoral immunity                                                                         |
| Alpha- <sub>1</sub> -antitrypsin | 1.5-3.0 g/L          | 4-7 days             | Inhibits neutrophil elastase                                                             |
| C1 inhibitor                     | 0.2-0.3 g/L          | 30-60 hours          | Inhibits complement C1 activation                                                        |

Plasma concentrations represent the 5th and 95th percentiles; biological half-lives represent the means or the 5th and 95th percentiles of elimination half-lives.

Despite all these important functions of albumin, it is remarkable that congenital analbuminemia causes only mild clinical symptoms (such as hypotension or discrete pretibial edema at all ages) or no symptoms at all.<sup>9</sup>

Commercially available albumin preparations are obtained from plasma fractionation according to Cohn and Oncley<sup>10</sup> or Kistler and Nitschmann<sup>11</sup> as fraction V and subsequently pasteurized for virus inactivation.<sup>12</sup> These solutions contain either 3.5% to 5% or 20% to 25% (w/v) of albumin at a purity of 95% to 98%. Albumin is also added to many drugs and plasma protein concentrates to stabilize the respective active ingredients.

**Immunoglobulins G and M**

IgG and IgM are glycoproteins synthesized in plasma cells and circulating in plasma at concentrations between 6 and 17 g/L and between 0.5 and 2.5 g/L, respectively. The molecular weights are 150 kD for IgG and 971 kD for IgM and the half-lives are about 23 and 5 days, respectively.

Polyvalent intravenous immunoglobulin (IVIG) preparations can also be administered subcutaneously and are prepared from fraction II during plasma fractionation.<sup>12</sup> Current virus inactivation and elimination procedures are low pH incubation, pasteurization, solvent/detergent treatment, caprylic acid treatment, and nanofiltration. While most IVIG preparations are primarily IgG with only trace amounts of other immunoglobulin isotypes, some IgM-enriched IVIGs contain up to 15% IgM and have been used for treatment of severe sepsis and septic shock.<sup>13</sup>

Hyperimmune immunoglobulin preparations are obtained from the plasma of actively immunized donors using ethanol fractionation or chromatography.<sup>12</sup> They can be administered intravenously or intramuscularly and are used to prevent postexposure infections, intoxication by tetanus toxoid, and immunization to Rh-positive red cells. For more details see Chapter 18.

**Alpha-<sub>1</sub>-Antitrypsin**

Alpha-<sub>1</sub>-antitrypsin synthesized in the liver is the most abundant serine protease inhibitor (serpin) in plasma. It inhibits a variety of serine proteases of which neutrophil elastase is the most important target. The molecular weight is 52 kD, the plasma concentration is 1.5 to 3 g/L, and the half-life is 4 to 7 days.<sup>14,15</sup> Hereditary alpha-<sub>1</sub>-antitrypsin deficiency resulting in plasma levels lower than 0.8 g/L occurs at a prevalence between 1 in 1600 to 1 in 5000.<sup>16</sup> It is associated with lung emphysema and liver disease in childhood. Plasma-derived alpha-<sub>1</sub>-antitrypsin concentrates are indicated for treatment of patients with emphysema secondary to congenital deficiency.

**C1 Inhibitor**

C1 inhibitor is a 105-kD serpin synthesized in the liver. The plasma concentration is 0.24 g/L, and the half-life ranges from 30 to 60 hours.<sup>17,18</sup> C1 inhibitor affects early activation of the classical complement pathway by blocking activated C1 and subsequent C2,4 complex formations.<sup>19</sup> It also inhibits activated Factors XI and XII and plasmin, and the formation of Factor XIa, kallikrein, and bradykinin.

An inherited or acquired deficiency of C1 inhibitor may cause angioedema characterized by subcutaneous or mucosal swelling in any part of the skin or the respiratory and gastrointestinal tracts.<sup>19</sup> The prevalence of hereditary angioedema is 1 in 10,000 to 1 in 50,000. C1 inhibitor concentrates purified by chromatography from the cryoprecipitate-reduced plasma produced during plasma fractionation are used successfully for the treatment of acute attacks of angioedema or for prophylaxis before surgery.<sup>17,20</sup>

**von Willebrand Factor Cleaving Protease**

The vWF-cleaving protease (ADAMTS13) is a 70-kD protein<sup>21</sup> expressed in the liver, platelets, and other tissues,<sup>22,23</sup> and circulates in plasma at concentrations between 0.7 and 1.3 mg/L.<sup>24</sup> The elimination half-life is 2 to 3 days.<sup>25</sup> The plasma enzyme cleaves the A2-domain of vWF. A defective cleaving protease results in unusually large vWF multimers, which are associated with thrombotic thrombocytopenic purpura (TTP). Therapeutic plasma contains normal vWF-cleaving protease activities and is effective for treatment of TTP through therapeutic plasma exchange.<sup>26,27</sup>

**Clotting Factors, Coagulation Factor Inhibitors, and von Willebrand Factor**

The coagulation proteins discussed here are responsible for normal hemostasis (Table 17-2). Except for Factor V, virus-inactivated plasma-derived concentrates have been developed for preventing or treating bleeding caused by hereditary or acquired vWF or any clotting factor deficiency states.<sup>12</sup> Antithrombin and protein C concentrates are also available and are used mainly for prophylaxis or treatment of thromboembolic complications in patients with hereditary deficiency of the respective blood coagulation inhibitor.<sup>12,49,50</sup> Because not all clotting factor and inhibitor concentrates are available in all developed countries, Factor V deficiency, for which a concentrate has not yet been produced,

**Table 17-2.** Clotting Factors, von Willebrand Factor, Antithrombin, and Protein C

| Plasma Protein | MW (kD)                 | Plasma Concentration (mg/L) | Plasma Activity (U/dL)  | Half-Life (hours)   | Main Functions                                                                                                  | Replacement by Plasma-Derived Concentrates <sup>12</sup> or Plasma                     |

and other clotting factor deficiency states (eg, Factor XI deficiency) are alternatively treated with plasma.<sup>28</sup>

Fibrinogen is the precursor of fibrin. Thrombin converts fibrinogen into fibrin monomers by cleaving fibrinopeptides A and B. Fibrin monomers polymerize to form an unstable fibrin clot, which is stabilized by Factor XIIIa-induced cross-linkage. Fibrinogen is also necessary for supporting platelet function. Prothrombin (Factor II) and clotting Factors VII, IX, X, and XI, and protein C are proenzymes of respective serine proteases. After activation by thrombin, Factor V accelerates activation of prothrombin, Factor VIII, and Factor X. Factor XIII is activated by thrombin to form a transglutaminase, which stabilizes fibrin clots by cross-linkage. vWF is essential for platelet-subendothelium adhesion and platelet aggregation, and for transportation of Factor VIII in plasma. vWF protects Factor VIII from early proteolysis. Antithrombin is a stoichiometric serpin that strongly inhibits thrombin and Factors IXa, Xa, and XIa. Once activated by thrombin-thrombomodulin, activated protein C inhibits Factor Va and Factor VIIIa.

Most clotting factors, antithrombin, and protein C are synthesized in the liver. Other sites of protein expression are megakaryocytes and endothelial cells for Factor V and for the  $\alpha$ -chain of Factor XIII. vWF is synthesized in megakaryocytes and endothelial cells.

The synthesis of functionally active prothrombin complex Factors II, VII, IX, and X, and protein C in the liver requires vitamin-K-mediated gamma-glutamyl carboxylation. Impairment of carboxylation occurs in vitamin K deficiency, in the presence of vitamin K antagonists, and in some cases of liver dysfunction. This results in synthesis of functionally impaired or inactive prothrombin complex factors, called PIVKA or proteins induced in vitamin K absence or antagonism.

## Factors Influencing Individual Plasma Composition

### Age and Gender

The physiologic aging process is accompanied by an increase in plasma levels of fibrinogen, Factors VII, VIII, and IX, and protein C in both genders.<sup>51</sup> A significant decrease of prothrombin activity levels with increasing age has been found in men but not in women.<sup>52</sup> Young women have significantly lower AT plasma levels than males of similar age. Because of a marked increase after menopause, AT levels in older women exceed levels in male contemporaries.<sup>53</sup> Gradually declining AT plasma levels have been observed in males older than 45 years.<sup>53</sup> Pregnancy is associated with marked increases in levels of fibrinogen, prothrombin, and Factors VII, VIII, and X, whereas Factor V, Factor IX, AT, and protein C levels are unchanged.<sup>54</sup>

### ABO Blood Group

Individuals with blood groups O, A<sub>2</sub>O, and A<sub>2</sub>A<sub>2</sub> have on average about 20 to 25% lower Factor VIII and vWF plasma levels when compared with other ABO blood group constellations.<sup>55-57</sup>

### Acute Phase Reaction

An acute phase response caused by any trigger of inflammation results in an increase in plasma levels of  $\alpha_1$ -antitrypsin, C1

inhibitor, fibrinogen, prothrombin, Factor VIII, and vWF and a decrease of albumin levels.<sup>58</sup> Smoking causes a low-grade systemic inflammatory response and concomitant increases in plasma fibrinogen.<sup>59-61</sup>

## Physical Exercise and Mental Stress

Both acute severe physical exercise and acute mental stress cause increases in fibrinogen, Factor VII, Factor VIII, and vWF levels.<sup>63-66</sup> In contrast, prolonged severe physical exercise results in a decrease in Factor VII levels, while fibrinogen levels continue to be increased during observation.<sup>68</sup>

## Hormones

Danazol, a weak androgen, improves the synthesis of C1 inhibitor, Factor VIII, AT, and protein C.<sup>68</sup> Oral contraceptives induce increases in plasma fibrinogen, prothrombin, Factors VII, VIII, IX, X, and XI,  $\alpha_1$ -antitrypsin, and protein C, while AT and protein S levels decrease.<sup>69-71</sup> Androgenic progestogens contained in oral contraceptives, but not progestogens with less androgenic profile, attenuate the ethinylestradiol-induced changes in hemostasis.<sup>72</sup>

## DDAVP

Desmopressin (DDAVP) has been used successfully to increase Factor VIII and vWF levels in plasma donors.<sup>73,74</sup> The yields of these plasma proteins were markedly improved when cryoprecipitate or Factor VIII concentrates were produced from plasma collected after pretreatment of donors with DDAVP.

---

## Regulation of Blood Coagulation and Fibrinolysis

Hemostasis encompasses all processes of clot formation, clot lysis, and wound healing with the aim of maintaining vessel wall integrity. The mechanisms of hemostasis incorporate the vascular endothelium and subendothelium, platelets, leukocytes, red cells, pro- and anticoagulant, and pro- and antifibrinolytic proteins. Primary hemostasis is characterized by the formation of a platelet plug at the site of vessel wall injury. vWF forms a bridge between platelets and vascular subendothelial structures and promotes platelet aggregation. Secondary hemostasis is achieved by formation of a stable fibrin clot, followed by fibrinolysis and tissue repair. Abnormal bleeding can result from impaired thrombin generation, clot formation, and clot stabilization, or from hyperfibrinolysis. Conversely, increased coagulation and diminished fibrinolysis may provoke thrombosis.

Previous models have suggested two independent pathways of coagulation activation, via the intrinsic and extrinsic cascade. But it is now recognized that the generation or exposure of tissue factor (TF) at the site of vessel injury is the first physiologic step in initiating blood coagulation.<sup>75</sup> There are three closely linked phases of coagulation, comprising the initiation, amplification, and propagation processes (Fig 17-1). Clotting is mainly controlled by several circulating inhibitors. Activation of fibrinolysis

**Figure 17-1.** Cell-based model of coagulation activation. Inactive clotting factors are in squares and active factors in circles. The coagulation cascade is initiated by tissue factor (TF) release at the sites of cell injury. During the initiation phase, TF complexes with Factor VIIa (FVIIa) at the site of cell injury. TF-Factor VIIa activates Factor IX and Factor X. Factor Xa generates small amounts of thrombin, which activates platelets, Factor XI, and cofactors V and VIII, allowing multiple positive feedback loops during the amplification phase. The tenase complex (Factor VIIIa-Factor IXa) generates large amounts of Factor Xa on the surface of activated platelets. The prothrombinase complex (Factor Va-Factor Xa) converts prothrombin to thrombin, which forms fibrin from fibrinogen and activates Factor XIII. PT = prothrombin; T = thrombin; TF = tissue factor.

results in fibrin cleavage by plasmin and subsequent restoration of vessel patency. The central role of thrombin in hemostasis by exerting both procoagulant and anticoagulant effects is illustrated in Fig 17-2.<sup>76</sup>

### Initiation and Amplification of Coagulation

Clotting is initiated by TF-Factor VIIa complexes after TF is exposed to the circulating blood by smooth muscle cells, fibroblasts, disrupted or activated endothelial cells, or activated monocytes (Fig 17-1). Circulating Factor VIIa represents approximately 1% of total Factor VII and can be generated from the inactive zymogen by an autocatalytic mechanism. Factor VIIa does not express its full procoagulant activity until it is bound to TF.<sup>78</sup>

TF-Factor VIIa activates Factors IX and X, and Factor Xa generates thrombin by activating prothrombin (*initiation phase*). These small amounts of thrombin ensure that coagulation activation and further thrombin formation are maintained (*amplification phase*). Thrombin activates Factors V, VIII, and XI, and platelets that provide the surface on which the *propagation phase* of coagulation occurs.

### Propagation of Thrombin Generation, Fibrin Clot Formation, and Fibrin Stabilization

The *tenase complex* consisting of platelet-membrane-bound Factor IXa, Factor VIIIa, and ionized calcium cleaves Factor X much more effectively than TF-Factor VIIa or Factor IXa alone.

**Figure 17-2.** The central role of thrombin in hemostasis. Procoagulant effects include platelet activation, the activation of clotting Factors V, VIII, XI, and XIII, and subsequent formation of a stable fibrin clot. Thrombin acts as an anticoagulant by activating protein C after complexing with thrombomodulin. It promotes fibrinolysis by activating plasminogen and inhibits fibrinolysis by activating TAFI. APC = activated protein C; F = factor; PC = protein C; TAFI = thrombin activatable fibrinolysis inhibitor; TM = thrombomodulin.

Factor Xa binds to platelet surfaces and complexes with Factor Va and calcium to form the *prothrombinase complex*, which rapidly generates large amounts of thrombin. Fibrin monomers resulting from thrombin-induced splitting of fibrinopeptides A and B from fibrinogen polymerize spontaneously to an unstable fibrin clot. Thrombin also activates Factor XIII to the transglutaminase Factor XIIIa, which stabilizes fibrin polymers by cross-linkage.<sup>78</sup>

### Inhibition of Blood Coagulation and Termination of Clotting

Several circulating inhibitors terminate the coagulation process (Table 17-3). The stoichiometric heparin-binding serpin AT mainly inhibits thrombin and Factor Xa and less strongly Factors IXa and XIa.<sup>47</sup> Thrombin binds to endothelial thrombomodulin and this complex activates protein C to the serin protease-activated protein C (APC).<sup>79</sup> Endothelial cell protein C receptor augments protein C activation by the thrombin-thrombomodulin complex. Together with its vitamin-K-dependent cofactor protein S, APC inactivates Factors Va and VIIIa. Tissue factor pathway inhibitor (TFPI) down-regulates blood coagulation by forming a quaternary complex with TF-Factor VIIa/Factor Xa. Heparin cofactor II is a specific inhibitor of thrombin in the presence of dermatan sulfate or heparin.<sup>47</sup>

The protein-Z-dependent protease inhibitor is a serpin inhibiting Factor Xa in the presence of the vitamin-K-dependent protein Z, phospholipids, and calcium.<sup>47</sup> Protein C inhibitor, a heparin-binding serpin, predominantly inhibits APC and thrombin.<sup>47</sup>

### Fibrinolysis and Its Inhibition

The role of the fibrinolytic system is to restore vessel patency once wound healing has maintained vessel wall integrity (Fig 17-3). The serin protease plasmin cleaves fibrin (and fibrinogen) at multiple sites, resulting in fibrin and fibrinogen degradation products. Plasminogen is activated to plasmin by tissue plasminogen activator (tPA) released by endothelial cells or by twice-chain urokinase plasminogen activator (tcuPA; urokinase) resulting from the activation of single-chain urokinase plasminogen activator (scuPA), which is synthesized in endothelial and kidney cells.<sup>80</sup> Besides plasmin, Factor VII activating protease is a potent activator of scuPA.<sup>81</sup> Plasmin cleaves not only fibrin but also fibrinogen and other plasma proteins. Fibrin specificity of plasmin is achieved by binding of plasminogen and tPA to the lysine binding sites of fibrin. Both plasminogen activators are mainly inhibited by plasminogen activator inhibitor type 1 (PAI-1) released from endothelial cells and platelets. Large

**Table 17-3.** Inhibitors of Blood Coagulation and Their Main Functions

| Plasma Protein                         | Main Functions                                                                                                                 |
|----------------------------------------|--------------------------------------------------------------------------------------------------------------------------------|
| Antithrombin                           | Heparin-binding serpin; inhibits thrombin, Factor Xa, Factor IXa, Factor XIa                                                   |
| Protein C                              | Serine protease; inhibits Factor Va and Factor VIIIa                                                                           |
| Protein S                              | Vitamin-K-dependent glycoprotein; cofactor of activated PC                                                                     |
| Thrombomodulin                         | Endothelial cell-surface glycoprotein; complexes with thrombin and activates protein C                                         |
| Endothelial cell protein C receptor    | Endothelial cell-specific transmembrane protein; augments protein C activation                                                 |
| Tissue factor pathway inhibitor (TFPI) | Trivalent protease inhibitor; inhibits TF-Factor VIIa by forming a quarternary complex of TFPI, TF, Factor VIIa, and Factor Xa |
| Heparin cofactor II                    | Dermatan sulphate-binding serpin; inhibits thrombin                                                                            |
| Protein-Z-dependent protease inhibitor | Serpin; inhibits Factor Xa in the presence of protein Z                                                                        |

amounts of plasminogen activator inhibitor type 2 (PAI-2) are synthesized in the placenta. Plasmin is predominantly inhibited by the very fast-acting plasmin inhibitor ( $\alpha_2$ -antiplasmin) and to a lesser extent by  $\alpha_2$ -macroglobulin. Plasma inhibitor cross-linked to fibrin by Factor XIIIa inhibits plasmin binding to fibrin. The thrombin-activatable fibrinolysis inhibitor is activated by thrombin-thrombomodulin complexes and protects clots from plasmin-induced degradation by removing lysine residues from fibrin.<sup>82,83</sup>

### Clinically Useful Coagulation and Fibrinolysis Screening Tests

Coagulation and fibrinolysis screening tests are used for detecting disorders of secondary hemostasis caused by coagulation factor deficiencies, dysfunctional coagulation factors, inhibitors against coagulation factors, anticoagulants, or hyperfibrinolysis. In addition to a detailed clinical history and examination and

**Figure 17-3.** Activation of fibrinolysis. Endothelial cells release sctPA or scuPA, which are activated by plasmin to tPA and urokinase, respectively. scuPA can also be activated to urokinase by FSAP. Both activators are able to generate plasmin from plasminogen. Plasmin cleaves fibrin and fibrinogen to degradation products. tPA and urokinase are inhibited by PAI-1 and PAI-2 and plasmin by PI, A2M, and AAT. TAFI inhibits plasmin-induced cleavage of fibrin. AAT =  $\alpha_1$ -antitrypsin; A2M =  $\alpha_2$ -macroglobulin; FSAP = Factor VII activating protease; PAI-1 = plasminogen activator inhibitor 1; PAI-2 = plasminogen activator inhibitor 2; PI = plasmin inhibitor; sctPA = single-chain tissue plasminogen activator; scuPA = single-chain urokinase plasminogen activator; TAFI = thrombin activatable fibrinolysis inhibitor; tPA, = tissue plasminogen activator; UK = urokinase.

laboratory investigation of disorders of primary hemostasis, coagulation and fibrinolysis screening tests are included in approaches to bleeding patients and to exclusion of bleeding disorders before operations or other invasive procedures.<sup>84</sup> Further applications of these tests are as follows:

- Monitoring of anticoagulant therapy.
- Monitoring of treatment with fresh frozen plasma or clotting factor concentrates.
- Detection of lupus anticoagulants.
- Detection of hypercoagulable states.

The historical division of coagulation activation and subsequent fibrin formation into an *intrinsic pathway* comprising surface-contact factors and an *extrinsic pathway* (TF-Factor VIIa) can be used for a better understanding of blood coagulation screening tests (Fig 17-4). The intrinsic pathway begins with the activation of Factor XII and prekallikrein at negatively charged artificial surfaces, as found on activated platelets and endothelial cells and at subendothelial collagen. Factor XIIa activates Factor XIa and further prekallikrein to kallikrein. Factor XIa and kallikrein accelerate Factor XII activation through a positive feedback mechanism. Factor XII and Factor XI activation is amplified by high-molecular-weight (HMW) kininogen. Factor XIa activates Factor IX and Factor IXa activates Factor X. The extrinsic pathway starts with the formation of TF-Factor VIIa complex, also resulting in production of Factor Xa.

The common pathway begins with Factor X activation, where the intrinsic and extrinsic pathways converge. Factor Xa converts prothrombin (Factor II) to thrombin (Factor IIa) in the presence of Factor Va. Thrombin cleaves fibrin to form fibrin monomers, which polymerize spontaneously to an unstable fibrin clot.

Coagulation screening tests use fibrin polymerization as a measuring signal and have limited sensitivity to detect mild coagulation factor deficiencies or weak inhibitors against coagulation factors. Their specificity is also limited by the fact that several causes of abnormal clotting times are not associated with bleeding or thrombosis. Therefore, coagulation screening tests must be combined with the clinical history and symptoms when assessing the individual risk of bleeding or thrombosis.<sup>84-87</sup> Laboratories performing coagulation screening tests must consider the different sensitivities of reagents to clotting factor deficiencies, therapeutic anticoagulants, or lupus anticoagulants. Each laboratory should establish its own reference ranges, which depend not only on the reagents but also on the instruments used for analyses. It is also important to define a grey area of borderline assay results that should prompt specific coagulation assays despite a lack of clearly abnormal screening test results.

The *activated partial thromboplastin time* (aPTT) measures the intrinsic and common pathways of coagulation activation. The recalcification clotting time of citrated plasma is determined after addition of kaolin, celite, micronized silica, or ellagic acid, providing a large artificial surface area, and phospholipids functioning as a platelet substitute. The *prothrombin time* (PT) is performed by adding brain tissue or recombinant thromboplastin and calcium to citrated plasma and recording the clotting time. This screening test assesses coagulation activation via the extrinsic and common pathways. The *thrombin time* (TT) measures the time for clot formation to occur in citrated plasma after addition of thrombin. It reflects the amount and quality of fibrinogen and the rate of fibrin formation. The reasons for abnormal aPTT, PT, and TT values and their clinical relevance are shown in Table 17-4.

**Figure 17-4.** Classical model of the coagulation cascade, with intrinsic, extrinsic, and common pathways. F = factor; HK = high-molecular-weight kininogen; PK = prekallikrein; TF = tissue factor.

**Table 17-4.** Reasons for an Abnormal Activated Partial Thromboplastin Time, Prothrombin Time, and Thrombin Time

| Abnormal aPTT                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | Prolonged PT                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 | Prolonged TT                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |

Hereditary dysfibrinogenemia may be associated with bleeding or thrombosis or both, or not associated with any symptoms. aPTT = activated partial thromboplastin time; PT = prothrombin time; TT = thrombin time.

The main use of aPTT is for screening coagulation defects and inhibitors. The test is relatively sensitive to Factor VIII, IX, XI, and XII deficiencies and to prekallikrein and HMW kininogen deficiencies. It may also be prolonged by more severe defects of fibrinogen, Factors V and X, and fibrin polymerization. Factors affecting the clotting response of the aPTT test include the composition and concentration of phospholipids, the type of contact activator and buffer, and the length of incubation with the plasma. An aPTT should be sufficiently sensitive to record single clotting factor deficiencies of 30% of normal or less.<sup>88</sup> Some aPTT reagents fail to detect individual coagulation factor deficiencies as low as 20%. When used as a screening test for lupus anticoagulant, the detection sensitivity is predominantly determined by the type and concentration of the phospholipid reagent. The aPTT is still the most widely used method for monitoring treatment with unfractionated heparin. Conditions associated with a prolonged aPTT but not with any increased risk of bleeding include Factor XII, prekallikrein, and HMW kininogen deficiencies; lupus anticoagulants; transient phospholipid antibodies; increased hematocrit resulting in citrate anticoagulant excess; and heparin contamination of samples. Recent findings suggest that moderate Factor XII deficiency might be associated with vascular mortality.<sup>89</sup> Transient phospholipid antibodies and

concomitant prolonged aPTT without any clinical symptoms are frequently observed in children suffering from repeated infections.<sup>90</sup> Increased plasma levels of fibrinogen, Factor VIII, and Factor IX sometimes cause an abnormally short aPTT, which has been associated with overall poor prognosis and venous thromboembolism.<sup>91,92</sup>

The PT reflects changes in the three vitamin-K-dependent clotting factors (prothrombin, Factors VII and X) and the non-vitamin-K-dependent Factor V. Its sensitivity to clotting factor deficiencies or to vitamin K deficiency or antagonism by oral anticoagulants strongly depends on the source and type of TF thromboplastin reagent. PT prolongations not associated with clotting factor deficiencies may be caused by lupus anticoagulants, increased hematocrit, or impaired fibrin polymerization. Because the heparin sensitivity of PT reagents is reduced by adding heparin neutralizing substances, only very high unfractionated heparin concentrations may cause prolonged PT. The PT is still the most widely used test for monitoring treatment with warfarin or other oral anticoagulants. For this purpose, the PT is calibrated against the international reference thromboplastin and given as international normalized ratio (INR).<sup>93</sup> Therapeutic thrombin inhibitors such as hirudins or argatroban also prolong PT substantially.

The TT detects an impaired fibrin polymerization resulting from fibrin(ogen) degradation products, monoclonal gammopathies, or dysfibrinogenemias more sensitively than the aPTT and PT. Hereditary dysfibrinogenemia is heterogeneous and may be associated with bleeding and/or thrombosis, or may be asymptomatic.<sup>28</sup> Unfractionated heparin causes a marked prolongation of the TT. The *reptilase time* performed by adding the snake venom reptilase to citrated plasma is unaffected by heparin and even more sensitive to impaired fibrin polymerization than is the TT. Because none of the coagulation screening tests are usually prolonged until the fibrinogen level falls below 0.1 g/L, a specific assay for *clottable fibrinogen* should be included in the basic screening tests for detecting coagulation factor deficiencies. Functional fibrinogen is either measured by the Clauss' method on the basis of thrombin-induced clotting or calculated from the change of turbidity during measurement of the PT (PT-derived fibrinogen).

Coagulation screening tests do not detect Factor XIII deficiency, which must be confirmed by appropriate assays.

There is presently no simple and adequately sensitive screening test for detecting mild *hyperfibrinolysis*. D-dimer latex agglutination and turbidimetric and enzyme-linked immunosorbent assays quantify the plasmin-degraded products of cross-linked fibrin in plasma using monoclonal antibodies. However, elevated D-dimer levels are found in numerous clinical conditions that are not inevitably associated with hyperfibrinolysis-induced bleeding. Severe hyperfibrinolysis can be diagnosed easily by markedly elevated D-dimers, prolonged TT and reptilase time, and low fibrinogen, plasminogen, and plasmin inhibitor levels. However, the detection of mild hyperfibrinolytic states associated with bleeding continues to be a diagnostic challenge.

The need for "global screening tests" allowing on-site assessment of the overall hemostatic potential has resulted in further developments of old assays using new technologies. Thromboelastography originally described by Hartert<sup>94</sup> is able to detect thrombocytopenia, platelet dysfunction, coagulopathies, impaired fibrin stabilization, and hyperfibrinolysis when performed in whole blood.<sup>95</sup> Although the test has been used successfully in guiding blood component administration in hepatic and cardiac surgery,<sup>96-98</sup> validation studies are lacking on its sensitivity and specificity to detect mild disorders of hemostasis in all clinical settings. Small studies demonstrated a low sensitivity of thromboelastography to detect platelet dysfunction.<sup>99,100</sup> The endogenous thrombin potential as measured by a thrombin generation curve invented by Hemker<sup>101</sup> may be a useful tool for estimating both the risk of bleeding and thrombosis. However, data justifying its use in clinical routine are still lacking.

## Summary

Plasma is used therapeutically or as starting material for manufacturing albumin, immunoglobulins, protease inhibitor, clotting factor, and coagulation inhibitor concentrates. Plasma protein

levels are subject to wide intra-individual and interindividual variation. Age, gender, ABO blood group, acute phase reactions, physical exercise, mental stress, and hormones substantially influence the plasma levels of therapeutically used plasma proteins. Hemostasis is now understood to involve complex interactions between vessel walls, platelets, blood cells, proteins circulating in blood or being fixed to cells, and other humoral factors such as ionized calcium. Clinically useful coagulation screening tests include activated partial thromboplastin time, prothrombin time, and thrombin time. The detection of mild hyperfibrinolysis and of mild coagulation disorders requires additional specific assays, a clinical history, and an examination.

# 18 Immunoglobulins

## Urs E. Nydegger

Professor Emeritus, University of Bern, and Consultant, Transfusion Therapy Consultancy, Bern, Switzerland

With worldwide use exceeding 60 tons/year, immunoglobulin (Ig) preparations for prophylactic and therapeutic use prepared from pooled donor plasma represent a significant plasma derivative. Because pool sizes may involve over 10,000 donors, the plasma from a given donor will reach a large number of recipients. The worldwide yearly volume of plasma processed in approximately 70 fractionation centers amounts to about  $20 \times 10^6$  L—and is increasing.<sup>1</sup> That volume is now driven by the need for intravenous and subcutaneous preparations, replacing the former drivers, which were albumin and Factor VIII. Efficacy and safety records, including hemovigilance tracking, are favorable and treatment with intravenous immune globulin (IVIG) and subcutaneous immune globulin (SCIG) preparations are possible in the outpatient and home-care settings. Understanding the mechanism of action for some indications has advanced the clinical rationale for utilization. Off-label use outnumbers labeled indications and continues to expand. Preparations are also being used with increased frequency in developing countries.<sup>2</sup> Treatment with Ig preparations attempts to replace antibodies in immune deficiencies or modulate the immune system in autoimmune disorders. In the latter, Ig therapy can result in a decrease in corticosteroid use. Ig therapy may be enhanced with hyperimmunoglobulins and monoclonal antibody (MoAb) therapy. Immunoglobulins appear throughout the body, are abundant in the bloodstream, and represent about one-fourth of total plasma protein concentration. They are synthesized by B lymphocytes and plasma cells with a synthesis rate as high as 2000 molecules per second per single B lymphocyte. The pooling of plasma from large numbers of donors results in a product that contains antibodies directed toward a wide range of antigens. The production of Ig preparations is a complex and costly process that takes 6 to 8 months from the time plasma is collected until the product is available for use.

---

### Immunologic Background for Immunoglobulin Therapy

The function of immunoglobulins is reflected in their structure, with the recognition site for antigens found at the outer tips of two branches. The effector part (“business end”) is endowed with the capacity to activate complement and to bind to Fc receptors. Once bound to a cognate antigen at the recognition Fab site, the resulting complex expresses different functions depending principally on its size and solubility.<sup>3</sup> Antibodies can fix the antigen to lymphoid tissues for the prolonged periods required for antigen recognition, using at least in part, the Fc gamma receptor IIB,<sup>4</sup> or they can present the antigen to monocyte-macrophages in the reticuloendothelial system for removal and disposal. The paired polypeptide chains, two heavy (H) chains and two light (L) chains, each contain a constant region shared by different clones and a variable (V) region (ie, a region that differs from one antibody specificity to the next). In contrast to the constant region genes, almost every B cell expresses a different pair of heavy- and light-chain variable region genes, a diversity that is generated during B-cell development by somatic recombination at the DNA level of three major building blocks:  $V_H$  (variable), D (diversity), and  $J_H$  (joining) segments. Each block has several genes that recombine and create diversity, enhanced by imprecise joining and the incorporation of untemplated nucleotides where the genes join (junctional diversity). The affinity of the antigen-antibody interaction is subsequently improved by somatic hypermutation of the rearranged genes followed by further rounds of selection, a process known as affinity maturation.

The repertoire of antibodies in a donor's plasma have specificity that is passed on in Ig preparations, resulting in availability for the recipient of therapeutic and prophylactic antibodies with high efficiency. The targeting of antibodies to specific antigens has been discovered in the example of infectious antigens distributed on pathogenic microorganisms, such as bacteria and viruses. A sufficient antibody response has to be present in the host in order for that host to remain disease-free. Beyond defense, the tasks of antibodies are part of a network that, in collaboration

with cellular immunology, participates in the homeostasis of the organism, including internal regulation of the immune system, apoptosis (Fas antibodies, see below<sup>5</sup>), and defense against malignant tumors.

Once antigenic stimulus ceases, healthy individuals develop a memory state and maintain low-grade antibody production. When reexposed to the same antigen, the healthy individual increases production of antibody. It remains elusive why certain self-proteins induce an autoimmune response.<sup>6</sup> One immunologic hypothesis is that only modified or altered self-proteins may become autoimmunogenic. Such alterations could reflect genetic polymorphisms revealed by analysis of amino acid sequence variability of known human autoantigens. Autoantigens have been found containing significantly more single nucleotide polymorphisms (SNPs) than other human genes.<sup>6</sup> Such findings might offer an explanation for autoimmune responses through allogeneic exposure. Besides other contributing factors in autoimmunity, SNPs may represent an essential prerequisite for the primary induction of an autoimmune response.<sup>7</sup> Memory and low-grade antibody production thus includes the response to autoantigens, eg, thyroglobulin or deoxyribonucleic acid, which results in production of normal autoantibodies.<sup>8</sup>

Excessive autoantibody synthesis is controlled by anti-idiotypic suppression. By virtue of their specific V regions, autoantibodies express an antigen-specific reactive site termed an *idiotype*. This site, in turn, can elicit the formation of a second antibody (Ab2), termed an *anti-idiotypic*. Anti-idiotypes can be antigen-site reactive, binding to the very cleft between the H and L chains of the outer tip of the Fab fragment where antigen is bound. Alternatively, anti-idiotypes can be frame-reactive and bind to outer parts of the Fab fragment and leave antigen binding by the idiotype-carrying primary antibody (Ab1) unaffected (Fig 18-1). Those anti-idiotypic antibodies that bind to the distal tip of Fab arms (ie, to the complementary determining region, or hypervariable region) are less likely to produce bivalently associated ringed dimers<sup>9</sup> than antibodies that bind to more proximal epitopes, projecting laterally from the surface of the Fab arms. Ab2 reacts with Ab1 not only in the fluid phase but also when Ab1 is expressed as surface immunoglobulin on B lymphocytes. In these cases, Ab2 may compromise synthesis of Ab1 and perhaps switch off the B-lymphocyte clone that produces Ab1.

These steps of the immune response (formation of specific Ab1 antibodies followed by Ab2 anti-idiotypes) explain why the design of drugs to replace these antibodies or the use of MoAbs remains complex at present.<sup>10</sup>

The therapeutic potential of IVIG remains to be elucidated in the field of influencing cellular signal transduction pathways involved in inflammation and immunity.<sup>11</sup> The goal of signal transduction is the alteration of gene expression to allow the cell to respond to the environmental signals. There are five fundamental components to every signal transduction pathway, which cells use to modulate immediate and long-term changes in gene expression. They are: 1) the ligand, 2) the receptor, 3) the cytoplasmic transduction molecule(s), 4) the transcription factor(s), and 5) the negative regulator(s). The presence in IVIG of antibodies against

**Figure 18-1.** The prefix “idio” comes from Greek language and means private. Thus, every antibody specificity directed against a given antigen, because of the specific recognition of this antigen, carries its own particular structural element at the site of the hypervariable regions termed idiotype. The immune system recognizes this idiotype and readily makes antibodies against it, termed anti-idiotypic. The latter may bind to the former and thus form idiotype-anti-idiotypic complexes. Such complexes are important in homeostasis of the immune system as a whole, because they occur not only in fluid phase but also on cell surfaces carrying Fc receptors or surface immunoglobulins or both. The idiotype-anti-idiotypic network is further regulated by polyspecific polyclonal IVIG preparations, which also carry members of this network present in the normal plasma donor population, which supplied starting material for their preparation.

one or several of such components<sup>12</sup> is now obvious. Overactivation or defective inhibition of selective receptors, kinases, and transcription factors can convert a normal immune response into a chronic disease state. Decades ago, researchers were reluctant to study mechanisms of action of human IVIG in animal models because of concern about heterologous immune responses. However, this concern has waned in the setting of short-term experiments that do not allow heterologous immune responses to become active.<sup>13</sup> Targets for intervention have been identified and the promise of rational drug design and/or IVIG application has come to fruition. An example is caspases (cysteine proteases), which play essential roles in apoptosis and inflammation. Once caspase-3 is processed, apoptosis is irreversible, because this enzyme directly activates the DNases, lipases, and proteases that destroy the cell. These cysteine proteases use a cysteine residue to cut the proteins, and are called caspases because the cysteine residue cleaves the substrate proteins at the aspartic acid residue. On the basis of the discovery a decade ago that IVIG contains antibodies against Fas,<sup>14</sup> researchers theorized that part of the antiinflammatory effect of IVIG is the result of its capacity to induce caspase-dependent cell death in Fas-sensitive cells. The Fas ligand or FasL is a type II transmembrane protein that belongs to the tumor necrosis factor (TNF) family. Fas ligand binds with its receptor to induce apoptosis. Fas ligand-receptor interactions play an important role in the regulation of the immune system. Induction of caspases upon Fas-ligand binding (CD95) is essential in cells for apoptosis, one of the main types of programmed cell death in developmental and most other stages of adult life, because caspases are “executioner” proteins in the cell.

RT = room temperature; S/D = solvent/detergent-treated.

Some caspases are also required in the immune system for the maturation of cytokines. Failure of apoptosis is one of the main contributions to tumor development and autoimmune diseases. This, coupled with the unwanted apoptosis that occurs with ischemia or Alzheimer's disease, has enhanced the interest in caspases as potential therapeutic targets. Concurrently, the CD33-related sialic-acid-binding Ig-like lectins (Siglecs) are cell surface receptors and members of the immunoglobulin superfamily (IgSF). Siglecs recognize sugars that are expressed on most immune cells, where they exert inhibitory signaling functions and downregulate cellular activation pathways via cytosolic immunoreceptor tyrosine-based inhibitory motifs. Human T cells are striking exceptions and do not express these molecules. The human-specific loss of T-cell Siglec might explain the hyperactivity of helper cells in AIDS and chronic active hepatitis.<sup>15</sup> IVIG activates Siglec 9, the receptor on the surface of neutrophils, thus inducing neutrophil cell death. One group of investigators studying the action mechanisms of IVIG concludes from these observations that IVIG exerts its immunoregulatory effects under pathologic conditions, at least in part, through its impact on Siglecs.<sup>16</sup>

With the advent of MoAbs, clinicians now have at their disposal an efficient antibody preparation devoid of unnecessary ballast (ie, antibodies carrying specificities not necessary for the recipient). In recent years, antibodies of defined specificities have also been engineered using gene rearrangement technology through phages, eliminating the immunization of any laboratory animals. Gene clusters encoding single-chain Fv (scFv) fragments can be made by randomly combining H- and L-chain V genes using the polymerase chain reaction (PCR), and the combinatorial library (>10<sup>7</sup> members) can be cloned for display on the surface of a phage. A single large phage display library can be used to isolate human antibodies against any antigen, bypassing both hybridoma technology and immunization. But even with the advent of engineered humanized antibodies or tailor-made antibodies with single or dual specificities (diabodies<sup>17</sup>), a number of difficulties have been encountered during administration, including production of

inhibitory anti-idiotypes, again suggesting that the complete network conferred by Ig preparations is difficult to replace with monospecific therapy.

### Polyspecific Immune Globulin Preparations for Prophylaxis and Therapy

IVIG, SCIG, and intramuscular Ig (IMIG) preparations are biologicals and stable blood derivatives. The Food and Drug Administration (FDA) uses the term immune globulin. In France, they are called MDS (médicaments dérivés du sang, or blood-derived drugs). Stringent requirements for IVIG have been set by the World Health Organization (WHO) and the European Committee for Proprietary Medicinal Products (CPMP; <http://eudraportal.eudra.org/>) (Table 18-1).

Immunoglobulins are hydrophobic and tend to adhere to surfaces during purification. Aggregated IgG molecules are common in purified IMIG and SCIG preparations and make up 10% to 20% of the total protein. Dimer formation is reversible,<sup>3</sup> but higher order polymers are stable and will cause serious side effects if infused intravenously. The preparation method of IVIG or SCIG is developed to maintain biological activity, provide a high degree of pathogen safety, and produce high yields of highly purified immunoglobulins.

More than 90% of total protein should be monomeric IgG with intact Fab and Fc functions. The subclasses 1 through 4 of IgG should be present at the same ratio as found in normal plasma. The half-life after infusion should be the same as the half-life of normal IgG. No complement-activating IgG polymers should be present.

Whenever Ig products are in limited supply, it is important to develop protocols that will ensure that patients in greatest need receive their treatments. Some countries, such as Australia, have increased the postmarketing supervision of Ig therapy.<sup>18</sup> The worldwide shortage<sup>19</sup> makes it necessary to review the appropriateness of Ig therapy for certain disorders.

Indeed, there is no acceptable alternative therapy to immunoglobulin in patients with primary immunodeficiency diseases (PID), where IVIG or SCIG is the treatment of choice. Gene therapy using allogeneic hematopoietic stem cell transplantation is necessary in certain patients such as those with severe combined immune deficiency (SCID) or other PIDs where Ig therapy and/or other therapies are ineffective. Gene therapy remains dependent on availability of HLA-matched sibling donors and gene-modified autologous marrow transplantation is not established.<sup>20</sup> Inclusion of IVIG in the WHO Model List of Essential Medicines will facilitate the possibilities of diagnosis and treatment of immunodeficient patients in developing countries. In addition, its inclusion will contribute to improving the access of developing countries to a range of blood-derived medicinal products already on the Model List that are used for replacement therapy in a variety of life-threatening diseases. For that reason, these patients are among those who should receive the highest priority in the use of IVIG and SCIG. Progress in simple IgG measurement using quantitative estimations of IgG subclasses by turbidimetric, nephelometric, or radial immunodiffusion technology has resulted in more precise dosages for patients. The use of IVIG or SCIG is guided by IgG concentration measurements before and after injection in order to study depleted levels (“trough levels”) and therapeutic IgG increments (Fig 18-2). Such measurements are important for pharmacoeconomic reasons and to ensure the appropriate dosing.<sup>21</sup>

Therefore, each patient must receive individualized therapy in order to optimize the response. Beneficial and cost-effective therapy results when the minimal effective dosage is used. PID patients who depend on lifelong IgG replacement therapy require meticulous laboratory follow-up<sup>22</sup> ([www.scid.net](http://www.scid.net)). Generally, health-care providers pay insufficient attention to laboratory expertise in the diagnosis and follow-up of immunodeficiency.

The clinical pathology laboratory performs the following functions:

- Ascertain the diagnosis, which leads physicians to prescribe IgG replacement.
- Monitor long-term safety and efficacy of IgG replacement.
- Ensure on-site good clinical practice for IVIG or SCIG administration using selected point-of-care tests.<sup>23</sup>

### Assistance of Laboratory Procedures in Prescribing Immunoglobulins

Because the main laboratory test for patients receiving Ig replacement therapy is quantitation of IgG levels, it is assumed that in published studies these tests are performed under standards for good laboratory practice. Agencies such as the National Academy of Clinical Chemistry, the International Federation of Clinical Chemistry and Laboratory Medicine, or the European Autoimmunity Standardization Initiative Group supervise standardization, traceability, and reproducibility. The preferred technique to quantitate immunoglobulins in fluid phase is nephelometry.

**Figure 18-2.** Two of the major injection sites for immunoglobulin preparations are depicted. The pharmacokinetic profile of repeat administrations is also given.

The plasma fractionation industry has developed production procedures for highly concentrated IgG preparations. Some IVIG preparations can reach 10% or 12% levels and those for SCIG administration can reach 15% to 17%, which raises concerns about hyperviscosity.<sup>24</sup> A final viscosity of  $>10$  centipoise for SCIG preparations increases the probability of local reactions. The viscosity of the solution may be the cause of the local site reactions that patients receiving SCIG experience. Viscosity techniques have now reached high measurement accuracy, provided the temperature of the fluid is adjusted. Close laboratory monitoring of IVIG and SCIG therapy will support appropriate dosing of a product that is often in short supply.

### Primary Immunodeficiency States Requiring Immunoglobulin Substitution

The normal average range of total IgG in humans is between 6 and 16 g/L, so that some healthy individuals are well protected against infection with approximately 7 g/L, whereas others require about 14 g/L to be free of infections. There are no gender or age differences and the levels of many antibody specificities (except those induced by vaccination) remain stable over time.<sup>25,26</sup> Clinical immunodeficiency can result from a deficiency of a single IgG subclass in the presence of normal, or elevated, levels of other IgG subclasses with non-functional antibodies. A typical example for such a disease

state is the specific polysaccharide antibody deficiency syndrome.<sup>27</sup> Therefore, assessment of both the concentration and the functionality of the specific antibodies where the clinical evidence dictates is superior to the measurement of only the total IgG.<sup>28</sup> More than three infectious episodes in a year that are resistant to antibiotic treatment over 4 weeks, make measurement of IgG along with basic complement system assays mandatory. Abnormal results in such screening indicate that a differential diagnosis can be made, including common variable immunodeficiency<sup>29</sup>; Wiskott-Aldrich syndrome; SCID; transient hypogammaglobulinemia of infancy; immune dysregulation, polyendocrinopathy, enteropathy, x-linked (IPEX) syndrome; chronic granulomatous disease; ataxia-telangiectasia; complement deficiencies; or mitochondrial depletion syndrome with T-cell immunodeficiency.<sup>30</sup> IgG subclass measurement is not advisable if the hypogammaglobulinemia is  $<2\text{ g/L}$ . However, with a moderate deficiency of  $<5\text{ g/L}$  IgG, a selective subclass deficiency must be excluded.

The hypogammaglobulinemia spectrum opens up a large array of further associations, such as metabolic disorders, deficiency of transcobalamine, and an increasing number of possible chromosomal abnormalities, all of which might be classified under the heading of primary forms of humoral immunodeficiency. A complete patient and family history improves diagnostic tracking before comprehensive laboratory testing. Toxic drug reactions with antimalarial agents, captopril, carbamazepine, or gold compounds may be followed by hypogammaglobulinemia. Malignant disease, typically chronic lymphatic leukemia and non-Hodgkin lymphoma, should be excluded as well. If malignant disease is suspected, marrow examination, colonoscopy, and thorax x-ray are performed on a case-by-case basis. Hypogammaglobulinemia is a laboratory finding in myotonic dystrophy with accelerated catabolism of IgG and in protein-losing enteropathy with intestinal lymphangiectasis. Some types of clinically overt immunodeficiency states with normal IgG levels require assessment of the complement system. Selective deficiencies of C1q, C4, or C2 suggest a genetic background, whereas C5-9 deficiencies are associated with meningococcal infection. Deficiency of C3 is also possible but the clinical evidence manifests in early infancy with *Hemophilus influenzae* and pneumococcal infections being associated with renal insufficiency. Preconditioned complement analysis kits are available for this purpose.

## Use of Immunoglobulin Therapy in Secondary Immunodeficiencies

IVIg therapy is useful in treating hypogammaglobulinemia induced by chemotherapy regimens, especially with intensified CHOP regimens and/or when associated with lymphoid irradiation.<sup>31</sup> Standard immunosuppressive therapy of autoimmune diseases with alkylating agents or with mycophenolic acid<sup>32</sup> might also, in some patients, require the use of IVIG.

However, this can be minimized by optimal tailoring of specific immunosuppressive drug therapy adapted to each patient's genomic makeup, a domain referred to as pharmacogenomics.<sup>33</sup> To determine the reason for hypogammaglobulinemia in its patient population, a large tertiary care pediatric hospital recently completed a review of all cases of laboratory-defined hypogammaglobulinemia between August 1990 and June 2006.<sup>34</sup> IgG levels in 8304 samples were analyzed and 1295 specimens from 680 patients exhibited hypogammaglobulinemia. In addition, 172 patients with an immune deficiency were identified; 7% of these had SCID. Evaluation of all patients with IgG levels less than half of the lower limit identified 122 generally immunodeficient patients, 33% of whom had primary immune deficiency. This study provides a framework for considering causes of hypogammaglobulinemia. At the study institution, hypogammaglobulinemia was found most often as a secondary immune deficiency caused by chemotherapy or complex cardiac anomalies.<sup>34</sup> Thus, IVIG and SCIG will most certainly be used in treating secondary immunodeficiencies. MoAbs that have been employed in cancer treatment have also demonstrated efficacy in nonmalignant diseases. Rituximab, a CD20 humanized MoAb, may induce hypogammaglobulinemia by virtue of its B-cell targeting but also other MoAbs, such as alemtuzumab (anti-CD52), express considerable infectious toxicity.<sup>35</sup> As more side effects of rituximab therapy are discovered<sup>36</sup> and the mechanism of side effect induction is elucidated, it may be determined that some of these side effects can be effectively managed with IVIG therapy.

## Intravenous Immune Globulin in Infectious Diseases

Immunoglobulins with antigen specificity that confers specific antibody reactivity to previously nonimmune individuals can be used to treat infectious diseases. Schedules, dosages, and routes of administration of immunoglobulins differ. Physicians should be familiar with the available IMiG preparations used in prophylaxis of infectious diseases as follows:

- Standard immunoglobulin preparations
  - hepatitis C
  - rubella
  - rubeola
- Hyperimmunoglobulins (higher specific antibody content)
  - hepatitis A
  - hepatitis B
  - diphtheria
  - rabies
  - rhesus isoimmunization
  - tetanus
  - tick encephalitis virus
  - varicella zoster

The IMiG and SCiG preparations may be sufficient for pre-exposure prophylaxis, but to prevent an outbreak in exposed

individuals an IVIG preparation may be needed. For anti-infectious immunoglobulins, donors with high titers are a source for antibody-enriched plasma. It can be difficult to determine the appropriate dosing with hyperimmune Ig preparations when treating complex antigens, because the preparation may not contain the necessary specificity of the antigen in question.

In diseases with hypogammaglobulinemia in which specific antibodies are insufficiently synthesized, resulting in more than three bacterial respiratory, intestinal, or urinary tract infections per year, IVIG infusions or SCIG preparations<sup>22,37,38</sup> must be administered on a regular basis. SCIG preparations, using liquid pasteurized polyvalent human 16% concentration (160 mg/mL) are appropriate for certain patients. Those patients who prefer to be treated at home or who cannot tolerate IVIG products are appropriate candidates. Patients can be trained and supervised once per week at a local hospital for four to six training sessions and tested for their practical skill and confidence in the SCIG administration route before being transferred to self-injections at home; parents give injections to children or supervise the treatment.<sup>39</sup>

It is well known that most infections provoke hypogammaglobulinemia except rubella, cytomegalovirus (CMV), and mycoplasma, which cause secondary hypogammaglobulinemia. In such cases, the laboratory will determine the titers of a selection of viral antibodies because anti-bacterial titers will not be informative. Clinically overt infections caused by some viruses might occur as an inherited monogenic trait. PID is not restricted to children<sup>40-42</sup> and is sometimes diagnosed in adults with recurrent infections and low IgG levels. The ongoing improvement of immunologic diagnostic procedures (using microarray technologies, genomic, and proteomic approaches), as well as recent discoveries in basic and clinical immunology, will likely increase identification of patients for the treatment.

## Intravenous Immune Globulin in Immune-Mediated Disease

A special feature of alloimmune and autoimmune diseases is the potential to affect virtually any system or organ of the body. Systemic autoimmune diseases are characterized by the production of autoantibodies that recognize a diverse array of cytoplasmic and nuclear antigens. Therefore, it is important to distinguish between the terms “autoimmunity” and “autoimmune disease.” The former is an adaptive immune response (T- or B-cell mediated) against self-antigens either with or without concomitant clinical manifestations. Autoimmune disease implies the existence of adverse manifestations, such as kidney disease, arthritis, rashes, and pleuritis arising as a consequence of a T- or B-cell mediated response to self.<sup>43</sup> The immune system must therefore discriminate between self and non-self. When self/non-self discrimination fails, the immune system destroys cells and tissues of the body and as a result causes autoimmune diseases. Immunologists are gaining insight into the body’s capacity to prevent autoimmune disease by maintaining

autoimmune recognition: regulatory T cells actively suppress activation of the immune system and prevent pathologic self-reactivity, ie, autoimmune disease. The critical role regulatory T cells play within the immune system is evidenced by the severe autoimmune syndrome that results from a genetic deficiency in regulatory T cells. As insight into the cellular network responsible to tune autoimmune recognition improves, the understanding of IVIG action mechanisms becomes possible in more detail.<sup>44</sup> If IVIG is efficacious in such different diseases as neurologic, hematologic, endocrinologic, and other disorders, there may be a common denominator among mechanisms. Accepted indications for IVIG in treating immune-mediated disease are the following:

1. Replacement in primary and secondary immunodeficiency diseases (such as in B-cell lymphoproliferative disorder).
2. Allogeneic marrow transplantation.
3. Kawasaki disease.
4. Guillain-Barré syndrome.
5. Chronic inflammatory demyelinating polyneuropathy (CIDP).
6. Myasthenia gravis.
7. Dermatomyositis.

The hematologic indications include immune thrombocytopenic purpura (ITP), pure red cell aplasia, and alloimmune-mediated thrombocytopenias.

Other situations where IVIG is lending increasing support, based on ongoing clinical studies, include the following:

1. Systemic vasculitis.
2. Hemorrhagic diathesis caused by Factor VIII inhibitor.
3. Recurrent pregnancy loss.
4. Prevention of neonatal sepsis.
5. Infections in polytraumatized and postsurgical patients.
6. Solid organ posttransplantation immunomodulation.

For most of these indications, observations of single cases favorably responding to IVIG were followed by the classic sequence of the four phases of clinical studies.

Many years of study on immune-complex-mediated diseases such as systemic lupus erythematosus (SLE), rheumatoid arthritis, and ankylosing spondylitis further define patients who will or will not respond to IVIG therapy. Thrombocytopenia and secondary myelofibrosis and/or cerebritis accompanying SLE seem to respond, and animal experiments of abrogation of experimental SLE with IVIG show benefit, suggesting there may be a role for IVIG in these diseases. With more in-depth definition of pathophysiologic processes in diseases now closer defined by molecular biologic approaches, MoAbs are becoming targeted tools that will be supported by simultaneous IVIG application.<sup>45</sup>

Conceptual design of a clear mechanism may lead to successful clinical trials of IVIG. Thus, two bleeding patients with autoantibodies against clotting Factor VIII responded to IVIG,<sup>46</sup> because the intrinsic regulation of the antibody network failed and could be reconstituted by IVIG. It appears that the inhibitor-designated suppressors of von Willebrand factor (vWF) cleaving protease ADAMTS13 may in fact be nothing else than autoantibodies. The clinical hemorrhage in the framework of resulting thrombotic thrombocytopenic purpura might be responsive to IVIG,<sup>47</sup> a

condition for which several clinical studies are under way with rituximab and Fresh Frozen Plasma.

As with infectious diseases, the search to help an additional number of autoimmune patients with IVIG therapy might open a new chapter using IgM-enriched preparations, because IgM isotype controls IgG autoreactivity. For the time being, most IgM from fractionated plasma is left unused. Substituting defective IgM with IgM from healthy donors might constitute an additional rationale currently being pursued in clinical studies. An IgM-enriched immunoglobulin preparation is a more potent downregulator of an in-vitro alloantigen-induced proliferation in the mixed lymphocyte reaction than a pure monomeric 7S IVIG.<sup>48</sup> Therefore, some studies now claim that IgM-enriched IVIG might exert a greater therapeutic potential than regular IVIG preparations.

---

### **Intravenous Immune Globulin in Neurologic Disorders**

Guillain-Barré syndrome (GBS), myasthenia gravis,<sup>49</sup> dermatomyositis, polymyositis, multifocal motor neuropathy with conduction block, and CIDP have become accepted as labeled indications by numerous health authorities. Furthermore, Lambert-Eaton syndrome and stiff-person syndrome might be additionally responsive to IVIG.<sup>50</sup> There has been substantial progress in explaining the disease mechanisms. It appears that autoantibodies to ganglioside GM antigen on Schwann cells are a major disease-inducing factor, which becomes inhibited by anti-idiotypic antibodies in GBS. IVIG also modulates the levels of proinflammatory cytokines in these diseases, selectively reducing TNF- $\alpha$  and interleukin-1, the levels of which can be correlated with disease severity. In dermatomyositis, IVIG therapy restores intramuscular capillaries by blocking the antibody-dependent formation of C5b-9 and the terminal membrane attack complex of complement that mediates endothelial cell damage. The response of patients with CIDP to IVIG might reflect factors in addition to Fc receptor blockade. In patients with multiple sclerosis (MS), hope exists that IVIG might at least relieve the patients from major symptoms. Several well-controlled clinical trials have been performed in different stages and phenotypes of MS. The results are mixed. Speculations that IVIG might be able to reverse fixed neurologic deficits from MS could not be confirmed. Adding IVIG to the conventional treatment of MS relapses with high-dose intravenous methylprednisolone also did not provide any additional benefits. Similarly, trials failed to establish a role for IVIG in the treatment of secondary or primary progressive MS. Most consistent beneficial results with a reduction of relapse rates and a slowing of disability have been obtained in relapsing-remitting MS including clinically isolated syndromes, although a most recent study did not confirm a reduction of disease activity based on clinical findings and magnetic resonance imaging results.<sup>51</sup> Trial results also suggest that IVIG might serve to suppress an increased recurrence of relapses immediately after delivery. Consequently, IVIG treatment is considered as second-line option for these indications, although there is still uncertainty regarding the actual

mechanism(s) of action and optimal dosage of this treatment.<sup>52,53</sup> Two-hundred and thirty-one patients stratified for primary MS (n = 34) and secondary progressive MS (n = 197) were randomly assigned to receive IVIG 0.4 g/kg/month or placebo for 24 months. Primary endpoints were 1) the time to sustained progression of disease, identified as sustained worsening of the expanded disability status scale (EDSS) score for 3 months, and 2) the improvement of neurologic functions defined by a patient's best EDSS score. Secondary endpoints were the proportion of patients with sustained progression, the relapse rate, the assessment of fine motor skills, visual evoked potentials, contrast sensitivity, depression, and quality of life. Analysis of the intention-to-treat population of combined primary MS and secondary progressive MS patients showed that the mean time to sustained progression was 74 weeks in the IVIG group compared with 62 weeks in the placebo group (p = 0.0406). There was no IVIG-mediated improvement in neurologic functions. More in-depth studies are required to see if IVIG halts progression of MS, at least in combination with MoAbs.<sup>54</sup>

---

### **Intravenous Immune Globulin in Cardiovascular Diseases**

The effectiveness of IVIG in Kawasaki disease (a children's illness also known as Kawasaki syndrome or mucocutaneous lymph node syndrome) has encouraged research in other cardiovascular diseases. Kawasaki disease and acute rheumatic fever are the two leading causes of acquired heart disease in children in developed countries. About 80% of the afflicted patients are younger than 5 years of age and males are affected more often than females. Although it is seen in a higher incidence in those of Asian ancestry, it can occur in every racial and ethnic group. More than 1800 cases of Kawasaki disease are diagnosed annually in the United States. In as many as 20% of the children with Kawasaki disease the heart is affected, most commonly the coronary arteries. This can result in aneurysms, thrombosis, and stasis. Other complications include myocarditis, arrhythmias, and valvular dysfunction. IVIG should be given early in the disease course—even in cases in which the heart is not yet affected. If Kawasaki disease has been observed after parvovirus infection, the IVIG may act through neutralizing parvovirus-B19-specific antibodies. However, in most children suffering from this syndrome the etiology remains unknown, and IVIG must be given early in conjunction with aspirin for at least 10 days to prevent the development of coronary artery aneurysms. Dosage should be 1.6 to 2.0 g/kg, administered in divided doses over 2 to 5 days, or 2 g/kg/day as a single dose.

Inflammation of the myocardium is a condition of serious clinical importance with inflammatory etiologies ranging from viral myocarditis, Chagas' disease, and AIDS, and noninfectious causes, including posttransplant cardiac rejection. Initial efforts to abrogate the development of cardiac dilation and dysfunction in patients with inflammatory myocarditis with immunosuppressive therapy were unsuccessful. When children with or without cellular inflammation shown by endomyocardial biopsy were

treated with IVIG, significant improvement was noted in left ventricular function. In a recent study the clinical presentation, severity, and outcome of enteroviral infections in children with malignancy were studied. All cases of enteroviral infections in a University Pediatric Hematology-Oncology Unit were assessed during a 5-year period. Reverse transcriptase PCR, immunohistochemistry, and indirect immunofluorescence assays were performed to document the enteroviral infection and the type of virus.<sup>55</sup> Among 104 patients evaluated for possible enteroviral infection, 55 children had documented enteroviral infection. Severe cardiac manifestations occurred in three of the 55 infected patients (one myocarditis, one dilated cardiomyopathy, one ventricular fibrillation). All patients received supportive care, IVIG, and/or pleconaril.<sup>55</sup> All patients who received high-dose IVIG developed early negative viral load. Infection-related fatality rate was 14.5% (n = 8). Enteroviruses caused more severe and lethal manifestations especially in children with lymphoid malignancy. The administration of high-dose IVIG was beneficial in viremia. Thus, the early therapeutic intervention with high doses of IVIG improves outcome in certain viral diseases. The use of IVIG in virus-induced myocarditis<sup>56</sup> is another area under investigation.

A mechanism of action in these conditions is the capacity of IVIG to deviate deleterious complement activation to innocuous targets with the IgG molecule itself binding C3b. However, the production of inflammatory complement breakdown products that induce vasodilation at the site of inflammation, and the adherence of phagocytes to blood vessel endothelium, support the potential role of MoAbs. Thus, eculizumab or its 25-kD single-chain version (scFv) lacking the whole constant region of the antibody, pexelizumab, may specifically block C5 cleavage<sup>57</sup> and may act similarly to, but more specifically than, IVIG.

## Immunoglobulin Therapy of Dermatologic Diseases

A sizable proportion of the worldwide use of Ig preparations benefits patients suffering from dermatologic disease. Toxic epidermal necrolysis (TEN) and bullous pemphigoid have become clear indications for IVIG therapy<sup>58</sup> and Ig preparations are being used in a number of other dermatologic diseases as well. Severe forms of pemphigus vulgaris were being treated with high-dose corticosteroids and immunosuppressive agents, but the use of IVIG has reduced titers of serum antibodies against keratinocytes, especially where IVIG has been used in conjunction with rituximab.<sup>59</sup> The mechanisms of action of Ig therapy in TEN have been elucidated: IVIG suppresses the proliferation of antigen-specific T cells without inducing apoptosis and the cells remain refractory to induction of apoptosis by CD95 ligation.<sup>14</sup> The infusion of high-dose IVIG is safe, well tolerated, and likely to be effective in improving the survival of patients with TEN. Early treatment with IVIG at a total dose of 3 g/kg over 3 consecutive days (1 g/kg/day for 3 days) is recommended.<sup>58</sup> With the development of several novel biologic immunomodulators, these drugs have

the potential to significantly affect the treatment of some inflammatory conditions in dermatology. For the moment, psoriasis remains the only condition in dermatology for which the use of biologic immunomodulators has been approved by the FDA but an understanding of the mechanisms of action provide an optimistic view for the IgE antagonist omalizumab; the TNF- $\alpha$  antagonists infliximab, etanercept, and adalimumab; and the T-cell response modifiers efalizumab and alefacept.<sup>60</sup>

Although only a minority of dermatologic indications (dermatomyositis, Kawasaki disease) are officially registered<sup>61</sup> and double-blind, placebo-controlled clinical studies are often lacking, the observed efficacy and safety profile of currently available IVIG sometimes makes this a treatment of choice for initiation of therapy or for replacement of more toxic alternatives, such as systemic immunosuppressive medications. With relatively rare diseases it is difficult to perform double-blind studies and therapy is often based on case reports. The increasing use of IVIG has been associated with a further understanding of its mechanism(s) of action, identification of areas of efficacy, and management of side effects. The fact that different brands of IVIG may have different efficacies has been demonstrated in the treatment of Kawasaki disease. Tsai and coworkers<sup>62</sup> studied four different brands of IVIG and determined that differences in efficacy were seen in the four products. Additionally, improvements in the purity, viral safety, and tolerability of IVIG products have been observed in some of the currently available products.<sup>61</sup>

## Intravenous Immune Globulin in Organ Transplantation

Organ transplantation is an important field for IVIG treatment, primarily for patients with high-titered HLA antibodies.<sup>63</sup> In organ transplantation, IVIG prophylaxis for rejection is now considered evidence-based<sup>64</sup> through a number of single case reports.<sup>65</sup> IVIG is now an established therapy for both conditioning of prospectively suboptimal donor/recipient matches and organ rejection. Acute antibody-mediated rejection of organ allografts usually presents as severe dysfunction with a high risk of allograft loss. Peritubular capillary complement C4d deposition with renal dysfunction, associated with circulating donor-specific HLA alloantibodies, heralds organ rejection.<sup>66</sup> Substantial reduction of alloantibody titers followed by suppression of antibody production has become possible with the appropriate use of IVIG therapy and other therapeutic strategies that include combinations of plasmapheresis (or immunoadsorption), tacrolimus, mycophenolate mofetil, rituximab, or splenectomy.<sup>67</sup> However, the optimal dosage for IVIG to treat acute humoral rejection still remains to be defined.

CD20+ MoAb therapy (rituximab) aimed at depleting B cells and suppressing antibody production has been used as rescue therapy in some episodes of steroid- and antilymphocyte-resistant humoral rejection. Plasmapheresis and/or IVIG, in combination with rituximab, have also been used to desensitize selected

high-immunologic-risk patients in anticipation of a previously crossmatch-positive solid organ transplantation.<sup>67</sup> In the near future, the possible role of new specific anti-B-cell approaches or, possibly, of new anti-T-cell activation approaches using selective agents such as belatacept should be assessed to further refine the present treatment of humoral rejection.

In the prophylactic setting (ie, prevention of organ loss in transplant recipients at high immunologic risk), IVIG is associated with reducing the risk of rejection in patients with previous positive complement-dependent cytotoxicity crossmatch.<sup>68</sup> Preformed antibodies to donor HLA or ABO antigens pose a major risk in organ transplantation. Conventional approaches to remove/circumvent this difficulty have included immunoadsorption, plasmapheresis/exchange, splenectomy, and use of cyclophosphamide. Availability of rituximab and IVIG have allowed transplantation in these high-risk patients with reasonable hope of successful outcome.

The ABO-histoblood group system must be considered as transplantation-associated donor-recipient disparity<sup>68</sup> because living donor kidneys from group A donors are now transplanted with increased frequency to group O recipients. This incompatibility was viewed as insurmountable until the advent of a new era of immunosuppressive/tolerance-inducing drugs. Modern genetic blood group typing now allows much more precise typing of histoblood groups, which improves transfusion practice and solid organ transplantation.<sup>69-72</sup> In addition, inhibition of excessive complement activation in organ transplantation might also be ascribed to IVIG preparations, whether enriched or not by IgM.<sup>73</sup> Allografts are given to infants suffering from hypoplastic left heart syndrome but in a recent pilot trial IVIG transfused before and after allograft patching failed to prevent sensitization.<sup>73</sup>

The CMV hyperimmunoglobulins are used both prophylactically and therapeutically. Although some transplantation centers switched to ganciclovir therapy alone, antiviral synergy might occur between ganciclovir and CMV hyperimmunoglobulins. In transplant recipients, CMV may be a risk factor for transplant vasculopathy. Some centers use a combination of the two therapeutic principles: specific viral antibody and virucidal synthetic nucleoside analogues. Prophylactic schedules may include the use of IVIG, rather than IMIG, even in preexposure prophylaxis, such as in the prophylaxis for CMV disease in renal or marrow transplant recipients. Dosage and timing of administration vary. In the postexposure situation, "the sooner the better" is an appropriate attitude. However, preexposure IMIG prophylaxis must be given 2 to 3 days before the exposure, because maximal serum levels of specific antibodies are not reached until 48 to 96 hours after injection.

Animal antibodies against human lymphocytes constitute a series of therapeutic IVIG preparations that are used for patients who have received allogeneic organ transplants.<sup>74</sup> The two major preparations (ATG-Fresenius and thymoglobulin) follow the principle of OKT3 MoAb, to bind to lymphocytes cell surface markers, thereby producing cell lysis or inactivation. Both are

elicited in the rabbit, the first being available in liquid, the second in lyophilized form. The human thymocytes used to immunize the rabbits have been tested for the absence of transfusion-transmitted viruses; the preparations obtained from the rabbits are sterile in this respect. When such preparations are used to treat transplant rejection, they are combined with agents that act in synergistic fashion to provide the potency, avoidance of side effects, convenience of administration, and cost appropriate for the individual patient.

## Coping with Overusage of Intravenous Immunoglobulin Preparations

Access to adequate supplies of IVIG has been a problem in recent years. Expense and limited availability of the product are causing concern for providers and patients alike.

In addition to improved laboratory surveys of Ig therapy, expert panels composed of experienced plasma product prescribers increasingly publish the results of their studies. According to a survey by the Public Hospital Pharmacy Coalition, only half of approximately 350 member hospitals have been able to obtain enough IVIG product to fulfill their patients' needs. That shortage may also be a problem of pricing; one must be aware that with IVIG, increasing usage cannot be offset by increased (bio-) reactor synthesis, as with most drugs, but indeed calls for more plasma donation. Canada was particularly motivated to review expert prescription because its per capita use of IVIG more than doubled from 1998 to 2006. This growth was attributable to off-label usage. To help ensure IVIG use is in keeping with an evidence-based approach to the practice of medicine, the National Advisory Committee on Blood and Blood Products of Canada and Canadian Blood Services convened a panel of national experts to develop evidence-based practice guidelines on the use of IVIG for hematologic conditions. The primary sources used by the panel were three recent evidence-based reviews. Recommendations were based on interpretation of the available evidence and where evidence was lacking, a consensus of expert clinical opinion was employed. A draft of the practice guideline was circulated to hematologists in Canada for feedback. Specific recommendations for routine use of IVIG were made for seven conditions including acquired red cell aplasia, acquired hypogammaglobulinemia (secondary to malignancy), fetal and neonatal alloimmune thrombocytopenia, hemolytic disease of the fetus and newborn, HIV-associated thrombocytopenia, idiopathic thrombocytopenic purpura, and posttransfusion purpura. IVIG was not recommended for use, except under certain life-threatening circumstances, for eight conditions including acquired hemophilia, acquired von Willebrand disease, autoimmune hemolytic anemia, autoimmune neutropenia, hemolytic transfusion reaction, hemolytic transfusion reaction associated with sickle cell disease, thrombotic thrombocytopenic purpura/hemolytic uremic syndrome, and virus-associated hemophagocytic syndrome. IVIG was not recommended for two conditions (aplastic anemia

and hematopoietic stem cell transplantation) and was contraindicated for heparin-induced thrombocytopenia. For most hematologic conditions reviewed by the expert panel, routine use of IVIG was not recommended. Development and dissemination of evidence-based guidelines may help to facilitate appropriate use of IVIG.<sup>75</sup>

## Side Effects Caused by Immunoglobulin Treatment: An Update

IVIG and SCIG administration may be followed by side effects. The incidence of side effects depends on the tolerability of each manufacturer's preparation. Comprehensive reviews of side effects of IVIG reveal few events except for a heterogeneous group of single cases<sup>76,77</sup> (Table 18-2). As with other plasma products, contamination of IVIG and SCIG with infectious agents is a possibility. Until the 1980s it was generally believed that IVIG and SCIG obtained by the Cohn fractionation method could not transmit viruses. However, between 1983 and 1994, more than 200 patients treated with non-virus-inactivated IVIG preparations developed hepatitis C. All manufacturers reevaluated the virus removal and inactivation capacity of their fractionation processes and many added specific pathogen inactivation and/or removal procedures to improve the viral safety of their products. As a result, there have been no further cases of viral transmission with IVIG preparations reported. The risk of infectious antigen transmission is the same for both IVIG and SCIG. Emerging viruses, such as avian influenza A (H5N1) or West Nile virus, are reliably removed by current virus inactivation procedures and are monitored by hemovigilance surveillance.

Prions are proteins responsible for the transmission of Creutzfeldt-Jakob disease (CJD). The variant form of this disease

(vCJD) is of concern because of its shorter incubation period and more severe expression of disease. Blood-borne transmissible spongiform encephalopathy (TSE) infectivity can be undetected for years in the blood of an asymptomatic vCJD individual. Although there is a possibility that vCJD may be transmitted through whole blood transfusions, there have been no reported cases of prion transmission through plasma-derived products.<sup>79,80</sup> This may be because the prions are removed during the fractionation process and the removal can be enhanced by depth filtration, adsorption chromatography, and nanofiltration (Roemisch J, personal communication). Other methods of prion removal have been investigated. The recently founded company, Pathogen Removal and Diagnostic Technologies, Inc, has developed a strategy to select resins that best adsorb the TSE causative agent from blood, although it is still experimental. The company has observed that selected resins can remove as much as 5–6 log<sub>10</sub> PrP<sup>Sc</sup>, if not up to 8 log<sub>10</sub>.

Reported reactions to SCIG include dizziness, malaise, chills, nongeneralized skin reactions such as swelling, redness, induration, and/or soreness.<sup>82</sup> Most of these reactions do not result in discontinuation of the SCIG treatment. A final viscosity of >10 centipoise for SCIG preparations increases the probability of local reactions. Although not routinely performed, IgA antibodies can be screened using standard particle gel immunoassay technique (DiaMed-AG, Cressier sur Morat, Switzerland) or ELISA methods.<sup>83,84</sup> It appears that SCIG is less prone than IVIG to induce anaphylactoid reactions upon IgA-anti-IgA immune complex formation.

The continuous improvement of purification and virus inactivation and removal by major manufacturers of IVIG and SCIG preparations has contributed to containment of side effects. The use of caprylate and nanofiltration are relatively newer methods that have been employed.

**Table 18-2.** The Adverse Event Spectrum Shared by Intravenous and Subcutaneous Immunoglobulins

| Adverse Event                            | IVIG*                                                                                                                                              | SCIG                                                        |
|------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------|
| <b>Time after administration</b>         |                                                                                                                                                    |                                                             |
| Immediate                                | Anaphylaxis (rare)                                                                                                                                 | None so far                                                 |

## Summary

Immune globulins as therapy have progressed significantly and have the potential for many more applications. New indications could result in a huge change in the requirement for this product. Further clinical trials and development for targeted antibodies suggest a complex but significant future for this form of therapy.

## Preparation of Plasma Derivatives

**Toby L. Simon,<sup>1</sup> Kirsten Seidel,<sup>2</sup> & Albrecht Gröner<sup>3</sup>**

<sup>1</sup>Corporate Medical Director, ZLB Plasma, a CSL Behring Company, Boca Raton, Florida, and Clinical Professor, Department of Pathology, University of New Mexico School of Medicine, Albuquerque, New Mexico, USA

<sup>2</sup>Corporate Medical Director, ZLB Plasma Services GmbH, a CSL Behring Company, Marburg, Germany

<sup>3</sup>Head of Virology, CSL Behring GmbH, Marburg, Germany

Plasma derivatives prepared from human plasma play a major role in the therapy of many diseases. Historically they have been used primarily in critical care settings and in the treatment of inherited diseases. However, in recent years intravenous immune globulin (IVIG), like therapeutic plasma exchange, has been used to treat a variety of diseases—usually with some type of connection to the immune system. Demand for the products has increased. For some preparations (such as Factor VIII and IX) alternatives exist in recombinant products; but for other products, no replacement appears on the horizon. Thus, this highly specialized area of medical therapy plays an important role in the care of many patients.

### Evolution of the Field

Derivatives of plasma for infusion into humans are developed through the fractionation of plasma. The scientific development of this field began in the laboratories of Edwin Cohn at Harvard University in the 1930s. Using ethanol, he developed a method that allowed the purification of albumin. Additional fractions were found to include other proteins of potentially clinical significance. With war on the horizon, the United States Navy took the lead in organizing studies and supporting Cohn's work, and partnerships with industry were developed.<sup>1</sup>

Albumin was sought as an alternative to freeze-dried plasma to treat battlefield casualties in shock. The most available source was bovine albumin. Early studies in volunteers (medical students at Harvard) had not demonstrated hypersensitivity. But when the bovine albumin was administered in clinical quantities to prisoner volunteers, serum sickness developed in a high proportion of the inmates, and one death occurred. Therefore, attention was focused on producing large quantities of human

albumin. Human albumin was taken to Hawaii after the attack on Pearl Harbor and used successfully to treat burn victims. In 1942 a National Research Council conference on albumin determined it was of value in shock and burns and found further advantages. Albumin could be packaged in one-tenth the space required for freeze-dried plasma, was ready in an emergency without reconstitution, and remained stable at room temperatures and even high outdoor temperatures. The American Red Cross was charged with collection of blood for further manufacture into this derivative, and contracts with pharmaceutical plants were arranged to ensure optimal production. Thus began the field of plasma fractionation, with its first phase dominated by albumin.<sup>1</sup>

Not immediately appreciated was the safety of albumin with regard to virus transmission. Pasteurization of the product from the beginning rendered it safe. At the time there was a lack of appreciation for the potential value of saline solutions, which awaited further research. Most of the blood collected during the war years was for albumin and the red cells were often discarded.

Albumin utilization continued after the war. Soon the demand for albumin could not be met by Recovered Plasma (plasma obtained as a by-product after separation and processing of whole blood into plasma and cellular components). The discovery of plastic bags, additive solutions, and the routine separation of whole blood into red cells and plasma allowed the development of increased Recovered Plasma collections. In the United States the use of plastic bags instead of glass bottles for blood collection facilitated emergence of an industry parallel to the field of blood banking to collect Source Plasma (plasma collected specifically for further manufacture). With the development of automated plasmapheresis devices for the collection of Source Plasma, accidents caused by returning red cells to the wrong donor could be completely avoided. Automated plasmapheresis was not only safer but also quicker and more comfortable for the donor; thus, Source Plasma establishments expanded. These organizations were usually for-profit companies, either independently owned or part of a company that also fractionated the plasma, and paid their donors in cash for

the donation. Initially, this did not differentiate them from many blood banks in the United States that also paid their donors until the all-volunteer system emerged in the United States in the 1970s.

Judith Poole's discovery of cryoprecipitation led to the development of antihemophilic factor. When home care started to be used extensively to treat patients with hemophilia A, the demand for clotting factor became the principal driver for plasmapheresis (a second phase in the field from approximately 1970 to 1990). When recombinant factor products appeared on the horizon, many predicted the end of the industry. However, the discovery of methods to manufacture an immune globulin product that could be given intravenously without precipitating or activating complement resulted in a third phase (1990 to the present)—characterized by immune globulin products as the principal driver of the industry.<sup>2</sup> Table 19-1 shows the products produced by the plasma industry. The composition of plasma is outlined in Table 19-2 and described in detail in Chapter 17.

## Plasma Procurement

Recovered Plasma is the plasma obtained after processing of whole blood into red cell and plasma components, while Source Plasma is the plasma obtained by apheresis after all the red cells and almost all of the white cells have been returned to the donor and is intended for further manufacture into injectable or diagnostic products. Availability of Recovered Plasma depends on collection of whole blood, which is driven by the demand for red cell components. The supply of Recovered Plasma is not sufficient to meet the demand for plasma derivatives; in fact, its current availability may be decreasing as a result of trends in red cell utilization and collection by apheresis. Thus, Source Plasma collections are needed to meet patient needs and the related market demands. Rapid changes in the market can be absorbed by opening and, if necessary, closing centers and increasing or decreasing donation numbers to meet actual need for the products. Although whole blood donors are limited to four to six donations per year depending on local regulations, Source Plasma donors can donate up to 104 times per year in the United States and up to 40 times per year in Europe. Thus, a Recovered Plasma donor can provide 1.5 liters of starting material per year, while a Source Plasma donor can provide almost 90 liters in the United States and approximately 25 liters in Europe. The concentration of Factor VIII is higher in Source Plasma (about 100 U/dL) than in Recovered Plasma (66-84.5 U/dL), but IgG is higher in Recovered Plasma (9.4 g/L compared to 8.2 g/L). Clotting Factor VIII is an acute-phase reactant not lowered by serial plasmapheresis. This attribute, combined with immediate freezing possible in a fixed site, facilitates the improved recovery. In addition, the immediate decrease in pH seen initially with whole blood collection is not seen with plasma collected by apheresis because of the continuous mixing and the lower concentration of anticoagulant (plasma to citrate ratios of 1:16 for Source Plasma

compared to 1:7 for Recovered Plasma). In addition, the release of proteolytic enzymes that destabilize clotting proteins occurs less often with plasmapheresis. When whole blood is drawn for red cells and Recovered Plasma, the collection should ensure good mixing, a short duration (ideally 15 minutes or less), and avoidance of temperature variation. The higher serum protein levels in Recovered Plasma are thought to relate to the less frequent donations.

In recent years, 63.5% of the plasma collected for fractionation has been Source Plasma and the remainder Recovered Plasma. About one-half of the plasma comes from North America, where the ratio of Source Plasma to Recovered Plasma is about 80:20. About one-quarter of the plasma comes from Europe, which accounts for half of all the Recovered Plasma. In the United States, there were between 10 and 13.8 million plasmapheresis collections per year between 2002 and 2006. More specifically, there were approximately 12.4 million plasmapheresis collections in 315 centers in the United States in 2006. As the number of plasmapheresis donor centers has declined from more than 400 in 2002, the collections per center have increased by about 16% with a mean of more than 39,000 collections per center annually.

The plasma industry has been a global one for many years. The plasma fractionation industry is considered part of biologics manufacturing, which, in turn, is a subset of the pharmaceutical industry. Intermediate preparations might be moved from a plant in one country after initial production steps to another plant in another country for completion of manufacture. Products are typically registered in multiple countries, although products sold in the United States must come from either plasma collection establishments in the United States or facilities overseas that are licensed by the US Food and Drug Administration (FDA). However, in some countries, particularly in Western Europe, national fractionation plants owned by nonprofit (tax exempt) entities remain. In all cases, the plant must use aseptic conditions, be in conformance with good manufacturing practice (GMP) regulations, and generally be licensed by regulatory authorities of all countries that receive products produced there. Similarly, United States plasma donor centers must be approved by European authorities if their plasma is sent to Europe.

The production of plasma derivatives (also known as biologics, biopharmaceuticals, or biological therapies) differs from standard pharmaceutical manufacturing in several respects. The cost of the starting material is high, reportedly 45% to 50% of the cost of these products, whereas the cost of the raw material for standard pharmaceuticals averages 19% of the total. Thus, the cost of procurement of plasma plays a key role in the economics of the industry. Exclusive use of nonremunerated donors remains a major goal of international and European organizations. However, the volume of Recovered Plasma for fractionation has declined by about 14% in the last 5 years, and the volume of Source Plasma from remunerated donors in the United States and donors compensated for time and transportation expense in Germany, Austria, and China has increased by about 4%.

**Table 19-1.** Clinically Used Plasma Products

| Plasma Product                                                                     | Preparations                                                                  | Indications (Usage)                                                                                                                                          |

| (approximately 120 well-characterized proteins) |              |

Remunerated donors from the United States have proven to be safe and dependable. They are the key group of donors in allowing the industry to respond to patient needs.<sup>3</sup>

More detail on recruitment, collection, and processing of donors for plasma is covered in Chapter 62.

## Plasma Manufacture

### Shipping Process

The overall process begins with the shipping of collected units once all testing has been completed and all information verified. Plasma stored at refrigerated (and even room) temperatures can be used for some products (albumin and immune globulins). But the efficacy of the process and the assurance of cost-effective production from the starting material require that labile clotting factor concentrates be made from each liter. Thus, plasma stored frozen at  $-20$  to  $-30^{\circ}\text{C}$  is the standard starting material. Frozen plasma also reduces issues of bacterial growth during shipment and storage. Plasma is held for 60 days after collection as part of the safety procedures (described below). After that time, the process begins under aseptic conditions in a manufacturing plant.

### Manufacturing Process

The manufacturing process has been reviewed in detail elsewhere.<sup>4,5</sup> The methods of large-scale plasma protein manufacturing are described in Table 19-3.

The plasma is expelled from containers and thawed at  $4^{\circ}\text{C}$  to produce cryoprecipitates. Typical batches are 2000 to 4000 L. Only those precipitation and other separation methods that do not lead to denaturing or inactivation of proteins are used. The basic Cohn fractionation procedure is shown in Fig 19-1 and

Table 19-3. Methods of (Large-Scale) Plasma Protein Fractionation

|                                                                     |

the relationship of the fractions to the products are described in Table 19-4. Figure 19-2 provides an overview of the manufacturing process for major products.

Methods for plasma fractionation are based on the principles of differential solubility of proteins and differential interaction of proteins with solid media. Differential interactions with physical fields have been used only rarely. The solubility of proteins is determined by charge, isoelectric point, size, composition, conformation, and physical and chemical properties. The cold-ethanol precipitation developed by Cohn<sup>6</sup> (later modified by Oncley<sup>7</sup> and Kistler and Nitschman<sup>8</sup>) induces changes in protein solubility to isolate various fractions. Successive processing steps are carried out at specific ethanol concentrations and pH, temperature, and osmolality. This results in selective precipitation of proteins, which are then separated by centrifugation and/or filtration.

The Cohn method uses five variables: ethanol concentrations ranging from 8% to 40%, pH levels between 4.5 and 7.4, temperature ranges from  $-5^{\circ}$  to  $-7^{\circ}\text{C}$ , ionic strength differentials from 0.14 to 0.01, and protein concentrations from 5.1% to 0.8%. As the ethanol concentration or pH is changed, different protein fractions are obtained. Removal of ethanol is by freeze-drying or ultrafiltration.

Chromatographic techniques were introduced in the 1960s through 1980s. One use was to isolate cryoprecipitates that were recovered using continuous centrifugation, with the precipitate recovered from the bowls and frozen at  $-30^{\circ}\text{C}$  or colder until processed into Factor VIII. The techniques were also used to increase IgG recovery and remove viruses.

Anion exchange chromatography and affinity chromatography using immobilized heparin or monoclonal antibodies

**Figure 19-1.** Plasma fractionation scheme showing one of the original schemes used by Cohn et al.<sup>6</sup>

(immunoaffinity chromatography) are examples of chromatographic techniques used. Chromatography is capable of improving purity, extracting trace labile proteins, optimizing protein recovery, and removing virus inactivation agents. It is used increasingly for anti-D production.

The principal advantage of the cold-ethanol or Cohn method is that it facilitates large-scale production in batches that can be traced. Ethanol is readily removed, bacterial growth is inhibited throughout the process, and materials are inexpensive. Ethanol's long history has created a comfort level with manufacturers and regulators alike. But it is unsatisfactory for recovery and maintenance of function of some proteins. Thus, the various newer chromatographic techniques have been essential for the field to move forward. The advantages of these techniques are selectivity and high yield. The disadvantages are the requirements for larger processing volume for the dilute proteins, potential for bacterial growth during processing, inability to handle high lipid content (degrading of the columns), and lost ligand from the columns (leaching).<sup>4</sup>

**Table 19-4.** Cohn Fractionation Method and Distribution of Plasma Proteins

| Fraction | % Ethanol | pH  | Proteins                                                                                                                                      |

### Factor VIII and von Willebrand Factor

The initial step in the production of antihemophilic factor or Factor VIII is cryoprecipitation. When the frozen plasma is thawed rapidly at 4°C, certain proteins are not dissolved, thus forming the precipitate that contains 50% or more of the Factor VIII in the original unit. Before extensive use of Factor VIII concentrates, this cryoprecipitate (when dissolved in a small amount of saline or plasma) was used as a blood bank component for therapy. It has the advantage of a very high concentration of the coagulation factor.<sup>9</sup>

Further purification, as shown in Fig 19-3, leads to the Factor VIII concentrate. The cryoprecipitate is typically subjected to a combination of aluminum hydroxide adsorption and precipitation or precipitation using glycine. This further removes traces of the other coagulation factors, particularly fibrinogen, which is also concentrated (40% of the starting fibrinogen in the cryoprecipitate). At this stage, the product contains all multimers marking the Factor VIII:Ag and the von Willebrand factor (vWF). It can be used to treat von Willebrand disease when desmopressin (DDAVP) treatment alone is ineffective or contraindicated or to manage acquired Factor VIII deficiency especially involving antibodies against Factor VIII (see Chapter 28).

In the late 1980s, further purification steps were introduced using the immunoaffinity technique and monoclonal antibodies. These methods led to a highly purified Factor VIII concentrate (without vWF) with a specific activity of 100 to 250 IU/mg of protein. This product is not suitable for treatment of von Willebrand disease, but is effective in patients with hemophilia A.

### Fibrinogen

Fibrinogen is prepared through the use of multiple plasma or cryoprecipitate precipitation steps using ethanol or glycine or is purified by further steps from fibronectin. Fibrinogen is mainly used in massive blood losses after severe trauma, obstetric complications with bleeding, tumors with disseminated intravascular coagulation (DIC), or lack of fibrinogen production because of liver disease (see Chapter 24). Currently, fibrinogen is not

**Figure 19-2.** A simplified plasma fractionation scheme showing progression of plasma to produce the primary products. vWF = von Willebrand factor; EtOH = ethanol; IM = intramuscular; SC = subcutaneous.

**Figure 19-3.** A sample fractionation scheme to produce a pasteurized Factor VIII concentrate beginning with cryoprecipitation.

available in the United States but is available in Europe as a licensed product.

### Fibrin Sealants

Fibrin sealants (glues) are thrombin-fibrinogen concentrates and are used topically to induce hemostasis, sealing, and healing. The fibrinogen comes from Cohn Fraction I or cryoprecipitate and generally is formulated to contain fibronectin, vWF, plasminogen, and/or Factor XIII. It is used increasingly in release systems for antibiotics, growth factor, and cytostatic medications.

### Prothrombin Complex and Other Clotting Factors

Initially developed as a mixture of vitamin-K-dependent factors (Factor II, VII, IX, and X), prothrombin complex concentrate is formulated by adsorption to anion exchangers. The final product contains heparin to avoid activation of clotting factors. In addition, some concentrates contain small amounts of antithrombin. In the late 1980s, purified Factor IX products were developed. The production process uses advanced biotechnology consisting of immunoaffinity chromatography that precisely targets and separates the Factor IX protein through the use of specific monoclonal antibodies. Similar processes have been used to purify

Factor VII, XI, and XIII. Factor XIII is used increasingly for patients with wound healing problems or with congenital disorders causing vascular diathesis or collagen defects. Factor VII and XI are not in widespread use. The Factor II-VII-IX-X complex product has been purified to reduce thrombogenic potential. It is now available in Europe and is undergoing clinical trials in the United States for reversing warfarin anticoagulation and treating liver disease.

### Antithrombin

Antithrombin (AT) concentrates are extracted from the 8% ethanol supernatant of cryoprecipitate-reduced plasma by affinity chromatography and adsorption in batch procedures. Other proteins are removed by washing with complex-forming solutions. The AT is then eluted, stabilized by saccharose and glycine, and pasteurized.

Inherited AT deficiency is associated with an increased risk of thromboembolic events. Prophylactic AT therapy is given to such adult patients typically during surgery or childbirth or to newborn infants during the perinatal period. The aim of treatment is to achieve AT activity of at least 80%.

Acquired AT deficiency can result from an increased consumption of AT such as with DIC or sepsis, reduced production

of AT associated with liver disorders, or an increased loss of AT seen in burn injuries and multiple trauma injuries. The usefulness of this concentrate in acquired AT deficiency has been challenged recently.<sup>10</sup>

### **Alpha<sub>1</sub>-Proteinase Inhibitor**

This product (also known as alpha<sub>1</sub>-antitrypsin inhibitor) can be isolated from Fraction IV by polyethylene glycol (PEG) precipitation and ion exchange chromatography or from supernatant Fraction II + III, where its extraction competes with albumin. It is used for patients with an inherited deficiency of the inhibitor that results in severe emphysema and liver disease. A recent study has shown that large-scale manufacturing results in structural heterogeneity among the products, but there was no demonstrated impact on therapeutic efficacy.<sup>11</sup>

### **Protein C**

The dominant concentrate of protein C in the United States is produced by recombinant technology in established human cells and activated by transfer into bovine cells. Its main function is the downregulation of the clotting cascade by splitting of the clotting Factors VIIa and Va.

### **C1-Esterase Inhibitor**

This component is collected from cryoprecipitate-reduced plasma after extraction of Factors II, VII, IX, and X and purified by different precipitation and filtration steps. Individuals lacking this inhibitor are subject to hereditary angioedema.

### **Immunoglobulins**

Immunoglobulin products, covered in more detail in Chapter 18, are obtained from the 25% ethanol fraction. Human immunoglobulin for intravenous and subcutaneous administration is indicated for immunodeficiencies and a variety of other conditions. The manufacturing process begins with dissolution of Fraction II/III in glycine followed by precipitation of accompanying proteins and inactivation of viruses. After addition of dicalite via multilayer filters, further purification steps to improve recovery are employed. Total chromatographic procedures are used for specific immunoglobulin preparations such as Rh Immune Globulin (RhIG).

Special immunoglobulins [hyperimmune globulins against cytomegalovirus, rabies, hepatitis A virus (HAV), hepatitis B virus (HBV), tetanus, varicella] are liquid preparations for intramuscular injection that contain a standardized amount of antibody to the specific infectious agent. The Source Plasma comes from either 1) donors screened for the specific antibodies with the relevant donations sorted and stored for a special fractionation pool or 2) compensated donors who have been immunized with specific commercially available antigens (vaccines). The latter is now the more common method and is termed hyperimmunization. It can achieve exceptionally high antibody levels for collection of what is termed "hyperimmune plasma," especially if the vaccine labeling permits frequent vaccination. Hyperimmune plasma is then added together in one fractionation pool for

production. These immunoglobulins are used in the treatment of patients at high risk but without adequate immunity for one of the above-mentioned infections. For example, rabies immune globulin treatments are lifesaving for a person bitten by a rabid animal who had not received the rabies vaccine. The immune globulin provides protective antibody before the individual completes the series of vaccinations that will provide this immunity.

Anti-D or RhIG is obtained from plasma from individuals sensitized to the D antigen or volunteers injected with specially matched and screened Rh-positive red cells. RhIG is used to treat Rh-negative females who through transfusion or pregnancy may acquire Rh antibodies that might harm future children by causing hemolytic disease of the fetus and newborn (see Chapters 26 and 27).

### **Albumin**

The Cohn cold-ethanol procedure was originally designed to prepare albumin. With depth filtration, relatively high-concentration and high-purification albumin is obtained. Nevertheless, some methods use ion exchange chromatography, anion exchange, cation exchange, and size exclusion chromatography as well. Concentration is adjusted by ultrafiltration.

Albumin represents two-thirds of the proteins in plasma. Albumin deficiency, seen in renal disease with increased protein loss and in liver disease with decreased protein production, leads to edema and circulatory issues because of diminished oncotic pressure in the circulation. Thermal injury also leads to loss of albumin. Current indications for albumin administration are discussed in Chapters 20 and 39.

### **Virus Inactivation/Removal**

Following the appearance of human immunodeficiency virus (HIV) transmission by transfusion of blood components and plasma derivatives, a major portion of scientific activity in the plasma industry has been directed at either inactivation (such as pasteurization developed by Norbert Heimburger<sup>12</sup> or solvent/detergent treatment developed by Bernard Horowitz<sup>13</sup>) or removal of viruses to ensure product safety. By 1994, the industry had largely achieved this goal, as indicated by the absence of disease transmission of hepatitis or HIV by any product manufactured by American or European biological producers. In fact, no antihemophilic product has transmitted disease since 1987. After the introduction of second-generation hepatitis C virus (HCV) antibody testing, the resulting loss of protection from the antibody in immune globulin products led to transmission of HCV. The introduction of dedicated virus-inactivation methods into the manufacturing process of IVIG has prevented such transmission from occurring again.<sup>14</sup>

The success of virus inactivation/removal requires not only validation of the reduction in viral load but also maintenance of the intact therapeutic protein. Techniques such as electrophoresis (especially capillary electrophoresis), size exclusion gel chromatography, isoelectric focusing, or antigen/activity ratio are needed. In addition, nonimmunogenicity must be demonstrated

to ensure that neoantigens have not been introduced. Amino acid analysis, cleavage with proteolytic enzymes, circulatory survival in animal models, and measurement of sedimentation and diffusion coefficients, viscosity, circular dichroism, and optical rotary dispersion are used.<sup>15</sup>

Product safety ultimately is achieved by the combination of donor selection, testing of donations and plasma pools, and virus inactivation and removal in the manufacturing process, demonstrated in virus validation studies. The virus validation studies must be performed in dedicated laboratories separate from manufacturing facilities so as not to contaminate the production facility. A process step that removes 4 logs or more of virus is considered effective when the process step can be reliably performed and is insensitive to modifications within the specifications of the manufacturing process.

Viruses chosen for validation studies should closely resemble the viruses that may potentially be present in contaminated plasma, ie, transfusion-relevant viruses. To test the ability of the production process to remove viruses in general, they should also represent a wide range of physicochemical properties. For these studies, strains of viruses should be chosen that replicate to high titers in cell culture and can be assayed in an effective, sensitive, and reliable manner in in-vitro infectivity assays. Routine infectivity assays are currently not available for HBV, HCV, or parvovirus B19. A research infectivity assay for parvovirus B19 has been established in different laboratories and parvovirus neutralization during manufacturing has recently been reported.<sup>16</sup> Consequently, these actual viruses cannot be used for virus validation studies and, where appropriate, model viruses are used instead.

Virus validation studies should be performed with HIV and HAV as relevant viruses. For those blood-borne viruses that cannot be propagated in cell culture systems, model viruses must be used. Model viruses for HCV include, for example, bovine viral diarrhea virus (a flavivirus) or Sindbis virus (a togavirus). A specific model virus for HBV is not available; therefore, nonspecific model viruses must be used such as herpesviruses, pseudorabies virus, or, potentially, duck HBV. A wide range of viruses must be used in virus validation studies. For parvovirus B19, currently only experimental cell culture systems are available; therefore, animal parvoviruses (canine or porcine parvoviruses) are used as model viruses. In case of interaction of human immunoglobulins with viruses used in virus validation studies, the use of model viruses may be essential: HAV can be replaced by porcine or bovine enteroviruses or encephalomyocarditis virus.

The virus reduction factor is determined as the difference of the virus load (virus titer  $\times$  volume) in the spiked starting material and in the final sample. In order to demonstrate a high virus reduction factor, it is often appropriate to detect low virus concentration, ie, the largest practical sample size should be evaluated for residual virus infectivity. However, the impact of potential cytotoxicity or interference of test matrix (composition of product intermediate) on the accurate determination of a virus titer has to be evaluated and taken into account in the calculation of the virus reduction factor.

In virus validation studies, selected steps (stages) of the manufacturing process are employed to assess how effectively they could remove a range of viruses. These experiments are based on a scaled-down version of the purification process, which is validated to mimic closely the production-scale manufacturing process. Virus validation studies are performed by deliberately adding cell-culture-derived stocks of either blood-borne viruses, or appropriately selected model viruses, to product intermediates derived from actual production lots. The amount of virus infectivity removed or inactivated by the stage or subsequent stages of the manufacturing procedure was demonstrated in virus validation studies. The extent of virus removal/inactivation at each individual stage or combination of stages of the production process should be tested at least twice, independently. The results of the virus validation studies (in scaled-down procedures) are predictive for production scale, as the laboratory scale was validated with regard to the comparability of the laboratory scale (model) and full scale (manufacturing), demonstrated in scaled-down validation studies. The use of a wide range of viruses in these validation studies also provides indirect evidence that the production process can inactivate or remove any novel or unpredictable virus contamination effectively.

In addition to providing an accurate reflection of the full-scale manufacturing procedure, scaled-down versions of the production process are also used in so-called “robustness” studies. These robustness studies evaluate the production parameters that may have an influence on virus inactivation and/or removal. These include parameters such as concentration of protein and other components such as precipitating agents, temperature, pH, reaction time, amount of stabilizer, temperature for the pasteurization step, and the amount of solvent or detergent in solvent/detergent (SD) treatments. Furthermore, for chromatographic steps, protein concentration, flow rate, washing and elution volume, and resin reuse should be assessed. These robustness studies are performed in the laboratory using parameters in the range of, or even beyond the specifications for, routine production, and assess the impact of these extreme production parameters on the effectiveness of virus reduction steps.

When inactivation processes are validated, the rate of inactivation and the shape of the inactivation curves are assessed. For virus removal, the mass balance of virus infectivity in the starting material vs virus infectivity in the final sample and the final fractions has to be established.

Virus reduction or clearance is achieved during the manufacturing process by removal of viruses. This is accomplished by manufacturing steps designed to purify and concentrate the desired protein, dedicated virus filtration steps, and inactivation of viruses. The inactivation of viruses uses dedicated steps introduced into the manufacturing process.

## Virus Inactivation

### Pasteurization

Albumin solutions are heated as a liquid at 60°C for 10 to 11 hours in the final containers. Low concentrations of sodium

caprylate alone or with N-actyl tryptophan are added before sterile filtration and filling to prevent albumin denaturation. The safety of the method has been demonstrated for decades, although there is partition of virus during the ethanol fractionation that contributes to the removal of viruses and, therefore, to the overall virus safety.

It was known that most proteins denature when heated in solution to 60°C, a fact that explains the reluctance to apply this method to coagulation factors and other derivatives. But it is possible to pasteurize Factor VIII concentrates in the presence of high concentrations of glycine and sucrose or selected salts. This approach was developed by Heimburger in the late 1970s, resulting in a Factor VIII/vWF product with no proven cases of virus transmissions in more than 25 years. All parts of the tank must be heated equally to provide constant temperature in the aqueous solution. The impact of stabilizers and temperature on the virus inactivation capacity for a wide range of viruses must be validated. Data demonstrate the effective inactivation of a wide range of viruses of diverse physical and chemical characteristics. Enveloped and nonenveloped viruses are inactivated by pasteurization even in stabilized solution.<sup>17</sup>

### **Dry Heat**

After lyophilization of proteins (in the final container) to remove water, heating at 80°C for 72 hours or 100°C for 30 minutes is also an effective virus inactivation step. Residual moisture interferes with the success of this method; the inactivation of some viruses was greater at higher residual moisture but under such conditions the stability of the product was reduced. Thus, the residual moisture has to be controlled in each vial to remain between predefined limits demonstrated in validation studies.<sup>18</sup>

### **Vapor Heat**

Lyophilized (intermediate) products are heated at defined (relatively high) residual moisture—for eg, 60°C for 10 hours followed by 80°C for 1 hour. Low residual moisture levels of dry heat treatment do not interfere with the success of this method because the product intermediate is further processed to the final product.

### **Solvent/Detergent Treatment**

Organic SD treatment works by disrupting the lipid membrane of enveloped viruses, rendering them unable to bind to and infect cells. This method is not effective against nonenveloped viruses. An example of conditions used for virus inactivation is: 0.3% tri(n-butyl) phosphate (TNBP) and 1% ionic detergent (usually either Tween 80 or Triton X-100) at approximately 24°C for 4 hours (with Triton X-100) or 6 hours (with Tween 80). It is even possible to treat some preparations at 4°C. Product intermediate has to be filtered to eliminate virus trapped in gross aggregates. Stirring through the process is used to ensure homogeneity. Every droplet containing virus must be treated; solutions

are often transferred from one tank to another to ensure that material on the lid or surface of the first tank is subject to the treatment. At the end of the process, the SD mixture is removed by extraction with 5% vegetable oil, adsorption chromatography, or absorption on C-18 hydrophobic resin. This method has been very successful in inactivating HIV, HBV, and HCV. In virus validation studies, the key process variables such as concentration of the solvent and detergent compounds, the temperature, and incubation time as well as the impact of potential lipid content in the product intermediate (because this interferes with the availability of the SD compounds for virus inactivation), have to be covered.<sup>19</sup>

### **Low pH**

Immune globulins prepared at pH 4 will benefit from inactivation of many enveloped viruses. In general, the use of low pH cannot be relied upon and is adjunctive to other techniques.

### **Virus Removal by Methods for Protein Purification and Concentration**

Precipitation of proteins (ie, the precipitation of impurities or the protein of interest) results in the retention of the protein of interest or the impurities in solution. Most often the precipitate is removed or collected by depth filtration or centrifugation. Because the precipitation conditions are designed to purify/concentrate the protein of interest, these partitioning steps often remove only a small range of different viruses. Careful virus validation studies are required to assess the reliable contribution of such precipitation steps to the overall virus reduction for a final product.

### **Ethanol Precipitation**

Precipitation with ethanol (Fig 19-4) does have disinfectant properties, but minimally at the low temperatures typically used in plasma fractionation. Therefore, it provides little inactivation but it can partially separate virus from protein, leading to partitioning through precipitation. This was largely successful in ensuring the safety of immune globulin products along with the neutralization benefits of the antibody present.<sup>20</sup>

Comparable principles related to ethanol precipitation steps apply to other precipitation principles such as PEG precipitation, glycine and NaCl precipitation, or ammonium sulfate precipitation. Precipitation by octanoic acid adds another factor to precipitation steps, as octanoic acid inactivates enveloped viruses.

### **Chromatography**

Chromatography, such as ion exchange or hydrophobic interaction chromatography, can remove viruses, especially when the flow-through of a column is discarded (Fig 19-5). A further development of this concept is affinity chromatography whereby the protein of interest remains on the column even after washing and is eluted under defined conditions. Specially selected affinity chromatography (eg, monoclonal antibody

**Figure 19-4.** A diagram of virus removal by ethanol.

**Figure 19-5.** A diagram of virus removal by chromatography.

affinity chromatography for Factor VIII purification) results in a highly purified product from which much of the virus has been removed. When the resin of the chromatography column is reused, efficient sanitization of resins (and column parts) is a necessary step to avoid batch-to-batch contamination.

## Virus Removal by Dedicated Manufacturing Steps

### Virus Filtration

The measures of ethanol precipitation and chromatography explain why some derivatives have less viral contamination than others. Virus filtration, formerly called nanofiltration (Fig 19-6), is specifically designed to remove virus. It does so by removing virus based on size while allowing flow-through of the desired protein. Large protein molecules or easily aggregated proteins pose a challenge for this method. But virus filtration is a complex process. The success depends potentially not only on pore size but also on adsorption of the virus to the filter surface and removal of virus aggregated by inclusion in antigen-antibody or lipid complexes. Virus filtration is gentle, but appropriate testing must ensure that shear forces are not damaging the proteins.

Besides the established virus reduction factors discussed above, research into methods as irradiation and nucleic acid

intercalating substances is ongoing. The suitability of these inactivation methods with respect to modification of proteins has still to be demonstrated.

In order to achieve virus-safe plasma-derived products, effective virus reduction steps inherent in the manufacturing process are essential. Often two distinct effective virus reduction methods are implemented that complement each other in their mode of action. If for one manufacturing step a gap is demonstrated in the virus reduction capacity for a range of viruses, a second step covering that gap has to be introduced into the manufacturing process, eg, dry heat treatment or virus filtration for the reduction of nonenveloped viruses together with SD treatment. If one virus reduction step is effective for a wide range of viruses including enveloped and nonenveloped viruses, the manufacturing process of a plasma-derived product has to contain further steps which reliably (but not necessarily effectively) contribute to the overall virus reduction (according to the European guideline).

### Prions

Prions, the causative agents of human neurodegenerative diseases such as Creutzfeldt-Jakob disease (CJD) and variant CJD, cannot

**Figure 19-6.** A diagram of virus removal by size exclusion.

be inactivated under production conditions for plasma-derived products. However, manufacturing processes of plasma-derived products are able to reduce transmissible spongiform encephalopathy infectivity, if it were in plasma, as assessed by the FDA and European regulatory agencies.<sup>21–23</sup>

### Assessment of Final Product

In general, it is not possible to test the final product for viral markers; such tests are not reliable and difficult to interpret. Also testing of final products by nucleic acid amplification testing (NAT) methods such as polymerase chain reaction is not suitable to demonstrate a safe product due to statistical methods of sampling (Poisson distribution); furthermore, NAT detects genomic sequences and not infectivity of a virus. This indicates the importance of the validation and the quality control of the manufacturing process.

The final product must be assessed to ensure virus reduction and intact product. Virus reduction is ensured by confirmation that the conditions validated for the process were rigidly adhered to and that opportunities for cross-contamination and recontamination have been prevented. This is particularly important in virus inactivation; there is less opportunity for this to occur with terminal virus inactivation such as the pasteurization of albumin. Regulatory authorities often require an assessment of virus safety. A probabilistic method is one that has recently been proposed and presented in some detail.<sup>24</sup>

Final product characterization is used to demonstrate that the therapeutic protein is present and intact. Total protein and pH assays are applied to all products, and tests for moisture and solubility are used for lyophilized products. Albumin is tested for protein composition and molecular size distribution; immune globulins are tested for IgG content, molecular size distribution, and potency of antibody reactivity; and in the case of intravenous and subcutaneous preparations, anti-complementary activity and clotting factor concentrates are tested for the activity of the specific clotting factor.

## Industry Safety Programs

### Regulatory Agencies

The major regulatory authorities for the global plasma industry are the FDA in the United States; the European Medicines Agency in Europe; the German Health Authorities and the Paul Ehrlich Institute in Germany; the Medicine and Healthcare Products Regulatory Agency in the UK; the Ministry of Health, Labor and Welfare in Japan; and the Therapeutic Goods Agency in Australia. Inspections must be carried out according to the national legislation as well as the Pharmaceutical Inspection Convention “GMP Guide for Blood Establishments for Whole Blood (Recovered Plasma)”<sup>25</sup> and “Guide to Inspections of Source Plasma Establishments and Plasma Warehouses”.<sup>26</sup>

### Voluntary Industry Standards

To assist with the regulatory and safety burdens, the Plasma Protein Therapeutics Association (PPTA), the industry trade group, has a certification program for collectors (International Quality Plasma Program or IQPP) and manufacturers (QSEAL). Table 19-5 shows the IQPP program and Table 19-6 shows the QSEAL program.

Donors must live in a set radius of the center (ie, not be transient or homeless). The PPTA in the United States maintains a national registry of donors who have been deferred for positive viral marker tests. That registry is checked for all new donors. Each donor is considered an applicant until the second donation is made and the test results from the first two donations are both acceptable. If the donor does not return, the unit is considered an “orphan” and cannot be used for injectable product. Viral marker results for the qualified donors (those who have passed applicant status) from a given center must be below a set level based on statistical analysis for the center to supply injectable product. Thus, the pillars of safety include: 1) selection including the donor questionnaire, collection activity, plasma testing for serology and NAT for HIV, HAV, HBV, HCV, and parvovirus B19, 2) the inventory hold to ensure no new information that

## Recombinant Deoxyribonucleic Acid Technology and the Manufacture of Plasma Derivatives

Genetic engineering has been used to isolate specific genes of human origin responsible for the production of distinct proteins. Transfer of these nucleic acid strands into cell culture systems and microorganisms has resulted in the economic production of the desired proteins. The derivatives produced by recombinant deoxyribonucleic acid (rDNA) technology that are in clinical use include Factor VIII, Factor IX, and Factor VIIa.

The process begins with a library of DNA sequences complementary to the messenger ribonucleic acid in a given tissue. Antigenic identification (using monoclonal antibodies raised against purified plasma protein) or hybridization (using oligonucleotide probes derived from amino acid sequences of the protein of interest) is used to create the specific complementary DNA.<sup>28</sup>

Currently two biologically active, full-length recombinant and one B-domain-restricted Factor VIII products are on the market after extensive clinical testing. More recently, B-domain-deleted recombinant Factor VIII has become available for clinical use.<sup>20</sup> In addition, a newly licensed recombinant Factor VIII grown in Chinese hamster ovary cells is free of any human or animal material. The in-vivo recovery and half-life are similar to those of plasma-derived Factor VIII.

The products are effective in preventing and treating hemorrhagic episodes in patients with hemophilia A.<sup>29,30</sup> The application of rDNA technology has led to the cloning and expression of other important plasma proteins, some of which (eg, Factor IX) are used routinely while others are still undergoing clinical evaluation.

## Summary and Outlook

The plasma industry exists in the interface between blood transfusion and pharmaceuticals. Some of its products could be replaced by recombinant products. The economics of the industry require fractionation of clotting factor concentrates from each liter. The products have become more costly, but the safety has been significantly enhanced. The cost has created challenges for patients, health insurance plans, and governments that purchase the products; thus, these products are much less available in developing countries.

There always remains the potential of finding a new therapeutic product in plasma. For example, a substance from plasma (apolipoprotein A-1) that increases HDL (good cholesterol) is now in clinical trials and could significantly affect the prevention of heart disease.<sup>31</sup>

Growth in the plasma industry worldwide is expected to continue as more products are brought to more patients. It is hoped that the major enhancement to public health seen with the near elimination of hemolytic disease of the fetus and newborn due to RhIG can be repeated for more and more patients in the years ahead.

## Acknowledgments

Tables 19-1, 19-3, and 19-4 and Fig 19-1 were reproduced from the chapter by W.G. Van Aken in the previous edition of this book. The authors of the current chapter appreciate the strong foundation provided in the earlier work.

Plasma is the aqueous component of blood in which many different cellular elements and macromolecules are suspended, but it is the proteins that have been the focus of interest for transfusion medicine, including specifically albumin, coagulation factors, and immunoglobulins. This chapter discusses clinical use of the first two groups, with a main focus on levels of evidence for effectiveness of Fresh Frozen Plasma (FFP). Related material is found in Chapters 17 and 38 through 40.

---

**Frozen Plasma and Fresh Frozen Plasma**

Plasma for transfusion can be obtained through centrifugation of whole blood or through the use of plasmapheresis. It can be stored frozen as whole plasma or used to produce more purified constituents, including concentrates of coagulation factors and fibrin sealant, immunoglobulins (normal or specific, eg, Rh Immune Globulin), anticoagulants (eg, antithrombin, protein C), complement-related proteins (C1-esterase inhibitor), and albumin.

Fresh Frozen Plasma is human donor plasma frozen within a short specified period after collection (often 8 hours) and then stored at a defined temperature, typically  $-30^{\circ}\text{C}$ . Plasma frozen at slightly later intervals (typically up to 24 hours) after collection is referred to as Frozen Plasma (FP) or Plasma Frozen within 24 Hours after Phlebotomy (FP24). Levels of the labile coagulation Factors V and VIII are slightly lower in FP in comparison to FFP, but both components are usually considered clinically equivalent. For the purposes of this chapter the two components are covered (interchangeably) using the common term FP, unless otherwise stated. However, the marginally lower levels for some

coagulation factors in FP24 may be clinically important—for example, in the context of transfusions to small neonates.

After thawing for transfusion, FP contains near normal levels of most plasma proteins, including procoagulant and inhibitory components of the coagulation system, acute phase proteins, immunoglobulins, and albumin, although all levels will be further diluted by citrate anticoagulant solution. Factor VIII is typically the only plasma protein whose level is quality-controlled to meet component specifications as required by guidelines in the United Kingdom (UK)<sup>1</sup> and European Union (EU) [but not in the United States by the Food and Drug Administration (FDA) or the AABB]; this threshold needs to be met for a proportion of units (typically 75%).

Coagulation factor content is well maintained in thawed FFP up to 5 days but with evidence of a decrease in Factor V and VIII. However, recommendations in many countries limit use to a defined shorter period after thawing. For example, current guidelines in the UK indicate that plasma may be used up to 24 hours after thawing. A typical unit of plasma derived from a collection of whole blood has a volume of just under 300 mL, and local and national guidelines for usage generally specify a dose of around 10 to 20 mL/kg.

The composition of FP can be influenced by many factors. These would include gender, age, and genetic, dietary, and other environmental factors, all potentially modifying levels of individual proteins. The composition of collected plasma would also be affected by the processing procedure, including how quickly the plasma is collected and then stored. Although clinicians tend to assume approximate equivalence in clinical effectiveness between individual units of FP, it is likely that there is heterogeneity. This variation reflects not only the biological differences in constituents between donors [eg, von Willebrand factor (vWF) and Factor VIII levels, being ABO dependent], but also differences in processing, storage, and preparation for administration. Such variation might be expected to be less marked for pooled plasma components such as solvent/detergent-treated FP.

Figure 20-1 shows data for procoagulant factor content from 66 FFP units.<sup>2,3</sup>

Which Patients Receive Frozen Plasma?

Clinical use of FP has grown steadily over the past two decades in many countries. Moreover, there is evidence of variation in usage both within and between countries. In a comparison of FP use in five countries, the ratio of FP units to Red Blood Cell (RBC) units transfused varied from 1:3.6 in the United States to 1:8.5 in France.<sup>4</sup> Two studies have reported a wide variation in the use of

**Figure 20-1.** A “box-and-whisker” plot for the 25th and 75th percentiles, with median and error bars as range, for normal plasma (leukocyte-reduced FFP).

FP among facilities within the same country for patients undergoing cardiac surgery<sup>5,6</sup> and critical care patients.<sup>6</sup> In the latter study, lower use of FP in critical care patients did not correlate with lower use in cardiac surgery patients, which suggests that important variation in FP use within hospitals also exists.<sup>6</sup>

FP is given primarily for two indications: to prevent bleeding (prophylaxis) or stop bleeding (therapeutic). Prophylactic transfusions, which may account for over 50% of all FP transfusions, are largely given before surgery or an invasive procedure.<sup>7</sup> In a subset of Finnish hospitals, over 6000 FP units were tracked to 1159 transfused patients, revealing that FP was transfused most often to surgery patients, especially cardiac patients.<sup>8</sup> This is consistent with reports of FP transfusions in other countries.<sup>9-12</sup> Likewise, in the UK, data from an epidemiology study (EASTR) indicated that most FFP is used for patients with general medicine, liver disease/gastroenterology, and hematology conditions, as well as cardiothoracic, oral, general, and neurosurgery patients (C. Llewelyn, personal communication). Critical care patients also appear to make up the other large recipient group for FP transfusions<sup>10,12</sup> although this group may overlap with surgical patients in some surveys. Local audits in many countries additionally identify other recipients of FP as including patients requiring reversal of warfarin effect, or patients with disseminated intravascular coagulation (DIC), massive transfusion, or thrombotic thrombocytopenic purpura (TTP).

Further information on FP use in the UK, United States (US), and Australia is summarized in Tables 20-1 and 20-2. Table 20-1 describes studies that reported on the indications for FP

### The Side Effects of Frozen Plasma

Crucial to recommendations in guidelines for FFP transfusion practice is the need for a clear understanding of the risk of harm. FP is not without risk, and indeed may be among the most “high risk” of all blood components.<sup>14,15</sup> The most immediate serious complication of FP is transfusion-related acute lung injury (TRALI), although there are ongoing issues of reporting and diagnosis of this condition, which make accurate estimation of prevalence difficult.<sup>16,17</sup> Other risks are transfusion-transmitted infection, including an unquantifiable risk of prion disease, and fluid overload, which may be a greater issue if larger doses of FP are transfused to attempt (full) reversal of abnormal coagulation tests (discussed later). These risks related to circulatory overload are poorly understood, but could be important for critically ill patients, for example those in the intensive care unit (ICU). Allergic reactions to FP are relatively common, with a frequency of around 1% to 3% of all transfusions, and can be extremely troublesome, or rarely, life threatening, for some multitransfused patients. In the UK, an association between cases of TRALI and female donors has been identified through the Serious Hazards of Transfusion hemovigilance system and male donors are now used as much as possible for production of FFP.<sup>18</sup> In the United States, the AABB has recommended that blood collecting facilities should implement interventions to minimize the preparation of high plasma-volume components from donors known to be leukocyte-alloimmunized or at increased risk of leukocyte alloimmunization.<sup>19</sup>

Understanding the risks of FP transfusion is important when physicians consider the use of FP as prophylaxis, which as stated is a common indication for FP in clinical practice. A prophylactic policy should be justified only if the risk of bleeding is greater than the risk of harmful effects. Without evidence of benefit, such a policy aimed at preventing (uncommon) bleeding

complications could involve transfusing (harmful) FP to a large number of patients, many of whom might not bleed even if prophylactic FP were not given.

### Summary of Recommendations from Guidelines for the Use of Frozen Plasma

Recommendations for the transfusion of FP have remained relatively consistent over the years for the transfusion of FFP, including: 1) active bleeding, or before surgery or an invasive procedure in patients (adults and neonates) with acquired deficiencies of one or more coagulation factors as demonstrated by an increased international normalized ratio (INR), prothrombin time (PT), or activated partial thromboplastin time (aPTT), when no alternative therapies are available or appropriate; 2) immediate correction of vitamin K deficiency or reversal of warfarin effect in a patient with active bleeding, or before surgery or an invasive procedure (in conjunction with use of prothrombin complex concentrates); 3) DIC or consumptive coagulopathy with active bleeding; 4) TTP; and 5) active bleeding, or before surgery or an invasive procedure in patients with a congenital factor deficiency when no alternative therapies are available or appropriate. Variations of these indications will be found in most national guidelines.<sup>20-25</sup>

Previous common uses of FFP that are now considered inappropriate include: volume replacement, correction of hypoalbuminemia, nutritional support, and immunoglobulin replacement.

### Evidence for Indications

It is important to identify whether the *presumed* benefits of FP really outweigh the *real* risks. The clearest evidence for a direct beneficial effect of FP would be expected to come from randomized controlled trials (RCTs) of FP compared with no FP/plasma. Studies of interventions comparing FP with a non-blood product (eg, solutions of colloids and/or crystalloids) may also assess effectiveness, but these studies would need to be separately evaluated given that these solutions have variable effects on in-vivo or in-vitro coagulation.<sup>26</sup>

Of a total of 57 RCTs published through 2004 on the use of FP, only 17 compared FP to no FP or a colloid/crystalloid solution in adults.<sup>27</sup> Many studies enrolled small numbers of patients, and provided inadequate information on the ability of the trial to detect, without bias, meaningful differences in outcomes between the two patient groups. When considering all RCTs evaluating prophylactic usage across a range of settings (including cardiac, neonatal, and other clinical conditions) as a group, the overall findings failed to document evidence for the effectiveness of prophylactic FP, for a range of clinical and laboratory outcomes.

In two large, well-conducted trials,<sup>28,29</sup> evidence for a lack of benefit for prophylactic use of FP was reported. Both studies were designed to evaluate carefully the effectiveness of FP in a large group of patients, and provided information about the sample sizes required to allow adequate power to detect clinically important differences between the groups of patients. In

\* Not including cardiac and orthopedic surgery

the first trial, the Northern Neonatal Nursing Initiative (NNNI) Trial Group randomly assigned 776 neonates to receive FP or volume expanders (gelofusin or dextrose-saline); results did not show any differences in the prevention of intraventricular hemorrhage.<sup>28</sup> Allocation concealment and blinding of outcome assessors (to monitor clinically relevant long-term developmental outcomes) was reported. Of note, the study did not include measurement of coagulation tests. In the other trial, the effectiveness of FP was evaluated in patients with acute pancreatitis.<sup>29</sup> In total, 275 patients were randomly assigned to receive either FP or a colloid solution. No evidence for benefit was reported.

In summary, this review of the RCT literature raises important questions about current levels of evidence to support use of FP in clinical practice, including in particular prophylactic use where evidence for a beneficial effect is weak. Specific information from RCTs and observational studies about additional selected clinical groups is discussed below.

### Cardiac Surgery

Epidemiologic evidence indicates that FP given before or during cardiac surgery accounts for approximately 5% to 10% of all use,<sup>10,12</sup> and a number of published RCTs have assessed benefit. However, RCTs comparing prophylactic use of FP to either no FP or a non-plasma product after cardiopulmonary bypass have not shown evidence of a consistent significant beneficial effect on blood loss or transfusion requirements.<sup>27</sup> A meta-analysis of the results from these trials has also failed to establish evidence for any benefit.<sup>30</sup> The hemostatic changes related to cardiac bypass are multifactorial, and not solely related to coagulation factor deficiency; thus, it is not surprising that prophylactic FP use fails to provide benefit.<sup>31</sup> Treatment of bleeding associated with abnormalities of coagulation tests after surgery should be treated with FP in the same manner as DIC.

### Massive Transfusion, Trauma, and Disseminated Intravascular Coagulation

Very few trials have evaluated the effects of therapeutic FP in patients with bleeding who have multiple or global deficiencies of coagulation factors (eg, DIC or massive transfusion), presumably in part reflecting the difficulties of trial design in this setting. From a pathophysiologic perspective, use of FP in this setting seems clinically appropriate. One study tried to address the effectiveness of FP use in DIC in a group of neonates, using defined criteria for a diagnosis of DIC.<sup>32</sup> In this small three-way controlled trial, neonates were randomly assigned to receive 1) exchange transfusion using whole blood, 2) FP and platelet infusions, or 3) no plasma (control group). Although there were no differences in rates of improvement for coagulation tests or in survival in either treatment group, the size of the trial was small (a total of 33 patients across three arms).

Bleeding in trauma patients is typically multifactorial, but there is now increasing evidence that early “coagulopathy” is a significant factor associated with poor outcome. Although guidelines for FP transfusion in this scenario frequently support use of

plasma when coagulation tests are documented to be abnormal, there is a risk that this reactive response, coupled with slow turnaround time for obtaining laboratory results and thawing plasma for transfusion, can lead to the development of marked disturbances of coagulation. This might be an example of the risk of undertransfusion of FP, in contrast to much of the emphasis in this chapter on the risks of inappropriate overtransfusion. There is interest in defining the optimal transfusion support for massive transfusion, including the evaluation of the early use of FP in trauma patients.<sup>33</sup> A number of retrospective studies point to improvements in survival for patients with trauma when red cell:plasma ratios of transfusion support are nearer to 1:1.<sup>34</sup> Strategies describing more aggressive use of FFP and platelets have also been reported recently in surgical practice.<sup>35</sup>

### Intensive Care

In the ICU setting, few prospective data exist on the frequency with which FP is given as prophylaxis—eg, before central venous cannulation or other invasive procedures. The use of FP before central venous cannulation is debatable; the evidence would suggest that the rate of important hemorrhagic complications associated with central venous cannulation is very low even in patients with normal or abnormal coagulation test results.<sup>36-39</sup>

Dara et al<sup>40</sup> reported a single-center retrospective cohort study of FP use in medical ICU patients. They identified patients in whom an INR  $\geq 1.5$  was found during ICU stay and evaluated FP use in the subgroup of patients who were not actively bleeding. In addition to variability in FP transfusion practice, the authors observed that patients who received FP had a similar rate of hemorrhage to matched cases, but had a higher incidence of “acute lung injury” during the 48 hours after transfusion (18% vs 4%;  $p = 0.02$ ). This association raises the possibility that critically ill patients, many with concurrent inflammatory problems, may be more susceptible to TRALI after receiving plasma-rich blood components, although distinguishing TRALI from other clinical problems such as volume overload remains problematic. These findings do not prove cause and effect, but again emphasize a need for concern about inappropriate use of FP, in view of the real risk of harm.<sup>16,41</sup>

### Liver Disease

The coagulopathy of liver disease is complex, with abnormalities of platelets, fibrinolysis, and inhibitors of coagulation as well as coagulation factor deficiency. Where possible, deficiency of vitamin K should always be corrected first before considering the role of plasma transfusion. One early RCT<sup>42</sup> attempted to assess the effects of regular prophylactic transfusions of FP in patients with paracetamol overdose. Twenty patients were evaluated and no effects on bleeding, morbidity, and mortality were observed. However, the small size of the study and the crossover design were not optimal for detecting differences between the two groups.

Other studies to investigate FP transfusion practice in patients with liver disease have been uncontrolled and observational.

Youssef et al<sup>43</sup> reported the effects of FP transfusion in 100 patients with liver disease, and found that it was difficult to correct abnormalities of coagulation screening tests unless large volumes of FP were transfused, and that the effects of transfusion were short-lived. Lack of evidence for an association between bleeding and laboratory tests of coagulation in liver disease has also been reported in a number of studies (eg, the retrospective studies of McVay and Toy<sup>44</sup>). Although these studies contain no control group data, there is again a consistent theme of lack of evidence for benefit for FP transfusion in patients with liver disease. Of note, the lack of bleeding in cirrhotic patients despite diminished procoagulant synthesis (and abnormal PT/aPTT) may be explained by a parallel reduction in the production of anticoagulant proteins, such as proteins C and S, leading to equivalent thrombin generation potential on activation of both pro- and anticoagulant pathways.<sup>45</sup>

In summary, guidelines for plasma transfusion typically include the multiple coagulation factor deficiency state of liver disease associated with bleeding or before invasive procedures. However, the number of relevant studies published to support these statements is very limited and it is far from clear just how effective this transfusion policy is. In particular, observational studies evaluating common invasive procedures such as liver biopsy, paracentesis, or central venous cannulation indicate that moderate disturbances of coagulation tests are, in fact, not predictive for bleeding risk.<sup>46,47</sup> Large volumes of FFP appear to be needed to correct abnormalities of coagulation tests, and the effect is short-lived. In addition, as mentioned later, although the PT or INR (and aPTT) are widely employed for patients with liver disease, their clinical validity in this patient group is unproven.

### Reversal of Warfarin Effect

In addition to vitamin K, guidelines recommend FP or prothrombin complex concentrates (PCCs) for reversal of excessive anticoagulation but only in patients with major bleeding.<sup>48</sup> However, there is continuing controversy over which component is preferable; this, in part, reflects a lack of clinical trials directly comparing the two components. PCCs are produced by fractionation of pooled plasma and contain coagulation Factors II, IX, and X at a significantly higher concentration than FP. But not all PCCs are the same and Factor VII levels do vary. In a retrospective single-institution study (n = 41), Makris et al<sup>49</sup> reported that patients receiving PCCs achieved more rapid and complete reversal of abnormalities of coagulation testing than patients receiving FFP. However, the results of this study should be interpreted with some caution because significant differences in baseline coagulation test results existed in the two groups and the authors did not report any bleeding outcomes. Further evaluation is required to ascertain whether the more rapid improvements in coagulation screening tests translate into clinical benefit, without an increased risk of thromboembolic complications. In the absence of major bleeding associated with excessive anticoagulation due to vitamin K antagonists, primary treatment should be initiated with oral or intravenous vitamin K.

### Therapeutic Apheresis—Thrombotic Thrombocytopenic Purpura

FP is frequently used as a replacement fluid in patients undergoing therapeutic apheresis procedures.<sup>50</sup> On the basis of findings from one RCT,<sup>51</sup> plasma exchange with FP is first-line treatment for TTP;<sup>52</sup> the FP providing a source of ADAMTS13. However, definitive randomized studies to define the optimal dose and schedule of FP or type of plasma (eg, cryosupernatant, solvent/detergent-treated) for therapeutic apheresis in patients with TTP have not been undertaken. Of interest, early studies investigating plasma exchange for conditions other than TTP have reported that despite repeated procedures with replacement fluids not containing coagulation factors, no bleeding complications occurred, even though marked reductions of coagulation factor levels were seen.<sup>53</sup>

### Is There an Optimal Dose of Frozen Plasma?

As described in the section on patients with liver disease, there are important questions about the optimal dose of FP, and not infrequently only large volumes achieve correction of coagulation test results. However, questions about appropriate or optimal dose for FP transfusion generally presuppose that evidence of dose-dependent effectiveness exists in the first place. Much of the evidence concerning appropriate dose comes from a derived synthesis of physiologic assessments of coagulation factor content and effects of plasma infusion.<sup>54</sup>

There is evidence that FP may be ineffective in correcting mild-to-moderate abnormalities of coagulation screen tests. Abdel-Wahab et al<sup>55</sup> prospectively evaluated the effects of plasma transfusions on PT/INR in hospital patients with prolonged INRs. They followed patients with a pretransfusion PT between 13.1 seconds and 17 seconds (INR equivalent 1.1-1.85). A total of 324 plasma units were evaluated in 121 patients. Fewer than 1% of patients had normalization of PT/INR following transfusion, and only 15% demonstrated a correction of halfway to normal. Of interest, there was also no meaningful correlation with clinical bleeding, as recorded retrospectively by patient chart review. Finally, when all cases of transfusion were reviewed for correction, there was little evidence for dose-response effect.

In another study,<sup>56</sup> 22 critically ill adult patients were allocated in consecutive groups to receive a lower dose of FP (median volume, 12.2 mL/kg) or a higher dose (median volume, 33.5 mL/kg) with the aim to increase hemostatic coagulation factor levels to >30 IU/dL (based on experience of treating patients with hemophilia). The lower dose increased the coagulation factor levels above the desired threshold in only one of five patients; with the higher dose, all seven patients achieved the target levels. Many patients who received the lower (standard) dose, but not larger dose, of FP failed to achieve the target level of coagulation factor replacement. Another study<sup>57</sup> reported on 103 adult patients with minimally prolonged INRs, and found that adding FP to their treatment failed to change the decrease in INR that occurred over time. When other studies or trials do report apparent “correction,” the overall absolute or mean changes again

appear very small. For example, in one RCT of patients with liver disease, the median reduction in INR attained after FFP was 0.2 (range 0–0.7).<sup>58</sup>

In summary, although the initial dose should be based on patient weight (typically 10–20 mL/kg), an optimal dose for clinical use has not been validated or defined in larger trials. The effectiveness of different doses may also be limited by clinical situation—eg, rapid ongoing consumption of coagulation factors in DIC, or risks of circulatory overload if larger doses are given with the intention of achieving full correction of coagulation screen tests.<sup>17</sup>

It should be appreciated that the outcomes for many studies of plasma, including dose, are laboratory-based, particularly centered around the PT/aPTT. But correlations between these coagulation screen tests and coagulation factor levels are poor and nonlinear, with limitations in expectations of achieving correction, particularly as factor levels approach normal. The laboratory tests of aPTT and PT were developed to investigate coagulation factor deficiencies in patients with a bleeding history by providing an end-assessment of thrombin generation by fibrin formation; therefore, the important issue of their applied clinical validity continues to be raised. The PT and aPTT results may be abnormal for a number of reasons not associated with bleeding risk (eg, the normal variation between individuals).<sup>59</sup> Some laboratories report the INR, and physicians then base decisions to transfuse plasma on results above a certain threshold, typically 1.5 times the control. But again, the INR is based on PT and was developed to monitor warfarin therapy, by standardizing results to account for different sensitivities of thromboplastins. The extrapolation of PT to INR may really be valid only for those patients stably anticoagulated with vitamin K antagonists.<sup>60</sup>

Finally, an important study by Deitcher<sup>61</sup> showed that over the INR range of 1.3 to 1.9 inclusive, mean factor levels ranged from 31% to 65% (Factor II), 40% to 70% (Factor V), and 22% to 60% (Factor VII). All of these levels are consistent with adequate concentrations of factors to support hemostasis. These results would be consistent with the findings from observational studies mentioned earlier, pointing to a lack of predictive effect for bleeding risk in patients with mild/moderate abnormalities of coagulation tests.<sup>47</sup>

### Clinical Effectiveness of Pathogen-Inactivated Plasma

Pathogen reduction has been applied to plasma to reduce the risk of transfusion-transmitted infection. The main methods are methylene-blue treatment, in which single-donor units are treated with methylene blue and light; solvent/detergent treatment in which several thousand plasma donations are pooled before exposure to a solvent and detergent; and amotosalen treatment in which a psoralen (S-59) is added to plasma before exposure to ultraviolet A light. Of these, only solvent/detergent treatment has been licensed by the FDA, and none of these methods are currently widely available in the United States. Although the methods offer good virus protection and can reduce microbial infectivity, it should be noted that these

processes are associated with alteration or loss of coagulation factor content.<sup>62,63</sup> There have also been some suggestions that solvent/detergent-treated FFP may be associated with reduced risk of TRALI, although this has not been confirmed.

Pathogen-inactivated formulations will probably increasingly find their way into clinical practice. In the UK, plasma is now imported from the United States for children and neonates up to the age of 16 because of perceived lower risk of variant Creutzfeldt-Jakob disease transmission. It is pathogen inactivated (methylene-blue treated) because there is a higher background level of viral markers in the US population compared to the UK.

Studies of efficacy comparing pathogen-inactivated products with standard FP have different aims than trials in which FP is compared to no treatment or a placebo.<sup>64</sup> Arguably, assessing the clinical efficacy of these pathogen-inactivated variants of FP is very difficult when evidence of benefit for the standard product is thin, which broadly is the case for use of plasma across many clinical settings. Although newer pathogen-inactivation processes are aimed at reducing the real but low risk of infection transmission, they may paradoxically have altered clinical “effectiveness”—at the cost of marginally increased safety. Solvent/detergent-treated plasma is known to have lower levels of some inhibitors of coagulation (eg, protein S) and there is one case report suggesting an increased incidence of thrombosis in patients with TTP receiving this product compared to standard FP.<sup>65</sup> Transfusion of pathogen-inactivated FP has also been associated with a need for a greater volume in at least one retrospective study,<sup>66</sup> although the reasons for this are unclear.

### Clinical Effectiveness of Cryoprecipitate

Cryoprecipitate represented the first practical preparation of a concentrated form of antihemophilic factor. It is prepared by controlled thawing of frozen plasma to precipitate high-molecular-weight proteins, including Factor VIII, vWF, and fibrinogen. In many developed countries, cryoprecipitate is transfused mainly as a concentrated source of fibrinogen. An adult dose of around 10 single-donor units of cryoprecipitate typically raises the plasma fibrinogen level by up to 1 g/L. The remaining product, following the removal of cryoprecipitate, is termed cryosupernatant (cryoprecipitate-reduced plasma). It has been used in the treatment of TTP, because of the theoretical benefit of its reduced content of vWF high-molecular-weight multimers, although the added benefit of cryosupernatant has not been proven.<sup>67</sup>

However, FP contains fibrinogen at near normal plasma levels, and so will correct low fibrinogen levels in many situations if the volumes for infusion are adequate. Therefore, cryoprecipitate should not be considered for transfusion solely as a more concentrated form of FP (eg, when there are concerns about fluid overload), because it predominantly contains only Factor VIII, vWF, fibronectin, Factor XIII, and fibrinogen. In other words, cryoprecipitate is not a source of all coagulation factors and, therefore, is not appropriate replacement therapy in patients with global coagulation factor deficiencies (eg, with liver disease). Its use should be reserved for patients with documented isolated

hypofibrinogenemia. There are few prospective trial data to define optimal use of cryoprecipitate. There is anecdotal evidence that the use of cryoprecipitate is rising in many countries, although the exact reasons for this remain unclear. Finally, a specific purified fibrinogen concentrate is now available, and it may represent a safer concentrate for direct fibrinogen replacement in isolated deficiencies (eg, inherited hypofibrinogenemia). However, this product is not licensed for clinical use in many countries.

### Use of Guidelines for Plasma Transfusion

Although practice guidelines produced by national and professional organizations for FP transfusion are readily available in many countries, there continues to be evidence for variation in practice.<sup>5-7</sup> The result is that FP appears to have the highest rate of inappropriate use (up to 50%<sup>68</sup>) among standard blood components with evidence of inappropriate practice derived from local audits. Table 20-3 summarizes results from a number of studies or audits that evaluate the appropriateness of transfusion of FP, according to local or national guidelines.

The reasons for poor compliance with guidelines are not entirely clear. Poor compliance may reflect misunderstandings about the limitations of coagulation tests; it may also reflect the difficulties in defining appropriate use in the face of a limited evidence base; and it may reflect that for many physicians, transfusion medicine practice is passed down from mentors who used blood components in a more liberal way. Perhaps now a more systematic approach is required to understand the determinants of this prescribing pattern and barriers to practice change.<sup>75,76</sup> This would include identifying better strategies for delivery and uptake of evidence-based health care, which are clearly demonstrated as unpredictable for FP.

No one would doubt the need to optimize FP transfusion practice; indeed, the best way to reduce the risk of adverse reactions is to define who really needs FP in the first place, and to reduce unnecessary transfusions. Unfortunately, even fewer data exist on the relative or absolute effectiveness of the different strategies or interventions that can be used to change transfusion prescribing behavior (eg, audit feedback, guidelines, educational sessions). A recent systematic review of the RCT evidence for the effectiveness of different educational strategies operating in transfusion medicine has pointed out the very weakness of the evidence itself for the success of these approaches to deliver sustained and effective behavioral change.<sup>77,78</sup>

### Conclusions

The recommendations for FP transfusion stated earlier form the basis for clinical indications for plasma. These specific limited indications should form the basis for local guidelines, which should help to minimize inappropriate use (eg, as prophylaxis in the absence of bleeding with mild to moderate abnormalities of coagulation tests or as volume expanders). Therapeutic uses of FP, in association with abnormalities of coagulation tests (except in emergencies) are based on a pathophysiologic rationale, but questions about optimal dose and schedule remain unanswered. A recurring theme in many settings is an overall paucity of high-level evidence to inform optimal FP transfusion practice, and there is a pressing need to undertake new trials of efficacy of FP transfusion. This will not only define which groups of patients really benefit from FP, but also identify the constituents in plasma that are providing the most benefit (eg, by analogy the role of ADAMTS13 in TTP). New studies need to take account of the extent to which adverse effects might negate the benefits of treatment with FP, including the unknown risks related to circulatory overload and TRALI.

NR = not reported.

In the future, with a better understanding of disorders with acquired deficiencies of one or more coagulation factors, replacement might be more appropriately managed with concentrates of multiple coagulation factors, which would minimize risks of circulatory overload. There should also be more open recognition of the limitations of current standard coagulation screening tests, and appreciation that in-vitro abnormalities of coagulation screening tests do not equate with an in-vivo failure of clinical hemostasis and the presence of clinical coagulopathy. Newer global tests of hemostasis may be better markers of abnormal bleeding risk, but should be assessed and validated in larger clinical studies.

## Albumin

The optimal fluid regimen for correction of fluid and plasma volume disturbances in critically ill patients continues to be an area of controversy. The relevant fluids that may be infused as expanders include crystalloids (aqueous electrolyte solutions) or colloids (whether semisynthetic colloid solutions including gelatins, starches, and dextrans, or solutions of human albumin). This section of the chapter focuses on solutions of human albumin as a volume expander; synthetic colloid solutions and crystalloids are covered in other chapters.

Albumin is a very negatively charged protein produced in the liver and is the largest protein component of human serum. Its general functions include maintenance of osmotic pressure, transport of lipid-soluble substances, and a range of other biochemical effects such as buffering. Serum levels of albumin reflect changes as a consequence of either excessive losses (such as through the kidneys) or reduced production within the liver. As a broad generalization, low albumin levels have been associated in many patient groups with poorer outcomes.

Human albumin for transfusion is derived from plasma collected either by whole blood donation or by apheresis. As for any other pooled component, the concern is that a single infected donor unit can transmit disease to a large number of recipients. Therefore, multiple steps (eg, pasteurization) are added to the manufacturing process to limit the risk of infection transmission. In the UK, solutions of human albumin are available at protein concentrations of either 4.5% or 20%. Both solutions also contain sodium, other plasma proteins, and a stabilizer. Instructions for administration include risks of fluid overload, particularly for the higher concentration products, reflecting in turn the potential for rapid increases in colloidal osmotic pressure and intravascular volume, in addition to risks of sodium overload.

In general, hypoalbuminemia itself should not be considered an indication for albumin infusions, but when associated with fluid shifts and clinical consequences, infusions of human albumin may be indicated. Examples might include cirrhotic patients with refractory ascites who require serial therapeutic paracenteses, or patients with nephrotic syndrome associated with severe peripheral or pulmonary edema where diuretic therapy appears

ineffective. A solution of 4.5% human albumin is often the preferred choice in therapeutic apheresis, because it is iso-oncotic with plasma, susceptible to pasteurization or virus inactivation, convenient to administer, and associated with few adverse reactions. Its use is associated with a transient decline in the levels of all normal plasma constituents except albumin; only rarely is this of clinical significance. Patients with burns are at risk for multiple component deficiencies including secondary hypogammaglobulinemia, consumptive coagulopathy, and hypoalbuminemia; replacement requirements with albumin solutions can be significant in patients with extensive burns.

Although there are theoretical reasons why colloids including albumin may be more efficacious than crystalloids for 1) maintaining and expanding intravascular volume during resuscitation and 2) volume expansion in critically ill patients, these uses have been the subject of ongoing controversy, particularly in the light of systematic reviews and meta-analyses. An earlier systematic review by Schierhout and Roberts in 1998<sup>79</sup> started the controversy because it not only failed to find any benefit associated with colloids and human albumin solutions, but also raised concerns of harm—in this case, more deaths with the use of human albumin solutions compared to crystalloids. Despite some concerns about the methods of the meta-analysis (see other reviews<sup>80</sup>), this review not only raised awareness of meta-analysis as a tool for investigating evidence for clinical effectiveness, but crucially it gave impetus for subsequent definitive trials in the field of fluid resuscitation.

In particular, it was a driver for the recent completion of the Saline vs Albumin Fluid Evaluation (SAFE) study, the only large RCT (7000 participants) so far comparing the effect of fluid type (albumin solution vs normal saline) on clinical outcomes in hospital patients.<sup>81</sup> The SAFE trial found no significant differences in mortality for patients receiving 4.5% albumin or saline for fluid resuscitation. However, some of the interesting subgroup analyses—in patients with trauma, severe sepsis, and acute respiratory distress where differences were reported—really require further study to evaluate differences, as, the SAFE study was not a priori designed to answer questions about albumin use in these selected groups of patients. This need to think about subgroups and individual decisions may be important in these other clinical settings, until the evidence becomes available clinically. For example, older patients with heart disease might not tolerate infusions of saline alone with the attendant risks of circulatory overload; therefore, a mixture with albumin might be more appropriate.

Although the SAFE study appeared to resolve some previous safety concerns about albumin use and increased mortality, it is interesting to speculate on how albumin use has changed since the results of that study were published. On one hand there is some reassurance regarding the safety of albumin use, but on the other hand there remain uncertainties about cost-effectiveness, particularly by comparison to less expensive alternatives and colloids. In addition, clinical outcomes other than mortality were not a focus in the SAFE trial but remain important in the minds

of many clinicians who advocate albumin usage. In conclusion, although in many ways the SAFE study has created more uncertainties than it resolved, it has provided a benchmark for further large clinical trials that can answer questions about the effectiveness of different fluid regimens, including albumin, as volume expanders.

In addition to issues of relative effectiveness between these fluid solutions, cost is also an important part of the debate, because colloids are much more expensive than crystalloids. Higher costs increasingly should be justified in terms of greater benefit to patients. Because large volumes of intravenous fluids are used, even small price differences are economically important. Not only are human albumin solutions the most expensive colloid solutions, but also they are produced from blood (with all the associated risks). Their use requires the scrutiny of properly conducted clinical research.

# Applications of Cellular Radiolabeling in Transfusion Medicine

**Larry J. Dumont,<sup>1</sup> James P. AuBuchon,<sup>2</sup> & Richard J. Davey<sup>3</sup>**

<sup>1</sup> Director, Cell Labeling Laboratory, and Assistant Professor, Dartmouth Medical School, Dartmouth-Hitchcock Medical Center, Lebanon, New Hampshire, USA

<sup>2</sup> President and Chief Executive Officer, Puget Sound Blood Center, Seattle, Washington, USA

<sup>3</sup> Professor of Pathology and Laboratory Medicine, Weill Cornell Medical College, and Director of Transfusion Medicine, The Methodist Hospital, Houston, Texas, USA

The ability to track the fate of injected cells can provide very useful information in the care of patients, in clinical trials of new blood component production or storage, and in investigation of new cellular therapies. The ability to distinguish the injected cells from the vastly larger quantity of autologous cells that have been circulating allows the determination of their short-term recovery and long-term survival, identification of their destination or site of destruction, or provision of clues regarding their distribution and function. The techniques used for radiolabeling are generally well established, and the methods for determining the kinetics of the cells have been standardized. This chapter provides an overview of these techniques and methods with the intentions of promoting standardization of practices and investigation of alternative approaches as well as broadening the application of these techniques.

The techniques described are those that have used labeling, either *ex vivo* or *in vivo*, to determine the fate of the cells of interest. Alternative, nonradioactive labels have also been developed, but are currently used only in research settings. Their application is also mentioned briefly. Although all of these techniques need to be applied carefully and according to protocol in order to generate reliable outcomes, their application is well within the grasp of most laboratories having the appropriate equipment and competent staff to conduct careful laboratory determinations. Their utility suggests that a broader application could provide additional, useful information to both clinicians and researchers.

## Concepts of Recovery Curves and Kinetic Analyses

There are multiple specifications for a useful and practical radiolabeling agent that is to be applied in human clinical trials.

No single radioisotope possesses optimal characteristics in all categories, so trade-offs are inevitable. The requirements listed below appear in no specific order. All are important and, yet, the failure to achieve the greatest benefit from use of any one element does not preclude a radiolabel's use. Specific problems or limitations may be circumvented through a variety of techniques.

## Recipient Concerns

Whether the recipient is a healthy volunteer receiving an aliquot of autologous cells or a patient undergoing a diagnostic study, minimization of the toxicity or potential harm to the individual is the prime requirement. Safety must be viewed in terms of the injected dose of the radioisotope as well as the persistence (half-life) of the isotope and the disposition of the radionuclide and any accompanying chelating agent. A "low" dose of a radionuclide with a long half-life may yield more exposure than a higher dose of an isotope with a short half-life. The site of sequestration of labeled cells or of storage of the radionuclide may serve to concentrate the radiation exposure in certain tissues. More latitude for potential toxicity might be regarded as acceptable if the recipient is a patient who will receive benefit through the diagnosis rather than if the recipient is a healthy volunteer participating in a clinical trial. Nevertheless, the principle of limiting exposure (as low as reasonably achievable, or ALARA) pertains to the radiation exposure received by any recipient.

## Radioisotopic Properties

Key properties of radioisotopes include half-life, distribution, and energy of emissions. The rate of decay should allow for tracking the cells over a sufficient time to answer the question at hand without exposing the recipient to unnecessarily protracted radiation. For example, determining the red cell volume (or mass) can readily be accomplished with <sup>99m</sup>Tc (with a 6-hour half-life) because the calculations depend only on the initial dilution. A longer-lived radioisotope, such as <sup>51</sup>Cr (with a 27.7-day half-life) is necessary for determining recovery at 24 hours and for determining survival over multiple weeks.

The distribution of the isotope is important not only for exposure and toxicity concerns as mentioned above but also for ensuring that the radioactivity being measured in the blood is associated with the expected cells. At what rate does the radiolabel elute from the labeled cells? On elution or release with lysis, can the label be taken up by other cells? Once released from a cell, does the label persist in plasma? (These last two issues affect the extent to which radioactivity found in a blood sample can be attributed to the labeled cells that were administered.) The energies of the emissions that occur on decay are also important. A gamma counter must be set to detect photons in the energy ranges (“windows”) associated with a particular isotope. The device must also be able to distinguish the presence of two different isotopes for simultaneous injection of two different populations of cells. (For example, the major gamma-photon emissions of  $^{51}\text{Cr}$  and  $^{99\text{m}}\text{Tc}$  permit simultaneous counting of these radionuclides.) Radionuclides with high emission energies may, paradoxically, have a low counting efficiency unless the gamma counter has a large NaI crystal that can intercept such photons and translate their energy to visible light detectable by the photomultiplier system. Radioisotopes with higher energy emissions are more useful in external imaging when location of the injected cells is important, such as when radiolabeled granulocytes are used to identify the site of an abscess.<sup>1-3</sup>

### Cellular Function

The metabolic impact of the radionuclide itself and any carrier molecule to which it may be bound or chelated is important to know in order ensure that the labeling process is not altering the cell's physiology. Besides significant direct toxicity that kills the cell and thus prevents its circulation and normal function, subtle derangements of function may have significant impacts on disposition of cells, such as alteration of the chemotactic response affecting the ability of a neutrophil to track to a site of infection.<sup>4</sup>

### Specificity

The more specific the radiolabel is for a particular cell type, the less prelabeling purification will be required. Similarly, the better the cells' uptake of the label, the less postlabeling washing will be necessary to ensure that the label being injected is contained in the (intended) cells. At the same time, consideration must be given to the relative uptake of label by different subpopulations. Are cells of all ages able to take up and retain the label equally? Does preferential labeling of a certain subpopulation occur?

### Procedural Issues

The issues above combine to determine the extent to which the sample will need to be manipulated. In general, better retention of cellular function can be predicted with fewer manipulations. This is more of an issue for platelets or granulocytes than for red cells. However, even seemingly innocuous steps can induce cell rupture and hemolysis or other effects that may not be experienced uniformly across the entire population of cells and thus yield a skewed subpopulation for labeling and/or infusion.

Furthermore, although procedures can be performed in laminar flow hoods to reduce the potential for bacterial contamination, using closed systems wherever possible and reducing the number of steps employed are to be encouraged.

### The Radiolabeling Process

The steps of radiolabeling procedures are similar for red cells, platelets, and granulocytes—purification, preparation, uptake, wash. Purification improves accuracy by limiting the radiolabeling of cells that might confuse the observation of the cells of interest. The necessary degree of purification is inversely proportional to the expected life span of the infused cells and directly proportional to the relative number of the target cell type among other cell types. For example, the number of platelets or leukocytes in a red cell preparation would be intrinsically low (even without leukocyte reduction filtration or differential centrifugation) because of their relative proportion in circulation, and their shorter circulatory half-lives would not be expected to perturb the red cell recovery curve significantly. However, red cell content in a suspension of platelets or granulocytes might dramatically alter the observed recovery and survival of the platelets.<sup>5</sup>

The proclivity of the radionuclide to label the contaminating cells in comparison with the target cell type also needs to be considered. Certain labels, such as  $^{111}\text{In}$ , require a plasma-free medium to avoid binding of the cation to transferrin, a problem that has a beneficial side in that a plasma wash at the end of the labeling quickly removes all of the radiolabel that is not intracellular.

Once the cell has taken up the label, various interactions occur to reduce the rate at which it diffuses back out (“elution”).  $^{51}\text{Cr}$  binds to the  $\beta$ -globin chain of hemoglobin, but  $^{99\text{m}}\text{Tc}$  first requires reduction from pertechnetate ( $\text{TcO}_4^-$ ) to  $\text{Tc}^{+4}$ . To do this, red cells are pretreated with stannous chloride (commonly referred to as tinning) to create a reducing environment that allows for this “capture” of the radiolabel. Tin pyrophosphate can also be administered to patients directly followed by  $^{99\text{m}}\text{Tc}$  to effect red cell labeling in vivo for scanning studies, but the efficiency achieved is lower than the 90% to 95% seen with ex-vivo labeling.<sup>6</sup>

$^{111}\text{In}$ , used most frequently in platelet and granulocyte labeling, does not bind to an intracellular target but is trapped in the cell on diffusion of its lipophilic carrier. The  $^{111}\text{In}$  chelate (such as indium oxine or indium tropolone) dissociates in a dynamic fashion and, when this occurs, the carrier can diffuse out of the cell again, thus trapping the  $^{111}\text{In}^{+3}$  inside. Following removal of radiolabel that has not been taken up by cells, the cells should be infused as soon as possible, and, for improved accuracy of the recovery calculation, the proportion of radiolabel within the cell as opposed to the supernatant should be determined concurrently with the infusion.<sup>7</sup>

### Determination of Recovery

The recovery of the injected cells can be calculated in one of several ways.<sup>8</sup> The simplest approach uses a calculated blood volume

(based on the subject's height, weight, and gender,<sup>9,10</sup> for example) and then applies the total amount of cellular radioactivity injected to determine the 100% recovery point. This approach is commonly used in platelet studies where a large proportion (usually at least 30%) of the label is retained in the spleen and the extrapolation method (described next) would not be accurate. It is also helpful in platelet labeling because separation of platelets in a blood sample in order to express their relative volume (a thrombocrit) is not usually feasible, and thus the relevant calculations cannot yield a "total platelet volume" (or mass) for the subject. The accuracy of this approach, however, is limited to the accuracy of the prediction of the subject's blood volume. Most formulae or nomograms display substantial inaccuracy, especially as the weight of the subject diverges from average.

A second approach depends on a back-extrapolation from the first several samples taken after infusion to the time of injection ( $T_0$ ) to identify what the activity of the blood would have been had the labeled cells instantly been uniformly mixed throughout the subject's blood volume. This establishes the 100% recovery point to which can be compared the actual recovery at later times. This is commonly referred to as the single-label recovery, or SLR. With knowledge of the total cellular amount of radioactivity injected, that activity can also be used to calculate the volume of distribution of the label.

Inherent in this calculation is the assumption that the disappearance of the labeled cells over the time used to create the curve from which the extrapolation to  $T_0$  is based, is the same as the kinetics of the cells before the first sampling. Even when sampling begins quite promptly after infusion (eg, 5 minutes), very rapid removal of a substantial proportion of labeled cells (such as through their accumulation of a lethal storage lesion, for example) would cause the extrapolation to miss this event and place the  $T_0$  point at too low a level.<sup>11</sup> This then overestimates the volume of distribution and may lead to an erroneously high estimation of the recovery. This approach is generally accepted as accurate when the immediate recovery exceeds 70% and possibly at even lower levels.

An alternative approach that would be expected to provide the best accuracy uses a second, independent method to establish the blood volume and then applies that determined volume to calculate the  $T_0$  on the basis of the observed dilution. (This is commonly referred to the double-label recovery, or DLR, method.) A freshly collected sample of red cells from the subject is labeled with a different radionuclide than that used for labeling the cells that are the subject of the study, that is, the "test" cells. Some have used albumin labeled with radioactive iodine for determination of blood volume, but the loss of the label and the distribution of the albumin molecules have raised questions about the dependability or advisability of this technique.<sup>8,12</sup> Because the volume-setting cells are fresh and autologous, the assumption is made that they will all circulate after reinfusion, and thus extrapolation of the recovery curve to  $T_0$  (using an SLR-like method) or an average of the first several recovery points as "100% recovery" will accurately determine the blood volume. In turn, this volume,

when divided into the total cellular radioactivity reinfused in the test cells, sets the 100% recovery point for the test cells. Any early loss of the test cells will not affect the recovery calculation because the  $T_0$  activity is not dependent upon extrapolation of the test cells' recovery curve. This approach reduces the error in blood volume determination to around 2%, less than half that seen with calculations based on height and weight.<sup>8</sup>

The DLR approach has several drawbacks, however. Most important is the extra radiation exposure of the subject. Although avoidance of exposure to unnecessary radiation is always desirable, the actual additional exposure is small in most red cell recovery studies. The usual isotope used for the freshly collected autologous cells (approximately 10  $\mu$ Ci  $^{99m}\text{Tc}$ ) adds <25% to splenic exposure and <4% to total body exposure compared to that imparted by longer-lived  $^{51}\text{Cr}$  used to label the test cells.<sup>13</sup> In addition, although the subject must be available for an additional phlebotomy to start the labeling process, a sample is usually collected the morning of reinfusion anyway in order to confirm the absence of a pregnancy via a serum test in females of childbearing potential. There is no doubt, however, that the DLR approach is more expensive, as it takes more time to complete the labeling and uses more supplies and a second radionuclide.

Is application of the DLR approach justified or necessary? The difference in single-label vs double-label red cell recoveries for most collection and storage systems that are evaluated in clinical trials is relatively small, on the order of 1% to 2%.<sup>14,15</sup> The direction of the difference that has been observed, however, is not what might have been predicted; that is, DLR is usually slightly higher (when looking at the mean for a clinical trial) than SLR. The reason for this difference remains to be elucidated but may be related to the early elution of  $^{99m}\text{Tc}$  from the freshly collected cells and clearance from circulation or less-than-complete recovery of the fresh cells. Perhaps even more important than the accuracy, however, is the objective determination of blood volume and thus  $T_0$  activity that DLR provides. The fitting of the SLR line to the initial points of the test cell's recovery curve is always subject to interpretation, and decisions must be made as to which points appear to be outliers and thus should be excluded. The DLR approach provides an objective determination of the 100% recovery point, at the least verifying the SLR  $T_0$  extrapolation or, in cases where this projection appears to be erroneous, providing an alternative or "back up" method to complete the calculations. Currently, the Food and Drug Administration (FDA) does not specify the calculation method (SLR vs DLR) to be used in clinical trials of red cell storage systems, but most laboratories prefer to use DLR for the reasons cited above.

The DLR approach of determining blood volume based on dilution of a known activity in the injectate is the method used to determine red cell volume in patients suspected of having polycythemia. Using  $^{99m}\text{Tc}$  to label autologous cells (to limit radiation exposure) and reinfusing them promptly, an average of the first points on the recovery curve (ie, 5, 7.5, and 10 minutes) are usually applied to determine the patient's red cell volume.

Also, as in DLR, the assumptions of 100% recovery of red cells and lack of any elution of radiolabel are made. This is compared to a reference range based on gender, height, and weight in order to determine whether the red cell volume is indeed elevated or whether a pseudopolycythemia exists (Gaisbock syndrome) in which the hematocrit is elevated because of a reduction in plasma volume.

For all of these calculations, additional accuracy is achieved by determining the proportion of the injectate's radioactivity that is cell-bound at the time of infusion.<sup>7</sup> This is accomplished by centrifuging an aliquot of the injectate at the same time as the reinfusion and multiplying the cellular fraction of activity (usually 95-99%) by the total radioactivity of the injectate.

The in-vivo survival of red cells beyond 24 hours is not routinely included in precensure clinical trials. Instead, it is assumed that cells able to survive for the first 24 hours after reinfusion will have a normal life span, as has been seen in most of the studies where this information has been sought. However, survival may be an important parameter to consider when evaluating an intervention that has the potential to modify red cell biochemistry.

In calculating the survival,<sup>16</sup> the recovery at each time point,  $N_t$ , is expressed in counts/minute/g of hemoglobin after correction for background, decay, and elution of the radiolabel from the red cell. The elution rate for  $^{51}\text{Cr}$  is approximately 1%/day but is slightly higher over the first 10 days, thus leading to recommendations for application of the elution correction factors developed by Mollison.<sup>17-20</sup> The fractional recovery,  $N_t/N_0$ , is then calculated at each time point where  $N_t$  = counts at time "t" corrected for elution and  $N_0$  = counts at time "zero." The survival curve may not be linear, and three possible regression models have been recommended,<sup>16</sup> including:

$$N_t/N_0 = \alpha * e^{-\beta * t} + (1 - \alpha) e^{-\gamma * t} \text{ (exponential; two component)}$$

$$N_t/N_0 = \alpha * e^{-\beta * t} + \gamma \text{ (exponential)}$$

$$N_t/N_0 = \alpha + \beta * t \text{ (linear)}$$

where  $\alpha$ ,  $\beta$ , and  $\gamma$  are arbitrary fitting parameters. Of these, the linear approach is generally used. The exponential models are useful for nonlinear survival curves when a random clearance mechanism is operating in addition to senescence. The mean life span is the projected x-axis (time) intercept of the tangent to the curve at  $t = 0$ . The  $T_{50}$ , the time required for half of the red cells to disappear, is reported.

The  $T_{50}$  does not bear a simple relationship to the mean life span.<sup>17</sup> Modest reductions in the  $T_{50}$  can correlate with a substantial increase in the rate of red cell destruction.<sup>21</sup> The  $T_{50}$  is usually best approximated with a log-linear extrapolation after correcting for elution of the label from the cells.

For platelets, the calculations of recovery and survival are undertaken in a slightly different manner. The currently accepted approach specifies that the recovery at time points beyond 20 hours are used for nonlinear curve fitting to estimate recovery

and survival.<sup>22</sup> The multiple hit model is most commonly used because of its congruence with the platelet kinetics found in normal subjects.<sup>23</sup> The recovery is determined by extrapolation back to  $T_0$ , analogous to red cell SLR studies. The "survival" parameter is usually taken as the numerical expected life span, the point at which a tangent to the survival curve crosses the x-axis. This value is very sensitive to the first portion of the curve (which usually includes more variance than the later recovery points), and thus the values obtained in the first 20 hours are not included in the curve fitting. These parameters may be estimated using a nonlinear curve fitting routine found in various statistical and pharmacokinetic computer program packages. (Most laboratories use the COST software,<sup>24</sup> but the calculations provided by commercially available software packages can produce identical results.<sup>25</sup>)

## Radionuclides Used in Kinetic Determinations

The first clinically useful red cell radiolabel,  $^{51}\text{Cr}$ , was described by Gray and Sterling<sup>26</sup> in 1950. This isotope was quickly identified as an excellent red cell label for survival and recovery studies.  $^{99m}\text{Tc}$ <sup>27</sup> and  $^{111}\text{In}$  were subsequently recognized as useful radiolabels of red cells, and McAfee and Thakur<sup>28</sup> in 1976 demonstrated  $^{111}\text{In}$  to be an effective radiolabel of leukocytes. Other cell radiolabels have also been evaluated and used, with varying degrees of success. However, the vast majority of blood cell kinetic and imaging studies are performed with  $^{51}\text{Cr}$ ,  $^{99m}\text{Tc}$ , or  $^{111}\text{In}$ .

Investigators should have an understanding of fundamentals of nuclear medicine and radiation biophysics to use these materials appropriately. Desirable characteristics relate to recipient safety as well as to ease and reproducibility of use (Table 21-1). Each of the three commonly used radionuclides has advantages and disadvantages that affect their applicability in clinical and research settings.

The selection of an appropriate radionuclide requires familiarity with the radioactive half-life, elution characteristics, and gamma-photon energy of  $^{51}\text{Cr}$ ,  $^{99m}\text{Tc}$ , and  $^{111}\text{In}$ . These features are listed in Table 21-2. The optimal range for detection of photoelectric events in a standard gamma counting instrument (gamma counter) is 100 to 300 keV. Thus, gamma-photon

**Table 21-1.** Desirable Features of Blood Cell Radiolabels

- Minimal manipulation of cells required during preparation
- Specific for the cell being studied
- Nontoxic to the labeled cell
- Nontoxic to the recipient
- Minimal radiation dose to the recipient
- No metabolism of the label by the cell
- No elution of the label
- Radioactive half-life appropriate for the duration of the study
- Radioactive emissions suitable for efficient detection or imaging
- No relabeling of other cells in vivo

**Table 21-2.** Major Features of Radionuclides Used for Blood Cell Labeling

|                                  | <sup>51</sup> Cr | <sup>99m</sup> Tc | <sup>111</sup> In          |
|----------------------------------|------------------|-------------------|----------------------------|
| Radioactivity half-life          | 27.7 days        | 6.0 hours         | 2.8 days                   |
| Major γ-photon emissions (yield) | 320 keV (9.8%)   | 140 keV (90%)     | 173 and 247 keV (90%, 94%) |
| Elution rate (red cells)         | 1% per day       | 1%-7% per hour    | 4%-8% per day              |
| Suitable for imaging?            | No               | Yes               | Yes                        |

energies in this range are desirable. The “yield” of gamma-photon emissions is the number of photons emitted per 100 radioactive decays. A high yield means that a lower radiation dose can be used to achieve adequate detection levels.

**Chromium-51**

<sup>51</sup>Cr can be used to label both red cells and platelets. Advantages of this radionuclide as a red cell label include ease of labeling, excellent uptake, low toxicity, and a low and stable elution rate. It is the standard against which other red cell labels are compared. <sup>51</sup>Cr is produced in a reactor by neutron activation. It decays by electron capture, with a radioactive half-life of 27.7 days. The principal gamma-photon emission occurs by electron capture at 320 keV, slightly above the optimal detection range of standard gamma counters. The high energy and low yield (9.8%) of gamma-photon emissions from decay of this radionuclide necessitate a larger NaI crystal (typically 3-inch) for efficient detection in a gamma counter. Smaller crystals require a larger dose of the radionuclide to achieve adequate counts.

The 27.7-day half-life of <sup>51</sup>Cr makes it suitable for most red cell survival and recovery studies. However, if multiple studies are performed, the overlapping survival curves make separation of the individual studies quite difficult. This problem can be addressed in recovery studies by correcting for residual radiation, by separating studies until the nuclide decays, or by using alternate radionuclides.

<sup>51</sup>Cr is supplied as sodium radiochromate (Na<sub>2</sub><sup>51</sup>CrO<sub>4</sub>) for cell labeling purposes. Hexavalent chromate labels red cells by binding rapidly and reversibly to the red cell membrane. After reduction to the trivalent state, the chromic ion binds more slowly and firmly to the β-globin chain of intracellular hemoglobin, and probably to other intracellular ligands as well. Younger red cells take up slightly more label than do older cells. The bond is quite firm, and any unbound trivalent (reduced) chromium does not label other red cells. Labeling efficiency is about 90%.

Chromium elutes from red cells in two phases. There is an early loss of 1% to 4% of the label within 24 hours, which may represent elution of a loosely bound fraction of the label.<sup>29</sup> Garby and Mollison<sup>17</sup> found that subsequent elution varies from 0.56% to 2.04% per day, similar to the 0.70% to 1.55% reported by Bentley and associates.<sup>30</sup> An estimated elution rate of 1% per day is satisfactory for most investigational and clinical purposes. Trivalent chromium that elutes from the labeled cells is rapidly excreted in the urine and does not relabel other cells in vivo.

The technical steps for the labeling of red cells with <sup>51</sup>Cr for the evaluation of blood storage and preservation systems have been described by Moroff and colleagues.<sup>31</sup> The International Committee for Standardization in Hematology<sup>16</sup> has described a slightly different technique suitable for labeling red cells for the determination of transfusion compatibility. A nonradioactive isotope of chromium has also been investigated as a red cell label. <sup>52</sup>Cr-labeled red cells have in-vivo survivals similar to red cells labeled with <sup>51</sup>Cr,<sup>32</sup> but the isotope must be detected by atomic absorption spectroscopy, making it impractical for clinical use.

Baldini and colleagues<sup>33</sup> first described the use of <sup>51</sup>Cr as a platelet radiolabel. The platelet-labeling efficiency of <sup>51</sup>Cr is low (9%) compared with its red cell labeling efficiency (90%). Therefore, it is important that platelet preparations be free of red cells before being labeled. A procedure for labeling platelets with <sup>51</sup>Cr, which is more difficult than that for red cells, has been described by Snyder and colleagues.<sup>34</sup> Further useful refinements were developed by Heaton, Holme, and colleagues.<sup>8,35</sup> <sup>51</sup>Cr is not a useful isotope for imaging studies, which require a high yield of gamma-photon emissions.

**Technetium-99 m**

<sup>99m</sup>Tc, which is widely employed as an imaging agent in nuclear medicine, has characteristics that are different from <sup>51</sup>Cr, making it a useful adjunctive red cell radiolabel. This metastable radionuclide is produced in a molybdenum generator as a product of molybdenum-99 decay. <sup>99m</sup>Tc decays with a half-life of 6.02 hours to <sup>99</sup>Tc. <sup>99m</sup>Tc emits a gamma-photon at 140 keV, which falls within the optimal range of gamma counters. The high yield (90%) of this radionuclide is useful for external imaging. This radionuclide is widely used as an imaging agent because of the ease of preparation, high yield, and easy detectability. Because of the frequent use of this radionuclide, many hospitals maintain a generator on site, and thus there is a readily available and inexpensive source of <sup>99m</sup>Tc for cell labeling applications.

<sup>99m</sup>Tc, as pertechnetate, diffuses across the red cell membrane into the cell, where it is reduced and binds to hemoglobin and other intracellular ligands with a labeling efficiency of about 90%. The short half-life of <sup>99m</sup>Tc makes it suitable for short-term studies of red cell mass but precludes its use for long-term red cell survival studies. Groups of samples must be counted rapidly, and a correction must be made for radioactive decay that occurs during the counting procedure. However, because of its short

half-life,  $^{99m}\text{Tc}$  may be useful as a red cell label when a series of survival studies must be performed for transfusion compatibility. It is also useful for the accurate determination of red cell volume as part of red cell recovery studies (using  $^{51}\text{Cr}$ ) or in patients being investigated for possible pathologic expansion of their red cell mass (eg, polycythemia).

This nuclide also has a high and variable rate of elution, which reduces precision in all but short-term studies.<sup>36,37</sup> The use of stannous compounds as intracellular reducing agents in the labeling process has permitted firmer binding of  $^{99m}\text{Tc}$ , but elution rates of 4% per hour with considerable variation may be expected. Heaton and colleagues<sup>7</sup> have described the technical steps necessary to minimize variability in labeling and elution with this nuclide.

### Indium-111

$^{111}\text{In}$  is a useful label for red cells, platelets, and leukocytes. The radioactive half-life of the nuclide is 2.83 days, making it appropriate for red cell mass determinations, platelet recovery studies, and leukocyte imaging.  $^{111}\text{In}$  is prepared in a cyclotron by proton bombardment of a cadmium target. It has two major gamma-photon emissions, 173 keV (90.5% yield) and 247 keV (94% yield), both of which are excellent for counting in a gamma counter and for external imaging.

$^{111}\text{In}$  must be complexed with a lipophilic chelating agent to enable it to cross cell membranes and label intracellular proteins. Although several lipophilic chelates have been studied, 8-hydroxyquinoline (oxine) is the only agent currently licensed for this purpose in the United States. Technical procedures have been published for labeling red cells,<sup>38</sup> platelets,<sup>34</sup> and leukocytes<sup>28</sup> with  $^{111}\text{In}$ . It is a nonselective label, preferentially taken up by platelets, with less by taken up by leukocytes, and still less by red cells.<sup>39</sup> Therefore, cell preparations must be free of extraneous elements before being labeled.  $^{111}\text{In}$  has a high and variable rate of elution from red cells.<sup>38</sup> Approximately 8% to 10% of the label elutes within 24 to 48 hours, with a subsequent loss of 4% per day. This renders  $^{111}\text{In}$  unsuitable for red cell survival and recovery studies, but it is useful for determining red cell volume when precision is not critical.

## Radiolabeling as a Tool for Evaluation of Cellular Kinetics and Traffic

### Red Cells

Short-term red cell recovery studies are useful for the identification of patterns of immune red cell destruction and for evaluating new methods of storing and preserving the cells. The normal red cell life span (110 to 120 days) was first approximated by differential absorption techniques<sup>40</sup> and subsequently confirmed by radioisotopic labeling studies using cohort (marrow or in-vivo) labels<sup>41</sup> and random (peripheral blood) labels.<sup>17</sup> When  $^{51}\text{Cr}$  is used as the label, the time at which the recovered counts are 50% of the originally injected counts is the  $T_{50}\text{Cr}$ , normally

$31 \pm 6$  days. Correction for elution will yield the true red cell life span. Modest reductions in the  $T_{50}\text{Cr}$  can indicate a substantial increase in the rate of red cell destruction.<sup>21</sup> The  $T_{50}\text{Cr}$  is also useful for evaluating the extent of hemolysis in a chronic hemolytic anemia.

Red cell life span studies also have been conducted to assess the therapeutic benefit of transfused units that are enriched in young red cells ("neocytes"). The transfusion of such units would have the theoretical benefit of reducing the iron burden in patients who undergo frequent transfusions by increasing the number of longer-lived red cells in the circulation.<sup>42</sup> Neocytes survive 30% to 60% longer in the circulation than do red cells derived from standard Red Blood Cell (RBC) units.<sup>43,44</sup> However, as neocyte units contain only about half the hemoglobin of standard units and are costly to prepare, they have not achieved wide clinical acceptance.<sup>45</sup>

In contrast to long-term life span studies, short-term red cell survival studies are useful in identifying patterns of immune red cell destruction. A careful assessment of the mechanism of red cell destruction may be necessary when an unexplained transfusion reaction has occurred or when standard pretransfusion serologic testing has not clearly identified or characterized red cell allo- or autoantibodies in a transfusion recipient. Furthermore, hemolytic transfusion reactions are not always immunologically mediated. In addition, patients with serologic findings suggesting a hemolytic reaction may not demonstrate clear evidence of clinical hemolysis.<sup>46,47</sup> In-vivo studies may be useful to identify accelerated red cell destruction when present and to identify characteristic recovery patterns that can influence subsequent transfusion decisions.

The factors that contribute to immune red cell destruction have been discussed in detail elsewhere.<sup>48,49</sup> Of primary importance are the immunoglobulin class and subclass of the recipient red cell alloantibody<sup>50</sup> and the extent to which that antibody activates complement.<sup>51,52</sup> The important role of cytokines in IgG-mediated red cell destruction has also been clarified.<sup>53,54</sup> Short-term (24-hour) recovery studies using fresh allogeneic red cells are performed for transfusion compatibility. A red cell phenotype is chosen on the basis of serologic results. The cells are usually labeled with  $^{51}\text{Cr}$ . If serial studies are required, a radionuclide with a shorter half-life,  $^{99m}\text{Tc}$  or  $^{111}\text{In}$ , can be selected, but problems with rapid elution of the label and overlapping counts may complicate interpretation of the results.

Red cell recovery curves observed in 24-hour survival studies conducted to determine transfusion compatibility fall into four characteristic patterns (Fig 21-1). They are 1) normal survival, 2) extravascular destruction characterized by a "two-component" survival curve, 3) extravascular destruction characterized by a "single exponential" survival curve, and 4) intravascular destruction.

### Normal Recovery

In a normal subject the recovery of fresh, compatible red cells is 97% to 102% at 60 minutes and 95% to 100% at 24 hours.

**Figure 21-1.** Red cell recovery curves 24 hours after transfusion show differing mechanisms of immune red cell destruction. (A) Normal recovery. (B) Partial complement activation with two-component extravascular destruction pattern (eg, IgM anti-Le). (C) No complement activation with single exponential extravascular destruction (eg, IgG anti-D). (D) Complete complement activation with intravascular destruction (eg, anti-A). The 1-hour recovery percentage is not always predictive of transfusion safety.

### Extravascular Destruction without Complement Activation (Single Exponential Survival Curve)

Most IgG antibodies do not activate complement. Instead, there is progressive removal of sensitized red cells with a survival curve described by a single exponential. The concentration of the antibody, its IgG subclass, and the generation of inflammatory cytokines are important determinants of the rate of removal of the cells. The four IgG subclasses vary in their efficiency to bind to Fc receptors on reticuloendothelial system (RES) macrophages.<sup>55</sup> IgG3 is often associated with immune hemolysis, while IgG2 and IgG4 are inefficient in removing sensitized cells. IgG1, the most common subclass, varies in its ability to remove red cells. IgG1 is present in higher titer than the other subclasses and is most often involved in IgG-mediated red cell destruction.

Antibodies of the Rh, Kell, Duffy, and Kidd blood systems are usually IgG and do not activate complement. The 60-minute red cell recovery in the presence of these antibodies may exceed the 70% minimum required for transfusion safety, but may fall well below this standard at 24 hours. This pattern of red cell destruction highlights the importance of extending red cell recovery studies to at least 24 hours. Transfusion based on the 60-minute recovery percentage alone may place the patient at risk for accelerated red cell removal.

### Extravascular Destruction with Partial Complement Activation (Two-Component Recovery Curve)

The transfusion of incompatible red cells may activate complement. Most IgM red cell alloantibodies and some IgG alloantibodies (eg, anti-Jk<sup>a</sup>) can initiate the complement cascade. IgM antibodies directly activate complement, with 20 to 40

IgM molecules per red cell being required to initiate red cell clearance. IgG antibodies can activate complement if two or more molecules are physically adjacent on the red cell membrane.<sup>56</sup> Thus, many more IgG molecules are required for complement activation to occur. In most cases, the kinetics of complement activation result in generation of the membrane-bound C3b fragment but not the final C5b-C9 “membrane attack” complex. C3b is subject to cleavage to C3bi by plasma factor I, with plasma factor H as a cofactor. Red-cell-bound C3b and C3bi adhere to the complement receptors CR1 and CR3 on RES macrophages in the liver and spleen.<sup>57</sup> These adherent red cells may be removed from the circulation by either antibody-dependent cell-mediated cytotoxicity or complete phagocytosis. They may also sustain membrane damage and spherocytic change after partial phagocytosis.

Only a minority of adherent red cells are damaged or destroyed by these mechanisms. C3bi may be degraded before red cell damage occurs. Plasma factors I and H further cleave C3bi to C3c, which detaches from the cell, and C3d,g, which remains attached to the cell membrane.<sup>58</sup> C3d,g-coated red cells do not effectively bind to complement receptors of the RES. Most red cells coated with C3d,g detach from RES macrophages and survive relatively normally.<sup>59</sup> The inactive C3d,g fragments may “protect” the red cell from further complement-mediated damage by occupying complement-binding sites. A “two-component” recovery curve, therefore, demonstrated the early loss of C3b-coated red cells and more normal survival of those cells on whose membranes C3b has degraded to C3d,g. Red cell antibodies that usually react optimally at temperatures below 37°C (eg, Lewis, MNS, P) will often yield “two-component” recovery curves. A “two-component” survival curve with more than 70% recovery at 24 hours indicates that the patient can safely receive larger quantities of similar red cells with little risk of acute immune hemolysis.

### Intravascular Destruction

IgM antibodies that are efficient activators of complement, such as anti-A and anti-B, can drive the kinetics of the reaction to the formation of the terminal C5b-C9 “membrane attack” complex. Insertion of this complex into the red cell membrane results in loss of membrane integrity and osmotic lysis of the cell. Transfused cells that generate complement activation of this magnitude are usually hemolyzed within minutes.

### Synergistic Effect of Complement and IgG

Selected antibodies of the IgG class, such as Kidd antibodies, activate complement. Complement and IgG appear to act synergistically in promoting red cell opsonization and destruction. The addition of complement to red cells sensitized with IgG alone will enhance phagocytosis.<sup>60,61</sup> A hybrid red cell survival curve may occur when both IgM and IgG antibodies are active. There is a rapid loss of a minor population of the cells from IgM-mediated complement activation, and a slower phase of cell destruction mediated primarily by the IgG antibody.

## Platelets

Studies of platelet life span and kinetics were originally performed with  $^{51}\text{Cr}$ .<sup>62</sup> However, the low labeling efficiency, long half-life, and poor imaging characteristics of  $^{51}\text{Cr}$  have led to preferential use of  $^{111}\text{In}$  when a single platelet label is required.<sup>63</sup> Serial studies in a subject using a single label may not be possible, however, as platelet kinetics vary over time. A reduction in this variability is seen with use of both chromium and indium labels for simultaneous infusion. Thus, a more accurate estimation of the difference between platelets stored in a standard (or licensed) system and those in a test system can be achieved.<sup>64</sup> This technique has also been used to create novel approaches to platelet storage studies. In one such experiment, comparing whole-blood-derived platelets stored for 5 days with those stored for 7 days, the test (7-day) platelets were derived from a unit collected on Day 0, and the control (5-day) platelets were derived from a collection 2 days later. Platelets from both study arms were labeled and infused simultaneously using the approach of two different radiolabels.<sup>65</sup>

Standard technical methods for preparation of radiolabeled platelets have been published.<sup>22,35</sup>  $^{111}\text{In}$ -oxine has a high affinity for red cells, leukocytes, and plasma proteins, primarily transferrin. Thus, washing and centrifugation steps are necessary before labeling to prepare platelets that are free from plasma and other cellular components. These steps, however, cause a substantial loss of platelets (~40%) and a “collection injury” that can distort test results if not performed carefully. Other compounds that form lipophilic complexes with  $^{111}\text{In}$ , notably acetylacetone,<sup>66</sup> tropolone,<sup>67</sup> and 2-mercaptopyridine-N-oxide (merc),<sup>68</sup> have been studied as possible alternative agents to overcome this problem. Tropolone is widely used in Europe, but oxine remains the only licensed agent in the United States.

$^{111}\text{In}$  begins eluting from platelets shortly after labeling and infusion. Heaton and colleagues developed a technique for determining the elution characteristics.<sup>7</sup> Application of this “elution correction” has shown that the recovery curves for platelets labeled with  $^{111}\text{In}$  are coincident with those labeled with  $^{51}\text{Cr}$ . This procedure is the basis of the standard platelet radiolabeling protocol that has been adopted by the Biomedical Excellence for Safer Transfusion (BEST) Collaborative. Murphy proposed fresh platelets as controls for assessing platelet recovery, thus avoiding “creeping inferiority” that may occur if platelets stored with standard methods are used as controls in sequential studies.<sup>69</sup>

The calculation of platelet life span can be performed by four different methods—linear, exponential, weighted mean, and  $\gamma$ -function (multiple hit)—each of which yields slightly different results. The  $\gamma$ -function analysis is the recommended method,<sup>34</sup> and is the most frequently used. Investigators often report their results using one or more additional statistical methods. Computer programs have been developed that model platelet survival by a variety of techniques,<sup>24,70</sup> or statistical analysis software can be used.

No radioactive tracer selectively labels newly formed platelets. Thus, cohort studies have not been practical to measure platelet

production. Instead, the kinetics of normal platelet production have been measured indirectly by determining the turnover rate of circulating platelets (platelet count divided by platelet survival corrected for recovery). Estimates of daily platelet production in the steady state using this method have ranged from 35,000 to 66,000/ $\mu\text{L}$  of blood.<sup>71</sup> The life span of human platelets ranges between 8 and 12 days; Harker and Finch<sup>72</sup> found it to be  $9.5 \pm 0.6$  days. Senescent platelets are removed from the circulation by RES macrophages in the liver and spleen and, to a lesser extent, by marrow and lungs.<sup>73,74</sup>

In addition to platelets removed through senescence, there is a fixed platelet requirement necessary to maintain vascular integrity. Hanson and Slichter<sup>75</sup> have demonstrated that approximately 82% of platelet turnover in normal persons results from senescence, and 18% (~7100 platelets/ $\mu\text{L}/\text{day}$ ) is due to the fixed requirement. This fixed requirement becomes an increasingly large component of platelet removal as thrombocytopenia from marrow hypoplasia worsens. Thus, an accelerated reduction in life span is noted as platelet counts decrease below 50,000/ $\mu\text{L}$ . The shortened platelet life span observed in thrombocytopenic patients, therefore, does not necessarily indicate an increased platelet destruction rate.

Increased peripheral platelet destruction, such as seen in patients with idiopathic thrombocytopenic purpura (ITP), results in platelet life spans that are shorter than predicted by Hanson and Slichter’s model. Platelet life span studies using  $^{111}\text{In}$  are useful in discriminating between thrombocytopenia caused by decreased platelet production and that caused by increased platelet destruction. Platelet life span studies are not generally useful in the alloimmunized patient. Posttransfusion platelet counts usually provide the clinician with the necessary information for the management of these patients.

## Leukocytes

Granulocytes, lymphocytes, and monocytes—all derived from a common pluripotent stem cell—have widely variant functions and kinetics. Radionuclides have permitted the study of the normal kinetics of these various leukocyte classes.<sup>76</sup>  $^{111}\text{In}$ -oxine is now the nuclide of choice for leukocyte radiolabeling. However, because labeling with  $^{111}\text{In}$ -oxine is nonselective, the leukocytes of interest must be separated from other cells and plasma before being labeled.<sup>77</sup>

## Granulocytes

Studies conducted with labeled granulocytes have demonstrated that the circulating cells had a half-life of 3.8 to 6.7 hours. About half of the injected cells were recoverable in the circulation, with the remainder constituting a “marginating pool” of cells.<sup>78,79</sup> Labeling studies have demonstrated that the marginating granulocyte pool is about 60% of the total granulocyte pool.<sup>80</sup> Other studies have shown that labeled and transfused granulocytes transiently sequester in the lungs. The extent and duration of the pulmonary sequestration appear to be more severe when the labeled cells are suspended in saline rather than plasma.<sup>81</sup>

Alloimmunized patients demonstrate a more prolonged and intense pulmonary sequestration phase than normal subjects.<sup>82</sup> In addition, HLA and granulocyte-specific antibodies appear to reduce the intravascular half-life of transfused granulocytes<sup>83</sup> and to impair their ability to migrate to a site of active infection.<sup>84</sup>

### Lymphocytes

Lymphocytes are extremely radiosensitive, which has hampered the conduct of kinetic and imaging studies. Autologous lymphocytes labeled with a low dose of  $^{111}\text{In}$  ( $<20\mu\text{Ci}/10^8$  cells) move rapidly from the circulation and sequester in the lung, liver, and spleen, followed by a more gradual accumulation of radiolabeled cells in the lymph nodes.<sup>85</sup> These findings are consistent with studies demonstrating that lymphocytes are part of a large recirculating pool consisting of long-lived, nondividing cells.<sup>86-88</sup> Lymphocytes in this pool migrate from the circulation to the various lymphoid tissues, where they have opportunity to interact with foreign antigen. The migration patterns are modified by the lymphocyte class and the immunologic history of the cell. T cells preferentially migrate to lymph nodes, whereas B cells tend to migrate to mucosal lymphoid tissue.<sup>86</sup> Lymphocytes collected from a specific type of lymphoid tissue (eg, gut mucosa) move to that tissue because of “homing receptors” expressed on the cell after specific antigenic stimulation.<sup>89</sup>

### Activated Mononuclear Cells

There have been few kinetic studies of human monocytes because of the difficulty in obtaining a homogeneous collection of cells, and because of technical problems with cell activation and clumping during preparation. In one study, monocytes prepared by leukapheresis, density gradient separation, and countercurrent elutriation were activated with interferon- $\gamma$  and infused intraperitoneally in patients with peritoneal spread of colorectal cancer.<sup>90</sup> In two of these patients,  $^{111}\text{In}$ -labeled cells remained in the peritoneal cavity for up to 5 days after infusion, indirectly supporting the observation of clinical improvement in a larger group of patients treated with nonlabeled, activated monocytes. In another study, a subpopulation of peripheral blood lymphocytes was activated with the cytokine interleukin-2 and was found to exhibit antitumor activity. These lymphokine-activated killer cells presumably migrate to tumor sites, but cell trafficking and imaging studies have been inconclusive.<sup>91</sup> Lymphocytes directly harvested from tumor sites (tumor-infiltrating lymphocytes), however, have been shown to localize at tumor sites and persist in the circulation after activation.<sup>92</sup>

## Development and Evaluation of Collection, Processing, and Storage Systems

With the development of new means to collect, process, and store cellular blood components comes the need to determine their clinical efficacy and the time over which they may be stored while retaining acceptable properties. The FDA has adopted a stepwise approach to this problem (Fig 21-2).<sup>93,94</sup> Relatively minor changes with a low probability of having an

impact on the recipients receiving the component are considered for approval on the basis of in-vitro biochemical and hematologic analyses. Changes that might have an effect on the ability of the cells to circulate after storage are evaluated using radiolabeled kinetic studies to document the parameters of recovery (and, in some cases, survival) in humans. Animal studies have generally not been able to be applied except to scaled prototypic systems because of volume considerations and differences in coagulation systems and cellular biochemistry. However, a severe combined immunodeficiency (SCID) mouse model for in-vivo evaluation of human platelets appears promising as an adjunct or alternative to infusion into human subjects.<sup>95</sup> Patient trials are usually required only when major alterations in the handling of the cells are being considered. The evaluation process begins at the bottom of the pyramid with the successful completion of the requirements of each phase used to qualify continuation of the evaluation higher up into the pyramid. This approach justifies the involvement of humans while, at the same time, reduces the risks they face and increases the chances for success of that phase of the evaluation. This approach also limits the use of more expensive and complex trial methods to situations where it is truly going to provide necessary information.

The FDA criteria for approval of red cell systems has evolved over the years with the intent of utilizing updated knowledge about red cell function and “raising the bar” to increase the probability that the new red cell system will provide a clinically more advantageous blood component than its predecessors, not just an equivalent one. Currently, the criteria applied to in-vitro testing (Table 21-3) state some requirements in absolute terms (that is, a particular standard must be met), while others are stated in relative terms where the analyte is compared between test and control system units. Members of this latter group are usually considered as secondary criteria where a change of more than 20% from control may be acceptable if the difference is explicable and not likely to be clinically significant. Of all these parameters, only adenosine triphosphate (ATP) levels have consistently been correlated with in-vivo recovery and, even then, primarily as a threshold: Red cells with ATP levels below about half of Day 0 values usually exhibit poor recovery.<sup>18</sup> The ATP content of red cells at the end of storage, for example, provides a better prediction of in-vivo recovery than their morphology.<sup>96</sup> Recently, the FDA has attempted to respond to concerns about the possible association between transfusion of older RBC units and poorer clinical outcomes by assessing the ability of stored red cells to use their metabolic machinery to recreate ATP and 2,3-diphosphoglycerate levels in response to incubation with a red cell rejuvenation solution. The clinical importance of this new requirement and its sensitivity in detecting changes in red cell function that are important to patients have not been determined.

The standard for recovery of radiolabeled red cells 24 hours after autologous reinfusion in healthy subjects on the last day of storage has evolved over time. Initially, 70% was regarded as

**Figure 21-2.** The progressive analysis of a new blood component illustrating 1) the stepwise nature of investigation (beginning with in-vitro testing and culminating with clinical trials) and 2) application of different degrees of scrutiny based on the extent to which the new component differed from previously investigated ones. Major changes involve extensive investigation using more complex testing techniques in response to an increased risk of adverse patient impact. Simpler changes to a collection or storage system require only in-vitro testing. Successful testing (indicative of safety and efficacy) at one level of the pyramid would be used to justify moving to the next “higher” level of testing, were that required. Reprinted with permission from AuBuchon,<sup>93</sup> adapted from a presentation of Vostal.<sup>94</sup>

adequate to avoid hemoglobinuria that could be confused with immunologic destruction of incompatible red cells. Ross and colleagues in their investigation of early candidates for RBC preservative solutions arbitrarily selected 70% as a minimum recovery.<sup>97</sup> In the early 1980s, the expectation was raised to a mean recovery of 75%. Additional expectations were later expressed that the sample mean from studies at two laboratories be at least 75% with a sample standard deviation not to exceed 9%. The most recent step in the requirements, proposed in 2004, included an additional requirement that the one-sided, lower limit of the 95% confidence interval for the proportion of the population

that would have a “successful” recovery must exceed 70%.<sup>98</sup> A “successful” individual recovery was defined as greater than 75%. This new stipulation translated into a successful trial having no more than 3 of 24 (or 2 of 20) recoveries below 75%. Studies were to be carried out at a minimum of two laboratories with a least 20 evaluable subjects. Retrospective application of the newest part of this tripartite criterion to RBC systems currently in use has suggested that defining a “successful” transfusion in this context as 67% would allow the new approach to better reflect the systems currently in wide and successful use.<sup>99</sup>

Some practical features of these evaluations have not yet been standardized. The analyses are generally easy to perform, but broad standardization of the analyses (particularly those not used in clinical practice and not subjected to periodic proficiency testing) may not always yield congruent results between laboratories involved in a trial.<sup>100</sup> Possibly even more important is the variability injected by the inherent variation between healthy subjects in both in-vitro analyses and in-vivo recovery. The most dramatic of these variations relate to inherited alterations in nucleoside metabolic pathways that result in a small proportion (perhaps 1% of normal donors) having red cells that yield poor recovery (50–60%).<sup>101,102</sup> Less striking differences are seen without demonstrable cause, and the impact of the subject’s biochemical individuality can be assessed only by using a paired control scheme in the study. Although this approach requires a study design that extends over a longer time and exposes subjects to more radioactivity, it is the only means of identifying interdonor variability as the cause of failure to meet a particular

outcome measure. In addition, a paired study design provides greater power to detect statistically significant differences between the results of test and control units. This is particularly important in the in-vivo portion of trials where the number of subjects is limited in order to reduce human radiation exposure.

## Platelets for Transfusion—Criteria for Regulatory Approval

Platelets prepared for transfusion were first described in 1963 by Freireich and colleagues.<sup>103</sup> In the intervening nearly one-half century, multiple changes and improvements have been developed and introduced into clinical medicine including: preferred storage at 22°C,<sup>104</sup> extended storage in gas permeable containers,<sup>105</sup> collection of platelets by apheresis,<sup>106</sup> platelet storage solutions,<sup>107</sup> leukocyte reduction,<sup>108</sup> and pathogen reduction.<sup>109</sup> Within each of these broad categories are multiple improvements, as competitive products have been and are continuing to be developed and introduced. Creative minds have also sought to mitigate the limited shelf life of platelets and combat the platelet storage lesion by examining metabolic or cellular signaling modulators,<sup>110</sup> freezing platelets for storage,<sup>111</sup> developing synthetic platelet-like particles,<sup>112</sup> and lyophilizing platelets.<sup>113</sup> Before any of these collection, treatment, and/or storage methods can be introduced for clinical use, the safety and efficacy must be reviewed and judged by regulatory bodies.

The FDA issued its original platelet testing guidelines in 1981 following a 1980 public workshop sponsored by the Bureau of Biologics.<sup>114</sup> These guidelines suggested a hierarchy of testing for new platelet preparations starting with a panel of in-vitro laboratory tests, followed by determination of the in-vivo recovery and survival of autologous platelets in healthy volunteers, and finally observations of the hemostatic efficacy in patients—the latter pointing to bleeding time assessments.<sup>115</sup>

Regulatory agencies have requirements for platelet content and residual contaminating cells (eg, leukocytes), which differ from country to country.<sup>116–118</sup> Generally, several in-vitro measures are required to be presented for approval to regulatory bodies. Various in-vitro tests such as platelet morphology,<sup>119</sup> extent of shape change, hypotonic shock response,<sup>120</sup> and P-selectin expression,<sup>121</sup> have been empirically correlated with in-vivo platelet recovery and survival in volunteers or corrected count increments (CCI) in patients. However, it is generally recognized that in-vitro measures are not predictive of in-vivo outcomes.<sup>122</sup> One in-vitro parameter that seems to be consistent over time as a performance indicator is the platelet pH. Yet, this is also mired in confusion because the FDA requires a pH  $\geq 6.0$  for whole-blood-derived platelets<sup>123</sup> and  $\geq 6.2$  for apheresis platelets<sup>124</sup>; AABB requires a pH  $\geq 6.2$  for both whole-blood-derived and apheresis platelets<sup>125</sup>; and the European Union requires a pH  $\geq 6.5$  and imposes an upper limit as discussed by Dumont and VandenBroeke.<sup>126–127</sup> A summary of measures applied to nascent platelet systems is provided in Table 21-4.

In-vivo kinetics of autologous platelets in healthy volunteer study subjects has been a touchstone for new and novel platelet products. These studies are generally not performed in countries other than the United States because of various regulatory issues related to the use of radiopharmaceuticals. Other countries may informally reference results from US studies in their review process, although they formally rely on in-vitro panels, CCI studies, and in-vitro predictors of hemostatic efficacy.

The understanding of platelet physiology and biochemistry as well as the development of new laboratory technologies have advanced over the decades. The development of platelet-specific monoclonal antibodies, applications of flow cytometry, analysis of cytokines, chemokine and microparticle generation, description of the platelet genome, and other potential roles of the platelet beyond hemostasis have prompted new approaches for evaluating the platelet for transfusion. Some of these measures may be added to or replace traditional in-vitro analyses. Recognizing these advances, regulatory requirements have evolved over time as new technologies for collection, storage, and secondary treatments of platelets have emerged. FDA issued a draft guidance in 1999 that expressed some of its current thinking on performance requirements for new or modified platelet preparations.<sup>128</sup> In this document, the agency delineated four categories for evaluation of platelets: in-vitro evaluation of platelet biochemistry and function, platelet survival in circulation, clinical hemostatic efficacy, and the evaluation of platelet substitutes. This document currently remains a draft document and officially is not for implementation. Even when this becomes a released guidance, it is neither binding nor obligatory. However, it does reflect the thinking of FDA, and the astute clinical protocol developer will pay close attention to it as a starting point. FDA also communicates modifications of current thinking through advisory board meetings and other communication vehicles. Thus, it is critical for those considering an approval or clearance path through FDA to have early discussions with the agency to clarify current expectations. The general categories are summarized below. These are specific to platelet function characterization. Additional requirements are prescribed that include platelet content, residual white cells, and allowable storage time. Currently there are no requirements to evaluate shipping effects on platelet preparations, although important effects from shipping have been demonstrated.<sup>129</sup>

### In-Vitro Performance Criteria

Evaluation of the in-vitro biochemistry and function of the platelet is the first step. Characterization of the platelet should be a paired comparison between a current approved or cleared storage container as a control and the test device or test process. This generally must consider the maximum time of storage for the platelet. Although not explicitly stated, it is common for FDA to expect the test outcomes to be within 20% of the control. This tolerance does not appear to be based on specific clinical outcomes. Characterization should include the platelet morphology (Kunicki scoring and/or electron microscopy) and biochemical

ATP = adenosine triphosphate; ADP = adenosine diphosphate; SCID = severe combined immunodeficiency

status (pH, glucose concentrations and rate of consumption, lactate concentrations and rate of production, and possibly ATP concentration). The platelet should be assessed for activation (P-selectin expression,  $\alpha_{IIb}\beta_3$  activation, fibrinogen binding,  $\beta$ -thromboglobulin or platelet factor 4 release, and/or platelet factor 3 activity). Platelet response to agonists such as adenosine diphosphate, collagen, and/epinephrine may be assessed using traditional aggregometry or by evaluating changes to the activation markers listed above. The Baumgartner apparatus to assess platelet adhesiveness to inverted rabbit aorta as described by Escolar is another outcome that an investigator may choose.<sup>130</sup> FDA has also suggested quantitation of platelet microparticles, although once again there is no clear clinical performance correlation between the number of microparticles in a platelet preparation and the clinical safety and efficacy. Other regulatory agencies have similar requirements with a list of various in-vitro measures necessary for approval of a novel platelet preparation.

### In-Vivo Performance Criteria—Healthy Volunteer Subjects

The second area of emphasis by FDA is platelet survival in circulation. The background, rationale, procedural, and calculation details have been published.<sup>131</sup> Although autologous radiolabeled platelet recovery and survival has been a touchstone of platelet function for decades, the BEST Collaborative, led by Dr. Scott Murphy, was concerned about the risk of having a decreasing reference for these parameters in a daisy-chain-like manner

as new preparations and treatment methods were compared to the current method over many years.<sup>69,132</sup> To avoid this “slippery slope,” a standardized control prepared from fresh whole blood was selected and evaluated.<sup>133-135</sup> The specific criteria for recovery and survival were based on historical performances and professional judgment of experts in transfusion medicine; and, lastly, on the opinion of the FDA. The requirements for this testing have been debated at length and evaluated by the BEST Collaborative. The current understanding of these requirements is that 20 to 24 evaluable subjects are to be studied in a least two laboratories. The in-vivo recovery and survival of radiolabeled autologous fresh platelets, as a control or reference, and the platelet preparation being evaluated (test platelets) are to be determined in a paired, randomized study. The aim of the study is to demonstrate that the test platelet preparation is not inferior to the fresh platelet control. The original development of this approach set the requirements that the recovery of the test platelets be at least 66% of that of fresh platelets and the survival be at least 50%.<sup>65</sup> The survival value was set lower than the recovery because the rapid clearance of platelets in thrombocytopenia renders long-term survival moot.<sup>136</sup> Current FDA expectations for recovery and survival of test platelets have evolved to them being no worse than 66% and 58%, respectively, of the fresh control. These requirements may be somewhat flexible with the agency as it weighs the risks and the benefits of a specific platelet preparation. For example, a method to inactivate pathogens in platelets adds important benefits to the unit by reducing the

patient risk of a life-threatening transfusion-transmitted infection. Therefore, the agency may be willing to accept a lower recovery and/or survival parameter when reviewing these studies.

Applying and interpreting autologous platelet kinetic studies in healthy volunteers is especially challenging for platelets prepared from multiple donors; for example, prestorage pooled platelets prepared by either the platelet-rich plasma method predominant in North America, or the buffy coat method predominant in Europe. It is generally considered an unethical practice to expose healthy study volunteers to allogeneic blood. Therefore, alternative approaches have been to study individual autologous platelet units prepared from whole blood by the applicable method, and treated as single units in secondary processes such as leukocyte reduction, pathogen reduction, and storage.<sup>65</sup> Although the results provide some information, they cannot be easily extrapolated to the final product, which is prepared from donations of four to six individual donors, ie, it is not truly the final component configuration. In these cases, the FDA and other regulatory bodies have moved to the next tier of evaluation.

### In-Vivo Performance—Patient Studies

Clinical hemostatic efficacy is the next tier of the FDA progressive requirements for platelet preparations. Depending on the degree of change associated with a new product, this tier may or may not be invoked for demonstration of efficacy. This is a judgment call by the agency often supplemented with advisory committee input. There are no universally accepted in-vivo surrogate outcomes for platelet efficacy. The first step is generally a CCI that can be determined in a transfusion-dependent patient.<sup>137,138</sup> Cutaneous bleeding time is not recognized as a sensitive or reproducible outcome that can be used as a surrogate outcome, and is generally not required.<sup>139</sup> The ultimate clinical outcome requirement is the demonstration that the novel platelet preparation is hemostatically effective when transfused to patients. These studies should contain an appropriate control arm for comparison from an approved or cleared platelet preparation method. One such trial has been recently published evaluating a pathogen reduction method.<sup>140</sup> This type of trial is expensive, complex in many facets, and lengthy to execute.

Discussion in various circles has led to the concept of an additional, fourth tier of studies in some circumstances, that of postmarket surveillance. For example, this is being considered with the introduction of pathogen-inactivated platelets as a means of providing additional verification of the safety of the new approach when applied many more times than could be included in a clinical trial. Some have recommended that hemovigilance systems be used to gather such data,<sup>141</sup> particularly when coupled with detailed, effective afferent systems to detect posttransfusion problems.<sup>142</sup>

### Platelet Substitutes

The criteria for the evaluation of platelet substitutes is quite broad and nonspecific. The ultimate requirements will be

developed by the FDA and other regulatory bodies based on the specific claim and intended clinical benefit of the product, ie, on a case-by-case basis. For example, a substitute intended for use only in acute trauma may need to demonstrate a reduction in bleeding time but may not need to have an extended circulating level in the patient—as would a product intended for prophylactic use in the marrow-suppressed patient undergoing treatment for cancer. Additional animal testing for the evaluation of prothrombotic potential, immunogenicity, and toxicity may be requested.

### Animal Models

Animal models of platelet hemostatic efficacy are not specifically required in any guidance from FDA or other regulatory body. However, these outcomes may be requested on a case-by-case basis and may be helpful in progressing through the hierarchy of proof-of-function, both from a regulatory and a general scientific query perspective. Blajchman's group has developed and published widely on the use of a rabbit bleeding model.<sup>143</sup> Thrombocytopenia is induced in the rabbit by pretreatment with gamma irradiation and platelet antisera, and the RES is blocked with ethyl palmitate. Ear bleeding time and platelet survival following infusion of study human platelet preparations is then assessed. Although some have found this model useful, it is not perfectly predictive of the response in humans. Several researchers have used murine models for evaluation of in-vivo platelet function.<sup>144</sup> There remain questions on the generalizability of murine models. In addition, it is extremely challenging to treat and store mouse platelets in a manner that is representative of how a human platelet preparation would be handled because of volume limitations. Thus, these models seem to provide some insight, but they should be interpreted with caution.

The FDA Cellular Hematology Laboratory has published their experience with a SCID mouse model for transfusion of human platelets.<sup>95</sup> They demonstrated that human platelets could be transfused to the SCID mouse and the recovery and survival kinetics described. This model is promising as an alternative to perhaps some initial human platelet kinetic studies. However, it remains to be replicated in other laboratories as well as showing a good correlation with radiolabeled recovery and survival studies in healthy subjects. Valeri and others have used the macaque monkey or baboon for evaluation of platelet preparations.<sup>145,146</sup> Again, the outcomes are useful but have not been accepted in lieu of human trials. Therefore, the complexity and expense of these studies is often a deterrent to the use of these species.

Demonstration of adequate safety and efficacy of platelets for transfusion remains a significant endeavor. Almost all tests listed above—from pH determined in the laboratory to CCI determined in patients—are surrogate measures of the ultimate clinical requirements for the transfused platelet component. Even the functional requirements of the platelet in the patient are elusive because the indications change from prophylactic use in ablative therapies, to chronic depletion in ITP, to blunt or penetrating trauma. Novel platelet products are difficult to clearly judge as

FDA, scientists, and commercial concerns all attempt to identify appropriate performance criteria. Clinical bleeding assessments are difficult to compile as consistent, precise outcomes. Heddl and others have discussed various clinical bleeding outcome methods such as days of bleeding and a recurrent event model that may find utility in these types of studies.<sup>147</sup> This remains an area where more research into appropriate clinical outcomes is needed.

The development rate of new methods does not seem to be slowing, and includes new methods to prepare components from whole blood,<sup>148</sup> pathogen reduction methods,<sup>5</sup> storage bag material changes, platelet storage solutions, novel platelet components, and evaluation of platelet substitutes.

### Specific Issues in Radiolabeling Studies

The specific procedural and methodologic details of platelet labeling studies have been examined and refined by several groups and are specifically detailed elsewhere.<sup>131</sup> Strict adherence to these methods will increase the intralaboratory precision of the technologies. Key methodologic items are the gravimetric determination of all sample volumes, determination of and correction for in-vivo radionuclide elution, and determination and correction for in-vivo baseline levels 10 to 12 days following infusion. The background and rationale for these corrections are discussed by Taylor and colleagues.<sup>23</sup> Simultaneous study of control and test platelets avoids the potential intrasubject effects that may be present over time such as a subclinical illness, described by Holme et al.<sup>35</sup>

Study design is key to permitting a clean hypothesis test and accounting for intersubject variability. Keegan et al<sup>149</sup> described the significant variability that may be observed among subjects. Although there may be various biological sources of variation between individuals such as spleen size or other aspects of the RES, some feel the most likely cause is a calculation bias imposed from poor blood volume estimates. Whatever the sources, however, the beauty of the paired design is that these effects within a subject will “cancel out” and provide a good estimate of platelet treatment effects with a smaller number of subjects than an unpaired study, as described by Dumont.<sup>150</sup> A randomized design provides further assurance of a prognostic balance between study arms.

The choice of fresh platelets prepared with a tube method as the control in studies has been the source of many animated discussions. The key advantage of this selection is the provision of a control preparation that will be consistent over time and subject neither to changes in medical device development nor variations between devices from different manufacturers. Yet, it is important to recognize that the question being asked in any given study (eg, one not leading to regulatory review) may direct that a different control be selected. For example, it may be of interest for the investigator to evaluate the difference between platelet treatment methods X and Y. Instead of comparing both X and Y to fresh, “en tube” autologous platelets, the investigator may wish to compare X and Y directly.

The analysis of platelet kinetic studies has taken many forms. The BEST Collaborative approach has specifically described a uniform method for initial data correction including adjustment for baseline levels, non-cell-bound radionuclide, and radionuclide elution in vivo. Specifically testing the difference between the two study arms by using methods such as paired t-test reduces the measurement variation and allows power to be maintained for small sample sizes. For example, studies powered on the difference in control and test can be conducted with as few as seven subjects to detect a difference of 20% recovery with 80% power with a Type I error of 0.05.

Interlaboratory variation in multicenter studies is always a concern to investigators, study sponsors, and, if applicable, regulatory reviewers. In a study evaluating the difference between 5- and 7-day stored platelets, Dumont et al<sup>151</sup> observed a 12% difference in recoveries between two laboratories. However, because the study design was paired within each subject, the interlaboratory difference did not affect the final hypothesis test. Whether this difference was because of a systematic difference in laboratory methods or subject characteristics is not known. The application of a common method between laboratories should help avoid large systematic differences. The need for laboratory proficiency evaluation as a means to qualify a laboratory to participate in this type of study has not been addressed. For the present, this is not a requirement.

### Safety

The laboratory that performs these studies must have proper procedures and practices for compliance with local, state, and national requirements for handling, dispensing, and disposal of radionuclides. These procedures safeguard users in the laboratory, the general public, and the study subjects. Procedures are generally well defined within each institution with oversight by a radiation safety committee. The welfare of the study subject is the responsibility of the principal investigator with oversight of the local institutional review board and, in the United States, the FDA. Because the use of a radionuclide as a radiopharmaceutical is approved by the FDA only for use in diagnosis and treatment in patients, use in study subjects requires FDA approval either through an investigational device exception or an investigational new drug approval.<sup>152</sup> The doses for these studies are very low (10-40  $\mu$ Ci or 0.37-1.48 MBq) and deliver an estimated total body dose of generally less than 0.24 mSv. This maximum dose is equivalent to four chest x-rays or about one-tenth of the annual exposure for a resident of the continental United States.<sup>153</sup> It is important to track total exposure of study subjects to ensure they do not exceed the annual radiation dose limit permitted, which is 5000 mrem or 50 mSv whole body dose according to the US Nuclear Regulatory Commission.<sup>154</sup> There has not been a report of any adverse events directly attributable to the use of radionuclides in studies such as this. Females of childbearing potential must be screened to ensure they are not pregnant at the time of infusion. Other potential risks to the subject participating in these studies are complications associated with venipuncture,

phlebotomy, apheresis, and infusion of blood components, such as infiltrations, infection at the venipuncture site, hypocalcemia (if anticoagulant is reinfused during the collection procedure), bacterial contamination of the blood component, fever, and chills. Such complications are rare in this setting. There may be additional concerns specific to any secondary treatment of the platelet and the teratogenicity, carcinogenicity, or mutagenicity of the product or byproducts of chemicals or reagents used in the treatment. This aspect must be investigated by the study sponsor before consideration for use in human subjects. The subject must be appropriately informed of these risks and the steps in place for their mitigation as part of the informed consent process.

### Alternatives to Radionuclides for Labeling and Determination of Platelet Kinetics

Biotin is a water-soluble vitamin also known as vitamin H or vitamin B<sub>7</sub>. Biotin is used extensively in immunologic, molecular, and biological assay systems to tag and track molecules. Biotin forms a specific and very strong interaction with avidins [dissociation constant ( $K_d$ ) is approximately  $4 \times 10^{-14}$  M for streptavidin], thus permitting highly specific detection of biotin-labeled cells in even a very dilute milieu.<sup>155</sup> As an alternative to radioisotope labeling of blood cells, biotinylated blood cells can be labeled with a streptavidin-fluorochrome conjugate and detected using flow cytometry. Biotin has been used to label red cells for estimating circulating red cell volume in infants and determining red cell recovery and survival.<sup>156,157</sup> Investigators have biotinylated platelets in several animal models, and its use for monitoring in-vivo platelet survival has been reviewed.<sup>158</sup> Ault and Knowles biotinylated murine platelets in-vivo, measured the life span of mature and reticulated platelets, and demonstrated that reticulated platelets are the youngest platelets in circulation.<sup>159</sup> Two groups have shown that two populations of platelets labeled with different biotin densities or levels per population could be simultaneously followed in the rabbit.<sup>160,161</sup> Valeri and Barnard have successfully used biotinylated platelets to measure the survival of various platelet preparations in the baboon.<sup>162,164</sup> Stahlawetz and colleagues tracked biotinylated platelets in vivo in humans to evaluate the effects of nitric oxide treatments on the platelet.<sup>165</sup>

Use of biotinylated platelets in humans has not been extensively applied, in part because of the concern for neoantigen formation in the subject. Cordle et al<sup>166</sup> observed IgG antibody formation in 3 of 20 healthy subjects exposed to biotinylated red cells. The plasma reactivity of these antibodies waned over time, and no clinical adverse events were observed. This raises the theoretical concern that there could be a cross-reactivity of these antibodies to a subject's own platelets or red cells, reminiscent of the effect observed with pegylated thrombopoietin, PEG-rHuMGDF.<sup>167</sup> For studies in neonates, there is a strong desire to avoid the use of radioisotopes, and thus investigators strongly prefer biotin labeling as the better choice to study blood volume and cell kinetics in this group of patients. Investigators using biotin in humans should follow the subjects for the formation of

biotin antibodies as a safety precaution. In addition to neoantigen formation, the presence of naturally occurring antibodies in a research subject would have unknown effects on platelet survival.<sup>168</sup> These two issues have hampered the adoption of biotin as a platelet marker.

Investigators have also used lipophilic compounds conjugated to a fluorochrome for labeling platelets. Rand compared two such compounds (PKH26-GL and PKH67-GL) to biotin-labeled platelets in the rabbit.<sup>161</sup> Michaelson used PKH2 to track the turnover of activated platelets in the baboon.<sup>169</sup> The compounds have not been used for in-vivo platelet studies in humans.

Hughes used the discordant expression of the HLA-A2 antigen on platelets to determine the survival of platelets in an allogeneic setting.<sup>170</sup> This approach, using this or other antigen systems, is intriguing for determining the kinetics of platelets in a patient without needing a specific label applied ex vivo before infusion. Further work is needed to correlate results obtained in this manner with standard, radiolabeled infusions. Allogeneic transfusions are not used in healthy volunteers for the determination of platelet survival because they raise ethical concerns related to transfusion reactions and the transmission of infectious diseases. However, use of this approach in stable patients requiring transfusions may provide a new, simple means of tracking novel platelet preparations in those for whom they are intended. The altered kinetics seen in a thrombocytopenic patient model, however, will need to be taken into account.<sup>136</sup>

# Autoimmune Hemolytic Anemia and Paroxysmal Nocturnal Hemoglobinuria

**Thomas P. Duffy**

Professor of Medicine, Department of Internal Medicine and Hematology, Yale University School of Medicine, New Haven, Connecticut, USA

Autoimmune hemolytic anemia (AIHA) and paroxysmal nocturnal hemoglobinuria (PNH) represent a group of disorders characterized by accelerated red cell destruction. The first is secondary to the presence of autoantibodies directed against self-antigens on red cells. The second is characterized by increased sensitivity of red cells to complement-mediated lysis. The first description of an autoimmune hemolytic disorder was Donath and Landsteiner's description in 1904 of three cases of paroxysmal cold hemoglobinuria (PCH). Dameshek and Schwartz created the first experimental model of immune hemolytic anemia (IHA) in 1938 by inducing hemolytic anemia in guinea pigs following the injection of heterologous red cell antibodies. In 1943, Dacie and Mollison showed that patients with acquired hemolytic anemia had an intrinsic factor (presumably an antibody) that caused increased red cell destruction. The introduction of the antiglobulin test in 1945 by Coombs et al permitted the identification of the immune etiology of AIHA and established the foundation of immunohematology. Its subsequent application in patients with acquired hemolytic anemia by Boorman et al and Loutit and Mollison in 1946 firmly established the importance of red cell autoantibodies in the pathogenesis of AIHA. Subsequent refinement of the antiglobulin test permitted detection of immunoglobulin classes and complement components on the red cell membrane, and dissection of the pathophysiology of the different forms of AIHA resulting from the different immune sensitizations.<sup>1</sup>

Since PNH was first described in 1882 by Paul Strubling, several hundred cases have been reported with parallel incremental advances in knowledge of the pathophysiology and clinical course of this rare disease.<sup>2</sup> This complement-mediated hemolytic anemia has its origin in the absence of a whole class of membrane-based proteins, including those responsible for protection of cells from random complement activation. The spectrum of this disease includes aplastic anemia and leukopenia with thrombosis as the leading cause of mortality.<sup>3</sup>

## Classification of Autoimmune Hemolytic Anemias

AIHAs are divided into warm and cold autoantibody types based on the temperatures at which the antibodies maximally react with red cells in vitro. Warm autoantibodies are more reactive at 37°C than at lower temperatures, whereas cold autoantibodies react optimally at 0°C to 5°C and less strongly at higher temperatures. These two principal types are further subdivided into primary (or idiopathic) forms and secondary forms, which are associated with an underlying disorder (Table 22-1).

**Table 22-1.** Classification of Autoimmune Hemolytic Anemia

### Warm Autoantibody Type

- Idiopathic
- Secondary: lymphoma, chronic lymphocytic leukemia, hairy cell leukemia, systemic lupus erythematosus, other autoimmune disorders, ovarian tumors, chronic inflammatory disorders, following hematopoietic, cardiac, and solid organ transplantation

### Cold Autoantibody Type

- Cold hemagglutinin disease
  - Idiopathic
  - Secondary
    - Transient (acute): *Mycoplasma pneumoniae* infection, infectious mononucleosis, other infections
    - Chronic: lymphoreticular malignancies
- Paroxysmal cold hemoglobinuria
  - Idiopathic
  - Secondary: viral and other infections, syphilis

### Drug-Induced Immune Hemolytic Anemia

- Drug adsorption (hapten) type, eg, penicillin
- Drug-dependent antibody type (also referred to as immune complex), eg, second- or third-generation cephalosporins
- Autoimmune induction type, eg, α-methyl dopa
- Nonimmunologic adsorption of protein, eg, cephalothin

Lymphoproliferative disorders are present in about half of the secondary warm and cold AIHAs with systemic lupus erythematosus (SLE), antiphospholipid antibody syndrome, and other autoimmune disorders accounting for a majority of the remaining warm types. Transient, acute cold hemolytic anemias are often seen in association with infections, especially mycoplasma pneumonia and infectious mononucleosis. The proportion of warm vs cold AIHA (20% to 80%) varies widely in reported series.<sup>4</sup> This variation reflects the type of patient population studied and the particular interest and location of the investigators. As patients with assumed idiopathic etiology are observed over time, the likelihood of recognition of an associated or secondary disease increases.

A third category comprises drug-induced IHAs. The drug-induced antibodies, usually of warm type, are directed against the ingested drug or its metabolites bound to the red cell membrane or to a combined drug-red cell membrane antigen. In IHA, the antibody can target a drug or its metabolite or, as with  $\alpha$ -methyl dopa, it can induce the formation of red cell autoantibodies in a fashion analogous to classical AIHA, with hemolysis persisting even in the absence of the offending drug.

## Epidemiology

Autoimmune hemolytic anemias are relatively uncommon, with an incidence of 1 in 80,000 to 100,000 individuals. The warm autoantibody type is the most common. In a study of 347 patients,<sup>5(p29)</sup> this type accounted for 70.3%; cold agglutinin syndrome, 15.6%; PCH, 1.7%; and drug-induced IHA, 12.4%. In a study of 865 patients,<sup>6</sup> warm-type autoantibodies were found in 41%, cold-type in 32%, drug-induced in 18%, PCH in 2%, and mixed warm and cold types in 7%. Mixed AIHA with features of both warm-and cold-type autoantibodies has been found in 6% to 8% of patients in several series.<sup>7</sup> Autoimmune hemolytic anemia affects all ages, with the peak incidence of idiopathic disease in the fourth and fifth decades. Secondary AIHA reflects the age distribution of the underlying disease; lymphoproliferative disorders affect an older age group, whereas SLE involves younger patients. Women have a higher incidence of both idiopathic AIHA and secondary AIHA associated with SLE and other autoimmune disorders.

## Etiology

The development of the autoantibodies results from a breakdown of immunoregulation, possibly determined by genetic factors as seen in the inbred NZB mouse model.<sup>8</sup> The loss of suppressor T-cell regulation of autoantibody production and the presence of overactive B cells lead to the emergence of autoantibodies. Purine nucleoside analog treatment of chronic lymphocytic leukemia (CLL) is not infrequently followed by the development of AIHA via this mechanism.<sup>9</sup> Infection, inflammatory disorders, or drugs often serve as triggers to initiate this process. Viral infections also trigger the onset of AIHA by dramatically increasing the ability of macrophages to phagocytose antibody-coated erythrocytes.<sup>10</sup> Patients with warm-type AIHA sometimes have antinuclear and

antiphospholipid antibodies without clinical manifestations of SLE, or may have symptoms of hemolysis before autoimmune disease is evident. In some instances, the autoantibody is directed against another target, but cross-reacts with red cell antigens. In the cold autoantibody type occurring with mycoplasma pneumonia, cross-antigenicity between the mycoplasma cell wall and the I antigen on the red cell membrane has been suggested.<sup>11</sup> Because I antigens on cells may be receptors for attachment of mycoplasma, the mycoplasma may alter the I antigen to render it more immunogenic.<sup>12</sup> There is, however, little evidence that red cell antigens have been significantly altered to induce immune responses, because eluted antibodies react equally well with normal red cells. Eluted red cell autoantibodies also have been shown to react with the patient's red cells years later, making it unlikely that a drug, virus, or bacteria had altered the red cells during the hemolytic episodes.<sup>13</sup>

The lymphoproliferative disorders associated with AIHA represent a wide spectrum of disease, which includes CLL, Hodgkin and non-Hodgkin lymphoma, hairy cell leukemia, large granular lymphocytosis, angioimmunoblastic lymphoma, and Castleman disease. Common variable immunodeficiency may be the backdrop to AIHA and immune thrombocytopenia. Chronic infections such as subacute bacterial endocarditis and inflammatory states such as ulcerative colitis and biliary cirrhosis may be complicated by warm-type AIHA. Interferon- $\alpha$  treatment in large doses may also give rise to a warm-type AIHA. Familial cases have been reported.<sup>14</sup> More than 30 cases have been recorded in association with both benign and malignant ovarian neoplasms.<sup>15</sup> AIHA also occurs after allogeneic stem cell transplantation<sup>16</sup> as well as after solid organ transplantation<sup>17</sup>; alloimmunization following transfusion may rarely be complicated by AIHA. Infection is a common antecedent to AIHA in children.

## Warm Autoantibody Type

### Pathophysiology

The destruction of red cells occurs by intravascular, extravascular, and cell-mediated mechanisms. The reticuloendothelial system (mononuclear phagocytic system) in the spleen and, to a lesser degree, the liver is responsible for extravascular destruction of red cells. Immunoglobulin G (IgG)-coated red cells in warm-type AIHA are sequestered primarily in the spleen where vascular anatomy greatly enhances red cell interactions with macrophages. The IgG-coated red cells bind to macrophages by specific membrane receptors for the Fc portion of the IgG, subclasses IgG1 and IgG3,<sup>18</sup> and phagocytosis of the entire red cell by the macrophage sometimes follows. More commonly, there is removal of only a portion of the red cell membrane with creation of a microspherocyte released back into the circulation. These altered cells, with a decreased surface area-to-volume ratio, have a greatly shortened life span because of their loss of plasticity and increased osmotic fragility.<sup>19</sup> These cells are eventually destroyed as they obstruct flow in the microcirculation, particularly in the spleen; the presence of microspherocytes in the peripheral blood indicates ongoing hemolysis. Enhanced function of the

mononuclear-phagocytic system and an increase in Fc monocyte receptors also contribute to red cell destruction in AIHA.<sup>20</sup>

Macrophages have IgG Fc receptors only for IgG1 and IgG3<sup>21</sup>; therefore, the quantity and type of IgG on the red cell surface influences the degree of hemolysis. Red cells coated with IgG1 alone or in combination with IgG2 or IgG4 require an average of 2000 molecules of IgG per red cell to stimulate phagocytosis and rosette formation *in vitro*, whereas an average of only 230 molecules of IgG3 per red cell are required for monocyte binding.<sup>22</sup> Removal of red cells is further accelerated when complement is also present on the red cell membrane. Only IgG1 and IgG3 are efficient in activating complement. Because two IgG molecules in close proximity are required to bind C1q and activate the complement system,<sup>23</sup> there must be a sufficient number of antibody molecules and antigenic sites for complement attachment. Once C1 is bound, C4 and C2 are activated to form C3 convertase, which then cleaves C3 and C3b. Several hundred molecules of C3b are bound to the red cell membrane through the action of a single C3 convertase enzyme complex.<sup>24</sup> Macrophages have receptors for C3b and inactivated C3b (iC3b), referred to as CR1 and CR3, respectively.<sup>25</sup> The IgG Fc and complement receptors act together to enhance binding of red cells coated with both IgG and complement. Removal of IgG-coated red cells with or without complement occurs primarily in the spleen. When large amounts of IgG are present on the red cell, the liver also participates in their clearance.<sup>18</sup> The spleen functions as a “fine” filter, the liver a “coarse” filter, of sensitized red cells in AIHA.

Autoimmune hemolytic anemia has also been associated with IgA and IgM warm autoantibodies.<sup>26</sup> IgA-sensitized red cells are removed by the same splenic process as are IgG-coated red cells. Receptors for IgA have been demonstrated on mononuclear phagocytes. Intravascular hemolysis, observed in AIHA associated with IgA autoantibodies, is mediated by the binding of C5b-9 complexes to bystander red cells independent of C3 activation.<sup>27</sup> IgM autoantibodies have been shown to agglutinate or hemolyze normal red cells and enzyme-treated red cells<sup>5(p29)</sup> and to sensitize red cells with or without fixing complement. Using IgM antiglobulin serum in the direct antiglobulin test (DAT), IgM has been detected on the red cells of 8% of patients with warm AIHA, always associated with either IgG, IgA and C3, IgG and C3, or C3. With use of the more sensitive enzyme-linked antiglobulin test, IgM was found on the red cells of 38% of patients with AIHA whose DAT results were positive for IgG.<sup>28</sup> With use of the AutoAnalyzer (Bayer Diagnostics, Leverkusen, Germany), cell-bound IgM was found in 73% of patients with IgG-positive DAT results.<sup>29</sup> Several cases of AIHA with warm-reacting IgM autoantibodies in association with cell-bound C3d have been reported. In one series of children, IgM was detected on the red cells by a radioimmune assay when the DAT result was negative.<sup>30</sup> Severe hemolytic anemia, with or without the presence of IgG, has been noted in patients with warm-reactive IgM autoantibodies exhibiting specificity for sialidase-sensitive red cell antigen determinants En<sup>a</sup>, Pr, and Wt<sup>b</sup>.<sup>31,32</sup>

The quantity of the antibody on the red cell is not always an indicator of the presence or severity of hemolysis, because the interaction of several variables determines the rate of hemolysis. These include the IgG subclass, simultaneous presence of other immunoglobulin classes, affinity of the antibody, activation and presence of cell-bound complement, number of receptors on macrophages for IgG and complement, and chemical and physical characteristics of the antigens on the red cell membrane. Although there is overlap in the amount of IgG antibody on the red cells of patients with or without hemolytic anemia, patients with hemolytic anemia, on average, have more IgG molecules on their red cells.<sup>33</sup> Patients whose red cells are coated with IgA and IgM in addition to IgG are more likely to have hemolysis than those whose red cells are coated with IgG alone.<sup>34</sup> The presence or quantity of IgG3 on the red cell may not distinguish patients with hemolytic anemia from those without hemolytic anemia, but IgG3 is more commonly associated with hemolytic anemia.<sup>35</sup> The presence of autologous IgM may also determine the autoreactivity of IgG in AIHA.

### Autoantibodies and Specificity

In a report of 2000 cases of warm-type AIHA, IgG was found alone in 64% and in association with complement in 33% of cases.<sup>36</sup> IgA or monomeric IgM autoantibodies were each found in about 1% of patients with warm-type AIHA and were frequently accompanied by complement. Warm-type autoantibodies are usually polyclonal, but there can be restrictions in their Gm allotype and/or light-chain type.<sup>37,38</sup> By far the most frequent subclass of IgG warm-type autoantibody is IgG1, which is found in most patients with warm-type AIHA.<sup>36</sup> IgG1 has been found in the majority of patients with AIHA with or without hemolysis, as well as in blood donors with positive DAT results; IgG3 alone has been found in only 3% of patients and in combination with other subclasses in 5%.<sup>39</sup> IgG1 was often the only subclass identified on the red cell. IgG1 was associated with other subclasses in 37% of patients with AIHA and in 12.5% of those without AIHA. The percentage of patients with IgG3 alone was approximately the same for patients with and without AIHA, being 6.3% and 6.6%, respectively. IgG3 was found in only 2.6% of healthy blood donors and in association with other subclasses in 22% of patients with AIHA.<sup>40</sup>

Initially most red cell autoantibodies were thought to be directed to antigens of the Rh system because of weak or negative reactivity with Rh<sub>null</sub> red cells (lacking determinants of the Rh complex) and the observation that some red cell autoantibodies react preferentially with defined Rh antigens such as e, E, or C. It is now appreciated that absent or weak reactivity of autoantibodies with Rh<sub>null</sub> red cells does not always signify specificity to an Rh complex determinant, because Rh<sub>null</sub> red cells also have other membrane abnormalities, including a lack of LW and Fy, a marked decrease of U and to a lesser extent Ss, and glycophorin B levels that are 30% of normal. Eluates nonreactive with Rh<sub>null</sub> cells were shown to contain anti-LW or anti-U reactivity.<sup>41,42</sup> Many patients with AIHA have autoantibodies that

react equally well with Rh<sub>null</sub> red cells and red cells with normal phenotypes, indicating specificity to antigens outside of the Rh system. The target of these autoantibodies in selected patients include (among others) W<sup>r</sup><sub>b</sub>, En<sup>a</sup>, Ge, A, B, and antigens within the Kell and Kidd blood group systems.<sup>43</sup>

The specificity of autoantibodies in the past has been largely determined by serologic techniques. More recently, immunochemical methods have been applied to elucidate better the autoantigens or epitopes in the red cell membrane reactive with autoantibodies. In addition to Rh antigens, membrane protein band 4.1,<sup>44</sup> band 3,<sup>45</sup> and glycophorin have been identified as targets for some red cell autoantibodies.

Another source of confusion is that autoantibodies sometimes have specificity for an antigen such as E, even though the red cells from which they are eluted are negative for E.<sup>46</sup> These antibodies are most likely reacting with an antigen on the red cell that is present in larger amounts on E-positive red cells. These antibodies are termed mimicking antibodies, because they seem to be alloantibodies with anti-E specificity. Autoantibodies also may mimic alloantibodies when the corresponding antigen on the patient's red cell is weak or absent. When the patient is in remission and no longer has the serum antibody, the red cells can be shown to contain normal amounts of the antigen. Furthermore, the stored autoantibody from the patient can be shown later to react with the patient's red cells. This phenomenon has been shown to occur with Rh, LW, Kell, Duffy, Kidd, and En<sup>a</sup>.<sup>47</sup> A naturally occurring IgG autoantibody has been demonstrated in the sera of healthy persons that is specific for a senescent red cell antigen that appears as the red cell ages and is a degradation product of band 3.<sup>48</sup> A case of AIHA associated with autoantibodies to stored red cells has been reported in which the autoantibody was inhibited by a synthetic senescent red cell antigen.<sup>49</sup> Some autoantibodies have been shown to react more strongly with immature red cells than with mature red cells.

Autoantibodies have been noted after transfusion,<sup>50</sup> sometimes weeks to months after a delayed transfusion reaction. Alloimmunization has been suggested as a stimulant for autoantibody formation usually not accompanied by hemolysis.

Autoantibodies to phospholipids have been demonstrated on the red cell membrane and may account for the DAT-positive hemolytic anemia found in some patients with primary antiphospholipid syndrome or antiphospholipid syndrome secondary to SLE.<sup>51</sup> Eluates were shown to contain IgG with anticardiolipin reactivity. Antiphospholipid antibodies directed to the red cell membrane may explain the finding of IgG and complement on the red cells of some patients with SLE.

A population of IgG molecules was identified on the red cells of DAT-positive healthy blood donors that reacted with IgG red cell autoantibody but not with the red cell membrane. Radiolabeled IgG autoantibodies in eluates prepared from IgG DAT-positive blood donors and adsorbed using nonhuman and human red cells with common and rare phenotypes contained several populations of autoantibodies.<sup>52</sup> Some were bound to human red cells of common Rh phenotypes, and another, in addition to binding

to Rh red cells, also was bound to Rh<sub>null</sub> red cells. Approximately 30% of the IgG in the eluates was not adsorbed. Subsequent studies showed that some of the nonadsorbable IgG in the eluates had auto-anti-idiotypic-like reactivity in that it was able to agglutinate red cells sensitized with F(ab')<sub>2</sub> prepared from alloanti-D sera.<sup>53</sup> Further studies are required to determine whether this antibody reacts with the epitope or with Fab of the red cell autoantibody. Auto-anti-idiotypic antibodies to red cell autoantibodies have been described in NZB mice with AIHA, suggesting that the idotype-anti-idotype network affects immune regulation. The demonstration of autoidiotypic antibodies in healthy blood donors with positive DAT results and their absence in DAT-positive patients with AIHA suggest that these autoantibodies have a protective effect.

### Clinical Features

The clinical picture of warm-type AIHA is highly variable. Most patients seek treatment for symptoms attributable to anemia, such as fatigue, palpitations, and shortness of breath, but occasionally massive hemolysis manifested by hemoglobinemia, hemoglobinuria, and profound anemia is seen at onset with secondary AIHA. The associated illness often dominates the clinical picture. Autoimmune hemolytic anemia, however, may precede by months or even years the development of a disease such as SLE. Physical findings in idiopathic AIHA are related to the degree of anemia and include pallor, resting tachycardia, and mild jaundice; fever may be present in AIHA. The spleen is usually only moderately enlarged. When there is massive splenomegaly, an underlying lymphoproliferative disorder should be considered. The degree of anemia is variable and depends partly on the compensatory capacity of the marrow to respond to the increased rate of red cell destruction. Reticulocytopenia accompanying hemolytic anemia is particularly life threatening. Parvovirus infection may compound the threat of AIHA by creating red cell aplasia and absolute reticulocytopenia.

### Laboratory Features

Peripheral blood smears show microspherocytes, polychromasia, and nucleated red cells. The presence of spherocytes indicates ongoing red cell destruction. Rosettes of red cells around white cells and erythrocytes may be seen in a buffy-coat preparation; erythrophagocytosis by circulating monocytes is sometimes present. Marrow examination reveals erythroid hyperplasia, as well as increased numbers of lymphocytes or plasma cells in patients who have underlying lymphoproliferative or collagen vascular diseases. Flow cytometry of the marrow sometimes identifies a clonal population of lymphocytes even when morphologic evidence of lymphoma is not evident. The reticulocyte count is usually elevated, above the normal level of 1.5% to 2%; the red cell mean corpuscular volume is often increased to a macrocytic range. Superimposed folate deficiency can dampen or even eliminate the compensatory reticulocytosis. A rare patient will have persistent reticulocytopenia caused by inadequate marrow response or hemolytic destruction of

erythroid precursors within the marrow. Unconjugated bilirubin is usually, but not always, elevated, and urinary urobilinogen is increased. Serum haptoglobin levels are reduced or absent. With severe hemolysis, hemoglobinemia, hemoglobinuria, and urine hemosiderin can be present. Mild leukocytosis (predominantly neutrophilia) is usually seen, sometimes with thrombocytosis. Neutropenia and thrombocytopenia, however, are occasionally found. The combination of autoimmune thrombocytopenia and AIHA is referred to as Evans syndrome, usually a complication of a lymphoproliferative disorder, collagen vascular disease, or common variable immunodeficiency. If hemolysis is equivocal, conducting a red cell survival study with chromium-51-labeled red cells or measuring endogenous carbon monoxide production provides needed information. The role of the spleen in the hemolytic process can be assessed during the course of the red cell survival study by comparing isotope uptake between liver and spleen; predominantly splenic uptake anticipates a favorable response to splenectomy.

### **Antiglobulin Tests**

The diagnosis usually depends on the demonstration of a positive DAT result, indicating the presence of immunoglobulin or complement components or both on the red cell surface. A positive DAT result is often seen without hemolysis. The DAT is performed by the addition of an antiglobulin serum to washed red cells, leading to agglutination when the antibody, complement, or both are present on the red cell surface. A broad-spectrum antiglobulin reagent that contains antibodies for IgG immunoglobulins and complement components is recommended. When the test is positive, antiglobulin reagents specific for IgG or C3 are used to determine the presence of IgG or complement on the red cell. The anticomplement reagent should recognize the complement fragment C3d, which remains on the red cell surface. In special situations, antisera specific for IgA and IgM is used to demonstrate their role in the rare cases of AIHA caused by these immunoglobulin types. By the use of anti-IgG and anti-C3, three basic patterns of sensitization are observed: IgG alone, IgG plus C3, or C3 without detectable immunoglobulin. In several series of patients with warm-type AIHA, the frequency of IgG alone ranged from 18% to 64%; that of IgG plus C3, from 34% to 65%; and that of complement alone, from 10% to 33%.<sup>5(p193),36</sup>

An indirect antiglobulin test (ie, red cell antibody screen) detects free serum antibody. This test is performed by incubating a patient's serum with compatible washed donor red cells at 37°C. The donor red cells are then washed and incubated with an antiglobulin reagent to detect any serum antibodies that have adhered to the donor cells. The presence of free serum autoantibody depends on the dissociation constant of the autoantibody. It is rare to find a positive indirect test result in the absence of a positive DAT result; however, a positive DAT result is not infrequently accompanied by a negative indirect test result. With the use of enzyme-treated donor red cells, however, autoantibodies have been demonstrated in the serum of patients with AIHA

who had negative DAT results. Care must be taken in interpreting the finding of a positive indirect antiglobulin test result, because it may represent an alloantibody stimulated by previous transfusion or pregnancy, binding to transfused red cells with the target antigen. These alloantibodies must be identified by adsorption studies to ensure compatibility of red cells intended for transfusion.

### **Negative DAT Results in Patients with Warm-Type AIHA**

A small number of patients have clinical AIHA but negative DATs. They usually respond to steroid therapy, with improvement of their hemolytic anemia similar to that of patients with positive antiglobulin tests. The frequency of DAT-negative AIHA has been reported in 2% and 4% of cases, but is probably much lower when more sensitive serologic techniques for cell-bound antibody are used. The manually performed DAT requires about 300 to 500 molecules of IgG per cell, based on quantitative studies of IgG red cell autoantibodies.<sup>54</sup> Using an antibody consumption test, small amounts of IgG antibody were found on the red cells of some patients with DAT-negative hemolytic anemia.<sup>54</sup> IgG was also detected on the red cells of some patients who had the complement-alone pattern.<sup>55</sup> Using an enzyme-linked antiglobulin test and a radioimmune assay, 158 patients with AIHA had red cells with 200 or fewer molecules of IgG per cell. Two hundred molecules of IgG per cell was the threshold in this laboratory for a positive DAT result.<sup>56</sup> A significant correlation between small increases of cell-bound immunoglobulins and hemolysis was shown in the 25% of patients with evidence for immune-mediated hemolysis. Several of these patients had complement and small amounts of IgA and IgM in association with the IgG. A sensitive radioactive antiglobulin test detected IgG in four of six patients with DAT-negative AIHA.<sup>57</sup> IgG was also detected on the red cells of 13 of 20 patients whose DAT results were positive only for C3. As few as 70 molecules of IgG per red cell were measured using a radiolabeled, purified staphylococcal protein A assay.<sup>58</sup> IgG was detected on the red cells of three of nine patients with DAT-negative AIHA. A two-stage immunoradiometric assay using radiolabeled staphylococcal protein A has been described.<sup>59</sup> In this assay, red cells were initially incubated with unlabeled antiglobulin serum. If red cell autoantibodies were present, the antiglobulin antibodies would bind to the autoantibodies and be detected in the next stage with radiolabeled staphylococcal protein A. A simpler and more readily available test that does not quantitate but is capable of detecting small amounts of autoantibody below the threshold of the DAT is the Polybrene test.<sup>60</sup> Polyvalent cation hexadimethrine bromide (Polybrene) reduces the electrostatic repulsive charges on the red cells, permitting the cells to come closer together. Antibodies from one cell can then cross-link another cell, leading to agglutination that will remain after neutralization of Polybrene with a citrate resuspending solution. In a study comparing these sensitive tests, no one assay detected all patients having small quantities of IgG.<sup>61</sup> Detection is increased with a combination of tests (eg, Polybrene and an enzyme-linked antiglobulin test or flow

cytometry). Even with these sensitive techniques, an antibody sometimes cannot be detected in patients suspected of having AIHA. With the use of a gel test with anti-IgA, these DAT-negative AIHA cases are often demonstrated to be mediated by IgA autoantibodies.

#### **Positive DAT Results in Patients without Hemolytic Anemia**

The frequency of positive DAT results was 1 in 14,000 healthy blood donors in one study.<sup>62</sup> A much higher frequency of 1 in 1000 also has been reported, although many of the DATs were only weakly reactive. The subclass of IgG on the red cell in these DAT-positive healthy blood donors is mainly IgG1. IgG3 was found in only one donor. Complement alone (C3d and C4d) was found in approximately 45% of healthy blood donors. With sensitive techniques, small amounts of C3d and both C3d and C4d have been found on all normal red cells. The quantity of C3d as measured by radioimmunoassay ranged from 50 to 160 molecules per cell, which is below the amount detectable by conventional antiglobulin tests. The presence of these complement fragments on normal red cells is thought to represent continuing low-grade activation of the complement system. The DAT for complement should be performed on freshly collected EDTA-preserved blood, because the amount of C3d and C4d on the red cell increases when clotted blood is refrigerated.<sup>63</sup>

Positive DAT results for IgG are frequently found in patients receiving  $\alpha$ -methyl dopa and are usually not associated with hemolysis. C3d has been found on the red cells of children with *Plasmodium falciparum* malaria.<sup>64</sup> In two recent studies, the frequency of positive DAT results in patients with AIDS was found to be 18% and 21%, respectively.<sup>65,66</sup> In another series, 85% of patients with AIDS were found to have positive DAT results.<sup>67</sup> Red cell sensitization was attributable to varying combinations of IgG, IgM, and complement, as well as each alone. Eluates from these cells did not show anti-red-cell activity. Positive DAT results were thought to be attributable to immune complexes attached to the red cell via the CR1 receptor. In the same study, red cell CR1 receptor activity correlated inversely with a positive DAT result. Red cells from these DAT-positive patients had increased osmotic fragility and were also found in patients with SLE and circulating immune complexes, low red cell CR1 activity, and positive DAT results.<sup>68</sup> On the other hand, several cases of hemolytic anemia have been noted in AIDS and human immunodeficiency virus (HIV)-related diseases in which red cell destruction was mediated by red cell autoantibodies.<sup>69</sup> Some of these cases had reticulocytopenia despite erythroid hyperplasia of the marrow.

#### **Concomitant Warm-Type and Cold-Type AIHA**

Patients have been reported with both warm autoantibody AIHA and cold agglutinin disease.<sup>70</sup> The DAT shows both IgG and C3. The cold agglutinin titer is usually high, being greater than 1:1000 at 4°C, and the thermal amplitude of the cold agglutinin is above 30°C. Eluates from these patients' red cells contain an IgG warm-type autoantibody. In other cases of mixed-type

AIHA, the titer of IgM cold agglutinins at 4°C was less than 64, and the cold agglutinins reacted with red cells at 30°C or higher. In these patients, exposure to cold did not increase hemolysis, and treatment with glucocorticoids was effective. Hemolytic anemia tends to be severe, having a chronic course with intermittent exacerbations. In most instances, patients respond to glucocorticoids, splenectomy, or cytotoxic agents. Lymphoma and SLE are frequently associated disorders.

#### **Autoimmune Hemolytic Anemia in Children**

Autoimmune hemolytic anemia in children is either an acute, transient, self-limited disease or a prolonged chronic disorder, with the former much more common. The peak incidence is in the first 4 years of life, particularly with transient disease, which often follows well-defined viral illnesses. Patients usually recover in less than 3 months. The DAT detects only complement in the majority of these patients. Donath-Landsteiner (D-L) antibodies associated with PCH are present in some patients, but in others no antibody is found. Autoimmune hemolytic anemia of the cold hemagglutinin type is unusual. The response to glucocorticoids is rapid and constant, but their necessity may be questioned in transient self-limited cases.

Children with chronic prolonged hemolytic anemia tend to be older, and the onset is more insidious. The DAT usually shows IgG or IgG and complement. Hemolytic anemia may be intermittent or persistent for months or years and has a variable response to glucocorticoids. The hemolytic anemia is controlled in some patients by splenectomy. The overall mortality in one study of patients with chronic disease was 11.2%.<sup>71</sup>

#### **Treatment**

##### **Transfusion**

Treatment with glucocorticoids usually leads to stabilization and improvement. Because the intravascular blood volume is typically normal in these patients, the decision to transfuse is based solely on the need to increase the oxygen-carrying capacity of the blood. Transfusions should be reserved for those patients at risk because of underlying heart disease, cerebrovascular ischemia, or life-threatening anemia; care must be taken to avoid producing pulmonary edema by transfusing red cells in elderly anemic individuals whose plasma volume is already increased. Simultaneous administration of diuretics should prevent this complication. Polymerized bovine hemoglobin has been used successfully to maintain adequate oxygenation in a patient with severe AIHA; heightened research in this field is occurring to identify means of transfusion that dispense with the encumbrances of typing and crossmatching blood but no solution to this problem has yet been identified.<sup>72,73</sup>

The major problem with transfusion is the difficulty of crossmatching, because the autoantibody may result in a positive antibody screening test and an incompatible crossmatch. An alloantibody masked by the presence of the autoantibody is the major concern. Red cells from the patient should be used to adsorb the autoantibody from the patient's serum, which

can be done only in a patient who has not received a transfusion within the past 3 months. If the patient has been transfused recently, adsorption with several heterologous cells and/or a cell phenotypically matched to the patient may be performed. The adsorbed serum then can be tested for the presence of an alloantibody. The patient's red cells also should be saved for subsequent adsorptions, should further transfusions be required, and phenotyped to help identify which alloantibodies the patient could make. If an alloantibody is identified, then donor Red Blood Cell (RBC) units lacking the target antigen should be chosen for transfusion. Otherwise, the most compatible blood should be given. If the autoantibody has apparent specificity for a defined blood group antigen, then donor RBC units lacking that antigen may be chosen. However, this practice is not universal because it is recognized that even antigen-negative RBC units may be hemolyzed. It also is not practical when the autoantibody appears to have specificity for a very high-incidence antigen.

The patient is slowly given red cells in suspension and closely monitored for signs of increased hemolysis. The transfused red cells are usually destroyed as rapidly as the patient's own red cells unless the patient has responded to glucocorticoids. The notion that blood transfusion should be avoided because of the high incidence of alloimmunization and worsening of hemolysis has been refuted.<sup>74</sup> No alloantibodies related to the transfusion developed in 53 patients with decompensated AIHA who received blood, nor did any of the patients have an increased rate of hemolysis. Despite this observation, transfusion should be reserved only for those patients with life-threatening anemia; conversely, no patient should be deprived of transfusions when severe anemia complicates AIHA.

### Glucocorticoids

The patient is immediately given a short-acting glucocorticoid. The initial dose of prednisone is usually 60 mg/day, given in three divided doses, for the first 10 to 14 days. The majority of patients will have marked improvements, with decreased hemolysis and stabilization, followed by an increase in hematocrit. At this time, prednisone is consolidated to a single morning dose and reduced by 10 mg/week until a dose of 40 mg/day is reached. If clinical improvement is sustained at this dose, the prednisone is then reduced by decrements of 5 mg/week until 20 mg/day is reached. At this time, the dose can be further reduced by decrements of 2.5 mg/week, depending on the clinical response. In some patients the dose cannot be further reduced because of increasing hemolytic activity, and these patients continue to receive 15 to 20 mg/day. To reduce the side effects of glucocorticoids, an alternate-day regimen can be tried. Patients who require more than 20 mg/day to control their hemolytic anemia after 2 to 3 months of treatment should be considered for splenectomy or other treatment.

Approximately 70% of patients show improvement with prednisone treatment, with 15% to 20% going into complete remission, which allows prednisone to be discontinued. Others require less than 20 mg/day to control their disease. About 10%

of patients have little or no response to the initial high doses of prednisone. In these patients, higher doses of prednisone in the range of 80 to 100 mg/day can be tried. Another option is to use pulse steroid therapy, giving high-dose dexamethasone 40 mg for 4 days monthly.<sup>75</sup> The patient is then placed back on a maintenance level of prednisone, which is reduced according to the clinical response.

Several mechanisms have been proposed for the beneficial effect of prednisone. Its most immediate action is to decrease red cell destruction by interfering with monocyte-red cell interactions in the spleen and liver.<sup>76</sup> A later action is a reduction of the autoantibody. Prednisone also may act by decreasing the binding affinity of the autoantibody for red cell antigens.

### Splenectomy

Splenectomy is considered in a patient who either has not initially responded to high doses of glucocorticoids or subsequently requires more than 15 to 20 mg/day for control of the hemolytic disease. The decision for splenectomy should be delayed until the patient has had an adequate trial of prednisone (usually 1 to 2 months). The exception is the patient with little or no improvement when receiving high doses of prednisone (60 mg/day or more) for 2 to 3 weeks, in whom splenectomy is performed sooner. Based on a large number of reports, approximately two-thirds of patients will show a complete or partial response to splenectomy. Unfortunately, some patients relapse months or years after splenectomy. In most patients the dose of prednisone can be reduced or even discontinued after splenectomy. The response to splenectomy is significantly better in patients with idiopathic AIHA than in secondary cases; splenectomy in the latter must be recommended cautiously.<sup>77</sup>

Splenectomy removes the major site of red cell destruction in warm-type AIHA, as well as a site for antibody production (as in autoimmune thrombocytopenic purpura).<sup>78</sup> Patients may show a decrease, no change, or an increase in cell-bound antibody.<sup>79</sup> The morbidity and mortality from splenectomy are low; laparoscopic removal of spleens is now common with shortened postoperative recovery. Pneumococcal vaccine is recommended before splenectomy but also may be of value afterward.<sup>80</sup> Postsplenectomy thrombocytosis may occur and persist chronically with the complication of thrombosis; pulmonary embolism may be a cause of death in splenectomized patients with AIHA. Anticoagulation is not routinely recommended after splenectomy for patients with AIHA, but is indicated for those patients who have been shown to have antiphospholipid antibodies also.

### Rituximab

The monoclonal CD20 antibody is being used increasingly in the treatment of immune cytopenias and Evans syndrome.<sup>81</sup> This therapy was once administered only to patients who had failed splenectomy and were refractory to steroids. Because of its efficacy and excellent toleration, it is now being administered in AIHA patients before splenectomy. Its dosing at 375 mg/m<sup>2</sup> weekly for 4 to 6 weeks is the same as that used in lymphoma

regimens. In patients who respond to this intervention, maintenance therapy with smaller doses at less frequent intervals is being administered.

### Immunosuppressive Therapy

Cytotoxic drugs are also effective.<sup>82</sup> They should be reserved for patients who have not responded to glucocorticoids and splenectomy or who are poor surgical risks for splenectomy. A favorable response to a cytotoxic drug allows reduction of the steroid dose. The drug is tapered and discontinued if there has been little or no response by 4 to 6 months. The most commonly used cytotoxic agents are azathioprine (1 to 2 mg/kg/day), cyclophosphamide (1 to 2 mg/kg/day), and chlorambucil (0.1 to 0.2 mg/kg/day). Intravenous cyclophosphamide, which has been shown to be effective in the treatment of lupus nephritis, also may be of benefit in AIHA. The dosage schedule is 0.5 to 1 g/m<sup>2</sup> of body surface area given at 1- to 3-month intervals, depending on the clinical response, marrow tolerance, and leukocyte nadir (no fewer than 2000 cells/ $\mu$ L). The initial dose is 500 mg/m<sup>2</sup>. The drug is administered in 1 hour, followed by 24 hours of hydration to ensure frequent voiding to reduce bladder toxicity. White cell counts must be closely monitored. Colony-stimulating factor administration helps reverse leukopenia after chemotherapy. The long-term use of these drugs is associated with an increased risk of subsequent neoplasia. Cyclophosphamide can cause alopecia, sterility, hemorrhagic cystitis, and bladder cancer.

### Other Treatments

Other forms of treatment that have exhibited variable success include danazol, cyclosporine, mycophenolate, antilymphocyte or antithymocyte globulin, vinblastine-loaded platelets, and plasmapheresis. Cyclosporine, 4 mg/kg/day, has been used in AIHA with some success.<sup>83</sup> Patients should be monitored closely for renal toxicity. Intravenous  $\gamma$ -globulin is effective less frequently than in immune thrombocytopenic purpura.<sup>84</sup> The usual dose is 400 mg/kg/day for 5 days, followed by single doses as needed. One rationale is that blocking the Fc receptors on macrophages within the reticuloendothelial system prevents trapping of IgG-coated red cells. Another therapeutic strategy is selectively injuring macrophages by exposing them to transfused platelets sensitized with IgG platelet antibodies and loaded with vincristine.<sup>85</sup> Danazol, a synthetic androgen, also has been effective.<sup>86</sup> The initial dose is 600 to 800 mg/day, tapered to 400 mg/day once the patient has a clinical response. Side effects include mild masculinization and cholestatic jaundice. Mycophenolate has recently been reported to be successful in AIHA<sup>87,88</sup>; it is introduced in dosing of 500 mg daily and increased to 1 g once or twice daily as tolerated. Patients with persistent hemolysis should be given 1 mg of folic acid daily. Plasmapheresis is only a temporizing maneuver in the treatment of AIHA because this intervention is only weakly effective in reducing the level of IgG autoantibody in the plasma.

### Cold Autoantibody Type

Cold-type autoantibodies react most strongly with red cells at 0°C to 5°C but achieve clinical significance when their thermal

range of reactivity extends to 28°C to 31°C or higher. These are the temperatures encountered in the microvasculature of the skin, particularly in the distal extremities, ears, and the tip of the nose. Cold autoantibody types account for 15% to 25% of AIHA in most series.<sup>5(p29),36</sup> There are two basic types of cold autoantibody hemolytic anemia: cold hemagglutinin disease and PCH. Both require complement for red cell destruction and cause intravascular and extravascular hemolysis of varying degrees.<sup>89</sup>

### Cold Hemagglutinin Disease

In 1903, Landsteiner demonstrated that the red cells of an animal could be agglutinated by its sera at temperatures near 0°C. In 1926, Landsteiner and Levine showed that the sera from most healthy persons agglutinated autologous red cells at 0°C. At about this time, Iwai and Mei-Sai reported two patients with Raynaud phenomenon. In one patient, impedance of blood flow was demonstrated in vitro; in the other, sludging of blood flow, resulting from autoagglutination of red cells, was observed in the nail bed capillaries at low temperatures. In the 1950s, the association between cold autoantibodies and hemolytic anemia was established. Schuboth introduced the term "cold agglutinin disease" to distinguish this disorder from paroxysmal hemoglobinuria; the term cold hemagglutinin disease is also used.

Cold hemagglutinin disease occurs in a transient or chronic form. The transient form occurs with mycoplasmal pneumonia or infectious mononucleosis, primarily affecting adolescents or young adults. The antibody is usually IgM and polyclonal. Chronic cold hemagglutinin disease (CCHAD) usually affects persons older than 50 years of age.<sup>90</sup> The majority of these patients have no underlying illness identified; the remainder have lymphoproliferative disorders, including CLL, hairy cell leukemia, lymphomas, and Waldenström macroglobulinemia.

Although most patients with idiopathic CCHAD have IgM monoclonal cold agglutinins, a clinical picture of Waldenström macroglobulinemia or lymphoma develops in very few.<sup>91</sup> Flow cytometry may identify a monoclonal B-cell population in some of these patients without other evidence for lymphoma.

### Cold Agglutinins and Specificity

Cold agglutinins are most often reactive with the Ii blood group system. The Ii antigens are carbohydrates closely related to the ABO and Lewis blood groups and are present on red cells as glycoproteins and glycolipids.<sup>12,92</sup> At birth, cord (neonatal) red cells express large amounts of i. During the first 18 months after birth, the proportion of i antigen decreases, and the expression of I antigen increases. Most individuals predominantly express I on their mature red cells, but rarely do cells express only the i antigen. During maturation of a red cell, I antigen is formed by the action of a branching enzyme on the red cell glycoconjugates. With repeated phlebotomy, the i reactivity of red cells of healthy individuals has been shown to increase, suggesting that increased i reactivity was inversely related to the marrow transit time.<sup>93</sup> Reticulocytes express large amounts of i and reduced amounts of I. When the glycoprotein bearing the Ii antigens is extracted

from the red cell membrane, both anti-I and anti-i react with their respective antigens at 37°C.<sup>94</sup> This indicates that conformational changes in the red cell membrane induced by cold are required for the expression of the Ii antigens.

The autoantibody in patients with idiopathic CCHAD or CCHAD associated with lymphoid malignancy is usually monoclonal IgM. The specificity of monoclonal IgM with  $\kappa$ -light chains is usually directed against the I antigen,<sup>95</sup> whereas IgM cold agglutinins with  $\lambda$ -light chains are usually directed against the i antigen and only rarely against the I antigen.<sup>96</sup> Monoclonal antibodies with IgA or IgG cold agglutinins occasionally have been reported.<sup>97</sup> Cold agglutinins associated with *Mycoplasma pneumoniae* pneumonia and infectious mononucleosis are IgM and polyclonal.<sup>98</sup> Cold agglutinins associated with mycoplasmal infections are usually reactive with the I antigen,<sup>11</sup> whereas in infectious mononucleosis the IgM cold agglutinin is often reactive with the i antigen.<sup>98</sup> Approximately one-third of the cold agglutinins with anti-i specificity are also cryoprecipitable. Some patients with infectious mononucleosis and angioimmunoblastic lymphadenopathy have a cold-reacting nonagglutinating IgG anti-i and an IgM anti-IgG that both agglutinate IgG-coated red cells in the cold.<sup>99</sup>

Other specificities of cold hemagglutinins have been occasionally observed in patients with cold hemagglutinin disease. Targets for cold hemagglutinins include Pr; Gd, Sa, Lud, and Fl, which are related to Pr; Vo, which is biochemically related to Ii; and A, B, type IIH, Lewis, M-like, P, D, IA, IP, I<sup>T</sup>, I<sup>T</sup>P, and Ju.<sup>36</sup> Determination of specificity is generally not necessary in clinical practice.

### Pathophysiology

The hemolytic potential of cold agglutinins depends on their titer and ability to fix complement on red cells in vivo.<sup>100</sup> Temperatures in the superficial blood vessels of the distal extremities range from 28 to 31°C, depending on the ambient temperature. Lower temperatures occur with extremes of cold. Patients who have cold agglutinins capable of reacting with red cells in the range of 28 to 31°C will have ongoing hemolysis at ordinary room temperatures, whereas those patients with antibodies that react at a lower thermal range may have episodes of hemolysis only on cold exposure. The thermal amplitude of the antibody, which is the highest temperature at which agglutination is still visible, usually correlates with the titer of cold agglutinin. Hemolytic anemia, however, has been reported in patients with low titers of IgM cold agglutinins that have a high thermal range.<sup>101</sup>

At sites of lower temperature, IgM cold agglutinins react with red cells and bind C1. Only a single molecule of IgM is required to bind C1 and initiate the activation of the classic complement pathway.<sup>24</sup> C1 sequentially activates C4 and C2, which bind to the red cell and form a C3 convertase enzyme complex. As the blood returns to the warmer temperatures within the body, cold agglutinins dissociate from the red cell membrane, but complement activation continues. C3 convertase cleaves C3 to C3b and

C3a. A single bound C3 convertase enzyme complex can cleave several hundred molecules of C3 to C3b, many of which bind to the red cell membrane. Circulating red cells coated with C3b and iC3b are trapped predominantly in the liver, where they are bound to the CR1 and CR3 complement receptors, respectively, on the membranes of hepatic macrophages.<sup>24</sup> This interaction of red cells with macrophages results in binding, sphering, and phagocytosis of red cells. The complement sequence goes to completion on some red cells, resulting in lytic destruction and intravascular hemolysis. The human red cell is relatively resistant to complement-mediated lysis because of regulatory proteins in the serum and on the red cell membrane.<sup>24</sup>

Patients with CCHAD develop a population of red cells with a normal survival.<sup>102</sup> These resistant cells are coated with C3d that blocks further uptake of complement and develop as a result of the interaction of C3b-coated red cells with the CR1 complement receptors on macrophages. C3b is degraded to iC3b by factor I with factor H and Cr1 as cofactors. Subsequently, iC3b undergoes a second cleavage by factor I, leading to the formation of C3dg, which is further cleaved into C3d by trypsin-like enzymes. Because receptors on macrophages do not recognize these breakdown products of C3b, the red cells are released from the liver. A substantial number of C3b-coated red cells initially cleared by the liver are released back into the circulation as C3d-coated red cells by this mechanism.<sup>18,103</sup>

Hemolysis secondary to cold agglutinin disease may also be exaggerated with any acute phase reaction that leads to an increase in complement production; infection frequently precipitates increased hemolysis in CCHAD.<sup>104</sup>

### Clinical Features

Patients with CCHAD often present with symptoms of chronic anemia. Episodes of acute hemolysis occur after cold exposure, manifested by hemoglobinemia and hemoglobinuria. Patients may note acrocyanosis of their distal extremities, nose, ears, and chin on cold exposure. Livedo reticularis, a sky-blue mottling of the skin of the extremities, is a result of agglutinated red cells impeding blood flow in the capillary bed. Some patients experience Raynaud phenomenon. Rarely, a patient develops a vascular occlusion, usually of a distal extremity, which is precipitated by prolonged exposure to cold. Patients with IgA monoclonal cold agglutinins manifest acrocyanosis but no hemolysis, because IgA does not activate the classic complement pathway. The course of patients with idiopathic CCHAD is characterized by either chronic anemia or episodes of hemolysis, depending on the thermal amplitude of the cold agglutinin. In a few patients this progresses to a malignant lymphoproliferative disease. Features of malignant lymphoma may overshadow cold agglutinin disease. A very large spleen should suggest malignant lymphoma; flow cytometry may demonstrate a monoclonal B-cell population with the light-chain restriction of the circulating IgM agglutinin.

In acute transient cold agglutinin disease, most often associated with *M. pneumoniae* pneumonia or infectious mononucleosis,

hemolytic anemia appears in the second or third week of the illness; this interval between the acute illness and the subsequent bout of hemolysis leads to significant under-recognition of this phenomenon. Cold agglutinin disease rarely has been observed in association with chickenpox and infectious diseases other than the ones noted.<sup>105</sup> The hemolysis in these disorders can be severe, resulting in significant hemoglobinuria and transient renal failure. Hemolytic anemia usually subsides spontaneously in 1 to 2 weeks, with the hematocrit quickly returning to normal. Patients may experience acrocyanosis, especially in a cold room. The spleen may be modestly enlarged.

Laboratory Features

The first indication that a patient might have cold agglutinins sometimes comes from the laboratory or blood bank after the observation of autoagglutination of the patient's red cells at room temperature. Blood smears show polychromasia, agglutinated red cells and, at times, spherocytes. The reticulocyte count and index are usually elevated. Clumping of red cells may lead to errors in calculating red cell indices because of autoagglutination. An elevated mean corpuscular volume that corrects to normal on heating the blood sample is good evidence for a cold agglutinin. Slight increases in unconjugated bilirubin and hemoglobinuria are sometimes present, especially after hemolytic episodes. Urine hemosiderin is often present.

Antiglobulin Tests

The DAT in patients with cold agglutinin disease shows C3 and, more specifically, C3d. When the DAT is performed, the red cells should be washed thoroughly at 37°C, because a small amount of cold agglutinin will interfere with the test. When cold agglutinins are being assayed, the red cells are separated from serum or plasma at 37°C so that cold agglutinin does not remain adsorbed to the red cell membrane. Normal donor cells warmed to 37°C are added to dilutions of the patient's plasma, which is also prewarmed to 37°C. Tubes are incubated at 37°C, then incubated at 4°C for at least 30 minutes to 1 hour. Agglutination occurring at cold temperatures should be reversible at 37°C. Healthy persons have low titers of IgM cold agglutinins that usually do not exceed a titer of 1:64 at 4°C. The specificity of these cold agglutinins is almost always anti-I.

Patients with pathologic cold agglutinins usually have titers at 4°C of 1:1000 or more in saline.<sup>5(pp213-23)</sup> When the cold agglutinin titer is less than 1:1000, a thermal amplitude test can be performed. The patient's serum is initially tested against normal cells suspended in saline at 20°C. If negative, it is unlikely that cold agglutinins are causing the hemolytic anemia. If positive, a test is performed at 30°C in albumin; a positive test indicates that the cold agglutinin is of clinical importance (Table 22-2).

Treatment

In most patients with CCHAD, anemia is mild and treatment is largely symptomatic. Patients are advised to keep warm (particularly extremities). Large amounts of ice-cold beverages should

Table 22-2. Autoimmune Hemolytic Anemia

| Type                           | DAT  | Serum Antibody                                                                                                             | Antibody Specificity                                                                                         |

| Paroxysmal cold hemoglobinuria | C3d  | Biphasic hemolysin antibody reacts with red cell in cold; hemolysis occurs at 37°C in presence of complement (fresh serum) |                                                                                                              |

\*IgG can be detected on red cells apparently coated with C3d alone by more sensitive techniques; warm-reacting IgM antibodies also may fix complement to red cells.

DAT = direct antiglobulin test; IgG = immunoglobulin G; IgM = immunoglobulin M.

be avoided. Because of the increased red cell turnover, folic acid (1 mg/day) should be given. In patients with more severe hemolytic anemia, chlorambucil or cyclophosphamide is given, and in some patients this results in decreased titers of cold agglutinins and reduced hemolysis.<sup>106</sup> Glucocorticoids and splenectomy generally are not effective, with some important exceptions. Prednisone was shown to be beneficial in patients with low titers of IgM cold agglutinins having high thermal amplitudes and in patients with IgG cold agglutinins.<sup>107</sup> In the latter group, splenectomy was also effective. Plasmapheresis may provide temporary amelioration of hemolysis.<sup>108</sup> α-Interferon therapy has been given to patients with severe cold agglutinin disease with variable results.<sup>109</sup> CD20 monoclonal antibodies have been successful in treatment of some patients with cold agglutinin disease<sup>110,111</sup>; flow cytometry of the marrow may identify a target for this effective and relatively innocuous immunotherapy.

Transfusion should be reserved for patients whose cardiovascular or cerebrovascular systems are significantly compromised by the degree of anemia. Washed RBC units are preferable, to avoid supplying additional complement components to a patient whose low complement levels may be limiting the rate of hemolysis. The donor red cells should be infused through a blood warmer, and the patient should be kept warm during the transfusion. If compatibility testing is performed using prewarmed techniques, difficulties are usually not encountered.

Because acute cold agglutinin disease associated with infection is self-limited, the best treatment is supportive therapy and judicious inaction. If the hemolysis is severe, these patients

should be well hydrated to maintain renal blood flow. Acute renal failure occasionally occurs in the setting of severe hemolysis.

### Paroxysmal Cold Hemoglobinuria

A rare form of AIHA, PCH is characterized by the sudden onset of severe hemolysis particularly after infection. Children are most commonly affected. The disorder was first characterized by Donath and Landsteiner in 1904. They demonstrated the bithermic nature of this hemolysis, which they attributed to an initial sensitizing cold-reacting autohemolysin and a subsequent lytic warm-reacting serum factor. The biphasic laboratory test for PCH carries their names. Originally, PCH was most often associated with congenital syphilis and appeared as a chronic disorder with acute episodes of hemolysis precipitated by cold exposure, hence the term “paroxysmal cold hemoglobinuria.” Today, PCH most often is encountered as an acute transient hemolytic anemia in children after a variety of infections with little if any cold exposure.<sup>112</sup>

### Pathophysiology

The D-L autohemolysin is an IgG autoantibody that reacts with red cells at reduced temperatures in the extremities and fixes the earlier components of complement (see Cold Hemagglutinin Disease). As blood returns to warmer temperatures within the body, complement activation continues. Some cells are coated with C3b and cleared by the liver and spleen, whereas others are lysed by the terminal components of complement.

The D-L antibody in patients with the acute transient form of the disease seldom binds to the red cell in vitro at temperatures higher than 20°C. However, hemolysis occurs in these patients even when they are not exposed to the cold, indicating that the D-L antibody is able to react with red cells at higher temperatures in vivo. The explanation for this paradox is not known. Patients with chronic PCH usually experience hemolysis only when exposed to the cold, similar to patients with CCHAD.

In most patients the D-L antibody is IgG with anti-P specificity.<sup>113</sup> The P antigen is a globoside. The D-L antibodies are inhibited by globoside and Forssman glycolipids, which are widespread in microorganisms.<sup>114</sup> The D-L antibody, therefore, may represent an immunologic response to cross-reacting antigens present in microorganisms.

Paroxysmal cold hemoglobinuria is reported to be associated with a wide variety of infections, including measles (and measles vaccination), mumps, cytomegalovirus, infectious mononucleosis, chickenpox, and mycoplasmal pneumonia, as well as *Haemophilus influenzae*, *Klebsiella pneumoniae*, and *Escherichia coli* infections. Frequently, the cause of the preceding illness is not identified.

### Clinical Features

An acute attack typically occurs during the time a patient is recovering from a recent upper respiratory tract infection. Attacks are characterized by the sudden onset of shaking chills,

back and leg pain, and abdominal cramps. Fever often follows and can be as high as 40°C. Fresh urine passed after the onset of symptoms usually contains hemoglobin. The attack may not be associated with any obvious cold exposure. The constitutional symptoms usually subside within a few hours. Cold urticaria may accompany an attack.

Attacks of PCH can be severe and life threatening. Most patients recover in a few days to several weeks without recurrence. Transient renal failure secondary to hemolysis develops in an occasional patient.

### Laboratory Features

The hemoglobin level can be quite low. Reticulocytopenia can occur initially, but reticulocytosis subsequently develops. Leukopenia is followed by leukocytosis. Unconjugated bilirubin is increased. Hemoglobinemia and hemoglobinuria can be present. Serum complement levels are usually depressed during an acute attack. Peripheral blood smears show autoagglutination of red cells, polychromasia, nucleated red cells, spherocytes, and erythrophagocytosis involving monocytes or neutrophils or both.

The DAT result is positive for C3d. The D-L antibody is detected by the biphasic D-L test. The patient's serum is mixed with donor red cells and fresh normal serum as a source of complement. The mixture is incubated at 4°C, then warmed to 37°C. Hemolysis will occur when the D-L antibody is present. In some instances, the sera of patients with cold agglutinin disease may give false-positive results when the cold agglutinin has the property of a monophasic cold hemolysin. The frequency of false-positive results is greatly increased if enzyme-treated cells are used in the D-L test, making a control for monophasic lysis essential. False-positive results appear in only 2% of cold agglutinin sera when untreated red cells were used in the D-L test.<sup>115</sup> A low titer of the D-L antibody may be present for several weeks to months after an episode of PCH (Table 22-2).

### Treatment

Paroxysmal cold hemoglobinuria is usually a self-limiting illness, with recovery occurring in a few days or a week. Patients are usually treated symptomatically by being kept warm. When transfusion is needed, P-positive red cells can be given and are unlikely to precipitate hemolysis, provided the blood is administered through a warmer.<sup>113</sup> Glucocorticoids and splenectomy are usually not effective. Glucocorticoids are often given empirically and, when given, should be tapered as quickly as possible. Although syphilis is rarely a cause today, it should be excluded in patients with chronic PCH. Patients with chronic idiopathic PCH should be advised to avoid cold and usually do not require any specific treatment.

### Drug-Induced Immune Hemolytic Anemia

Several drugs can produce a positive DAT result and, in some patients, hemolytic anemia. Drug-induced IHA has been reported in 12.4% and 18% of patients with AIHA.<sup>5(p29)</sup> The first description of drug-induced, immune-mediated cytopenia was

by Ackroyd<sup>116</sup> in 1949, who reported thrombocytopenic purpura after allylisopropylacetyl carbamide administration. In 1953, Snapper et al<sup>117</sup> described a patient with pancytopenia, hemolytic anemia, and a positive DAT result who was receiving mephenytoin. In 1956, Harris<sup>118</sup> reported hemolytic anemia recurring in patients after they received a second course of stibophen used in the treatment of schistosomiasis.

Three mechanisms by which drugs induce IHA have been described<sup>5(pp267-304)</sup>; drug adsorption (hapten), immune complex (innocent bystander), and induction of autoantibody. A fourth mechanism, nonimmunologic adsorption of proteins to the red cells, produces a positive DAT result but not hemolytic anemia. The so-called immune complex mechanism, which has accounted for the majority of reported cases of drug-induced IHA, is presently thought in most instances not to be mediated by circulating drug-antidrug immune complexes that bind non-specifically to red cells, but by a specific interaction of a drug, the antibody, and red cells.

Evidence for this drug-dependent mechanism is provided by studies<sup>119</sup> showing that quinidine-induced antibodies in the presence of quinidine were bound to the platelet through the Fab region or antigen-binding site and not through the Fc region of the antibody, as would be expected for binding of immune complexes. In studies on tolmetin-dependent, antibody-associated hemolytic anemia, the drug antibody in the presence of the drug was bound to the red cell through the Fab region.<sup>120</sup> Drug-dependent antibodies react with a certain cell line (red cell, platelet, or white cell) and may recognize well-defined specific cell membrane antigens.<sup>121</sup>

Types of drug-induced IHA discussed below are 1) a drug adsorption mechanism, 2) a drug-dependent antibody mechanism, 3) an autoimmune induction mechanism, and 4) a nonimmunologic adsorption of protein (Table 22-3). The

situation may be more complicated because some drugs may create hemolytic anemia via multiple mechanisms simultaneously in the same patient; diagnostic tests must be pursued with this in mind.

Drug Adsorption Mechanism

In the drug adsorption mechanism, drug-induced antibodies react with a drug already firmly bound to the red cell membrane. Penicillin is a prototype of drugs that produce IHA by this mechanism.<sup>122</sup> Penicillin is covalently bound to red cell membrane protein and is not removed by washing the cells. Penicillin can be demonstrated on the red cells of 30% of patients receiving 1.2 to 2.5 million U/day and of all patients receiving 10 million U/day.<sup>122</sup> Penicillin on these red cells does no harm if immune sensitization does not occur. Approximately 3% of patients receiving massive doses of intravenous penicillin in the range of 10 million U/day continuously for several days eventually will have a positive antiglobulin test result, but hemolytic anemia is rare. For hemolytic anemia to develop, intravenous doses of 10 million units or more over several days are necessary. Although IgM antibodies directed against the benzylpenicilloyl determinant of penicillin develop in approximately 90% of patients who receive penicillin, these antibodies are usually not involved in the pathogenesis of hemolytic anemia.<sup>123</sup> The antibody involved is the IgG directed against the benzylpenicilloyl determinant or other metabolites of penicillin. The onset of hemolytic anemia is usually after 7 days of treatment but may be sooner in patients who have been previously immunized to penicillin. The mechanism of red cell damage is largely extravascular, occurring mainly in the spleen. The degree of hemolysis is usually mild to moderate.

The DAT shows IgG or occasionally IgG and complement.<sup>5(pp267-304)</sup> An indirect antiglobulin test result is negative unless donor cells coated with penicillin are used. Similarly, eluates from the patient's red cells react only with penicillin-coated donor red cells. The finding of a positive DAT result by itself does not dictate discontinuing the drug unless there is evidence for hemolysis. Once the drug is stopped, the hemolytic anemia abates within a few days. Prednisone is usually not required to control the hemolytic anemia, because the disease is self-limited. Penicillin antibodies can cross-react with cephalothin-treated red cells, and antibodies against cephalothin can cross-react with penicillin-coated red cells.<sup>124</sup> Although cephalothin also binds strongly to the red cell membrane, it rarely causes hemolytic anemia. Other drugs that induce hemolytic anemia by this mechanism include tolbutamide, tetracycline, and streptomycin.<sup>125</sup>

Drug-Dependent Antibody Mechanism

In this mechanism (formerly termed immune complex/innocent bystander mechanism), a drug is thought to bind transiently with proteins on the red cell membrane to form an immunogen that stimulates production of an antibody.<sup>126</sup> The demonstration of the antibody in vitro requires the presence of a free drug or its metabolites on red cells. For some drug-dependent antibodies, reactivity occurs only with red cells of a specific blood group.

Table 22-3. Drug-Induced Immune Hemolytic Anemia

| Type                                         | DAT         | Serum Antibody                                                                                                      | Hematologic Manifestations                                              |
|----------------------------------------------|-------------|---------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------|
| Drug adsorption (eg, penicillin)             | IgG<br>C3d* | Antibody reacts with drug-coated; eluates react only with drug-coated red cells                                     | Moderate degree of hemolysis, usually extravascular mechanism red cells |
| Drug-dependent antibody type (eg, cefotetan) | C3d         | Ab + drug + red cell → sensitization, agglutination or hemolysis of red cells; Ab is IgG or IgM; eluate is negative | Abrupt onset of severe intravascular hemolysis; renal failure           |
| Autoimmune induction (eg, α-methyl dopa)     | IgG         | Autoantibodies against red cell; eluate reacts with red cell                                                        | Mild-to-moderate degree of extravascular type hemolysis                 |

\*Present in approximately 40% of penicillin-induced immune hemolytic anemia. DAT = direct antiglobulin test; IgG = immunoglobulin G; IgM = immunoglobulin M.

In previously sensitized patients, only a small quantity of the drug is required to initiate hemolysis. Hemolysis is abrupt and can be severe, causing massive hemoglobinemia and hemoglobinuria. Renal failure develops in approximately one-third of patients.<sup>5(p29)</sup> Other complications include shock and disseminated intravascular coagulation.

All drugs should be discontinued until the responsible drug can be determined in the laboratory. Hemolysis usually disappears within a few hours or days. Patients should be observed closely for renal failure. The drug-dependent antibodies can persist for years, placing patients at great risk if they are exposed again to the responsible drug. Drug-induced autoantibodies, which also may be present, rapidly disappear within a few days after drug administration is stopped.

The responsible antibody may be IgG or IgM and is capable of activating complement. The DAT shows only C3d. In many cases the responsible drug is recognized by the antibody only when it is associated with a specific blood group antigen. In such cases, the drug and its antibody will not react with red cells lacking the specific antigen. Drug-dependent antibodies associated with rifampicin, nitrofurantoin, and dexchlorpheniramine have been shown to react with cells rich in I antigen.<sup>127,128</sup> Drug-dependent antibodies associated with thiopental and nomifensine are reactive with adult, but not cord, red cells.<sup>129</sup> Drug-dependent antibodies in a patient with chlorpropamide-induced hemolytic anemia were detected only with Jk<sup>a</sup>-positive red cells.<sup>130</sup> In some patients with drug-dependent IHA caused by nomifensine, the serum did not react with red cells in the presence of the parent drug but did react with red cells in the presence of urine, which contained the ex-vivo antigen-metabolite.<sup>131</sup> An ex-vivo antigen-metabolite was also required to detect drug-dependent antibodies in a case of IHA caused by diclofenac.<sup>132</sup> In cases of suspected drug-dependent IHA that are negative with the parent drug, it is important to test with ex-vivo antigens-metabolites present in urine or serum collected from volunteers or patients after ingestion of the drug.<sup>133</sup>

Many drugs have been reported to cause drug-dependent IHA; examples include nonsteroidal anti-inflammatory drugs (NSAIDs) and second- and third-generation cephalosporins.<sup>134,135</sup> In a patient receiving cefotaxime, severe intravascular hemolysis developed, which showed in-vitro characteristics of drug-dependent and drug adsorption mechanisms.<sup>136</sup> In a patient treated with cefotetan in whom hemolytic anemia and fatal renal failure developed, the serum contained antibodies that reacted with cefotetan-treated red cells, antibodies that reacted only with untreated red cells in the presence of the drug, and drug-independent autoantibodies.<sup>137</sup> Both drug adsorption and drug-dependent antibodies were associated with ceftazidime-induced IHA.<sup>138</sup> A case of sulindac-induced IHA was associated with a drug-dependent antibody having no blood group specificity.<sup>139</sup> A patient receiving both suprofen and tolmetin (NSAIDs) had severe intravascular hemolysis and renal failure. Drug-dependent antibodies to both were discovered; autoantibodies also were present.<sup>140</sup> Phenacetin<sup>141</sup> and carbimazole<sup>142</sup>

also have been associated with drug-dependent antibodies and autoantibodies.

### Autoimmune Induction Mechanism

$\alpha$ -Methyldopa induces a positive antiglobulin test result in 11% to 36% of patients after 3 to 6 months of therapy.<sup>143</sup> The incidence of a positive DAT result seems to correlate with the drug dose. The DAT results were positive in 11% of patients taking 1 g/day or less, 19% in those taking 1 to 2 g/day, and 36% in those taking more than 2 g/day.<sup>143</sup> However, hemolytic anemia develops in less than 1%. On second exposure to the drug, the interval for the development of a positive DAT result is again 3 to 6 months, thus differing from the usual anamnestic immune response.

The positive DAT result shows IgG and occasionally IgG and complement.<sup>5(pp267-304)</sup> The indirect antiglobulin test is also positive, especially in those patients with hemolytic anemia. Eluates from patients' red cells as well as serum antibody do not require the drug to react with the red cell. The antibody specificity is to antigens related to the Rh complex.<sup>144</sup> This conclusion is supported by the observation of Bakemeier et al<sup>144</sup> that antibodies associated with  $\alpha$ -methyldopa AIHA recognize a 34-kD polypeptide and a 37- to 55-kD glycoprotein, which seem to be antigens of the Rh family.

The mechanism by which  $\alpha$ -methyldopa induces AIHA is unknown. It has been proposed that  $\alpha$ -methyldopa alters the red cell membrane to form neoantigens recognized as foreign, but there is little evidence to support this concept.  $\alpha$ -Methyldopa causes an increase in lymphocyte cyclic adenosine monophosphate, which may inhibit suppressor T cells<sup>145</sup> and lead to overproduction of red cell autoantibodies. However, Garratty et al<sup>146</sup> were unable to confirm  $\alpha$ -methyldopa depression of suppressor cell function.  $\alpha$ -Methyldopa-induced red cell autoantibodies rarely produce hemolytic anemia. Although impaired reticuloendothelial function has been demonstrated in patients receiving  $\alpha$ -methyldopa,<sup>147</sup> this cannot by itself explain the infrequency of immune hemolysis in these patients.

The degree of hemolysis is usually mild to moderate, and anemia develops gradually. Hemolysis usually regresses within a few days after the drug is stopped but may continue for several weeks to months. Generally no treatment is necessary. Glucocorticoids may shorten the period of recovery but are usually not required. A positive DAT result is not by itself an indication to discontinue  $\alpha$ -methyldopa unless there is evidence of hemolytic anemia. The DAT result may remain positive for months to years after discontinuation of  $\alpha$ -methyldopa. Other drugs that may induce hemolytic anemia by this mechanism include levodopa,<sup>148</sup> mefenamic acid,<sup>149</sup> and procainamide.<sup>150</sup>

### Nonimmunologic Adsorption of Protein

A small number (5%) of patients receiving cephalothin eventually have positive antiglobulin test results because of nonspecific adsorption of serum proteins.<sup>5(pp267-304)</sup> The DAT result becomes positive after a few days of treatment. Albumin, fibrinogen, complement, and immunoglobulins are detected on the red cell

membrane.<sup>151</sup> As noted earlier, cephalothin can produce hemolytic anemia by the drug adsorption mechanism, but this is unusual.<sup>152</sup>

Red cells treated in vitro with the chemotherapeutic agent cisplatin can adsorb IgG nonimmunologically and produce a positive DAT result.<sup>153</sup> Several cases of hemolytic anemia associated with cisplatin treatment have been reported, but in only one were antibodies to cisplatin demonstrated.<sup>154</sup> Conceivably, nonimmunologic binding of IgG was responsible for the positive DAT results, whereas other unknown mechanisms may have caused that anemia.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria is a rare acquired hemolytic anemia with protean manifestations that have their shared origin in the absence of an essential anchoring protein for many cell membrane-based molecules on the surface of hematopoietic elements.

Clinical Features and Biology

Clinical Picture and Course

Mild to moderate anemia is the most frequent initial clinical sign (Table 22-4). Complement-mediated intravascular hemolysis and hemoglobinuria can create the double insult of iron deficiency and hemolytic anemia. Passage of dark, hemoglobin-containing urine upon arising is the initial symptom in only a minority of cases. Chronic low-grade hemolysis is punctuated by hemolytic crises that are precipitated by infection, drug administration, transfusions, and other stresses.<sup>155</sup> Adults 25 to 45 years of age are most frequently affected, although no age group is free of its involvement. Physical findings are related to anemia; some patients have mild splenomegaly.<sup>156</sup> The course of the disease varies greatly, with 50% of patients surviving more than 15 years<sup>155</sup>; interventions such as marrow transplantation now offer the possibility for cure

Table 22-4. Clinical Features and Diagnosis of Paroxysmal Nocturnal Hemoglobinuria

| Features            | Clinical Manifestations                                                                                                   |
|---------------------|---------------------------------------------------------------------------------------------------------------------------|
| Signs and symptoms  | Anemia, hemoglobinuria, thrombosis, infection                                                                             |
| Age at onset        | 25–45 years                                                                                                               |
| Laboratory findings | Moderate pancytopenia; elevated reticulocyte count, lactic dehydrogenase, and bilirubin; hemosiderinuria; iron deficiency |
| Confirmatory tests  | Flow cytometry for DAF and MIRL; positive acidified serum and sucrose hemolysis tests                                     |
| Survival            | Averages >10 years from diagnosis with cure possible with marrow transplantation                                          |
| Complications       | Venous thrombosis (especially hepatic vein); infection; aplastic anemia; acute leukemia                                   |

DAF = delay accelerating factor; MIRL = membrane inhibitor reactive lysis.

of the disorder. Fatalities most frequently result from thrombotic and infectious complications. Hepatic and portal veins are often the sites of atypical thrombosis in this disorder.<sup>157</sup> Smooth muscle dystonias with esophageal spasm, erectile dysfunction, and pulmonary hypertension all have their origins in lowering of nitric oxide levels secondary to its binding to free hemoglobin. Paroxysmal nocturnal hemoglobinuria often occurs against the backdrop of aplastic anemia with this relationship contributing to theories regarding the etiology of the disorder.<sup>158</sup> It may also evolve into aplastic anemia or acute nonlymphocytic leukemia.<sup>159</sup>

Etiology

Paroxysmal nocturnal hemoglobinuria results from a somatic mutation in the X-linked phosphatidylinositol glycan (PIG)-A gene in a hematopoietic stem cell line; more than 100 mutations in the gene have been described with the most common a “frameshift” mutation.<sup>160</sup> The PIG-A gene product contributes to the construction of the glycosylphosphatidylinositol (GPI) anchor protein, which constitutes the cytosolic tail of numerous transmembrane cell surface proteins. Almost 100 different GPI-anchored proteins have been identified, helping to explain the many manifestations of PNH. The deficit in two GPI-based molecules [decay-accelerating factor (CD55 or DAF) and membrane inhibitor of reactive lysis (CD59 or MIRL)] results in an inability to inactivate complement on the red cell surface, leading to hemolysis. A deficiency of a urokinase plasminogen activator receptor on the surface of monocytes has been suggested as contributing to the thrombophilic complications of PNH.<sup>155</sup>

The appearance and persistence of the PNH clone(s) in aplastic anemia has suggested that the PIG-A– cells possess a selective advantage over PIG-A+ cells. The correlation of PNH with immunologically mediated aplastic anemia supports the hypothesis that the altered PNH clone escapes an immune-mediated assault, leading to aplastic anemia.<sup>161</sup> An interaction between certain GPI-anchored proteins and the immune system may be crucial for PNH pathogenesis. Affected cells may have a survival advantage after some injury sustained by the normal progenitors, consistent with the hypothesis of immune escape.<sup>162,163</sup>

Pathogenesis

The increased sensitivity to complement (C′) of blood cells from patients with PNH is the result of the PIG-A membrane defect, and the C′ system itself is normal.<sup>164</sup> Red cells of patients with PNH exhibit augmented binding of C3<sup>155</sup> and increased sensitivity to lysis by the C5b-9 membrane attack complex (MAC), as do PNH platelets, granulocytes, and some lymphocytes.

The biochemical lesion in PNH is deficiency of PIG-anchored proteins in the affected cell membranes. The deficiency of DAF (CD55) impairs inactivation of the C3b convertase complex,<sup>165</sup> while reduced levels of MIRL (CD59) impair inactivation of the MAC.<sup>166</sup> Sensitivity to C′ varies inversely with levels of membrane expression of these proteins.<sup>167</sup> Lymphoblastoid cell lines developed from patients with PNH express the PNH defect and are incapable of synthesizing PIG core substance,

although they produce messenger RNA for PIG-anchored proteins. The specific abnormality in PNH is deficiency of uridine diphosphate-glucose-*N*-acetyl: phosphatidylinositol- $\alpha$ -1, 6-*N*-acetylglucosaminyltransferase.<sup>168</sup> A kindred has been described in which there is a hereditary deficiency of MIRL (CD59). A single member of this kindred, born to cousins, is homozygous for MIRL deficiency and expresses a PNH phenotype.<sup>169</sup>

The nature of the thrombotic tendency in PNH is incompletely understood.<sup>155</sup> Paroxysmal nocturnal hemoglobinuria platelets are partially activated by sublethal C'-mediated damage, and this activation may predispose to thrombosis.<sup>170</sup> However, because the clotting in PNH is principally venous,<sup>155,171</sup> the absent urokinase receptor may be important in decreasing the fibrinolytic system in resorbing venous clots.<sup>172</sup> Thrombocytopenia in PNH is attributable more to defective synthesis than excessive consumption in clotting.<sup>173</sup>

### Diagnosis

Paroxysmal nocturnal hemoglobinuria may be diagnosed by demonstration of chronic intravascular hemolysis attributable to C'-sensitive cells (deficient in PIG-anchored proteins) in the blood. Paroxysmal nocturnal hemoglobinuria should be considered in cases of hemolytic anemia with a negative DAT, aplastic anemia, and poorly understood pancytopenia or iron deficiency; hemolytic transfusion reactions in the face of a negative immunologic evaluation should also raise consideration of PNH. Atypical thromboses, leukopenia, and thrombocytopenia are subtle signs of PNH.<sup>174,175</sup>

### Laboratory Findings

Most patients with PNH have a cell volume of less than 30%, and many exhibit hypochromic, microcytic indices because of iron deficiency.<sup>156</sup> Reticulocytosis may be blunted because of the attendant iron deficiency. Elevated levels of serum bilirubin and lactic dehydrogenase are usual; haptoglobin levels are always reduced or absent. Virtually all patients have chronic hemosiderinuria, and absence of this finding should call the diagnosis into question. Granulocytopenia (cell count less than 1500/ $\mu$ L) is common.<sup>156</sup> The majority of patients also have mild thrombocytopenia (cell count less than 150,000/ $\mu$ L), with some platelet counts less than 50,000/ $\mu$ L.<sup>156</sup> The marrow cellularity varies from aplastic to hypercellular with erythroid hyperplasia. Maturation of marrow precursors is usually normal, but iron stores are characteristically reduced or absent.

### Confirmatory Tests

Several serologic tests demonstrate the C' sensitivity of PNH red cells. The acidified serum (Ham) test and the sucrose hemolysis test have been the standard confirmatory tests required for specific diagnosis.<sup>155,156,176</sup> More recently a variety of monoclonal antibodies that recognize the PIG-anchored proteins deficient in PNH have become available.

### Serologic Tests

In the acidified serum test, PNH red cells, but not normal cells, are lysed by normal human serum acidified to pH 6.5. With

appropriate controls this test is specific for PNH, but it is more time-consuming and technically difficult than the sucrose hemolysis test.<sup>176</sup> It rarely gives false-positive results in cases of hereditary erythrocyte multinuclearity with a positive acidified serum (HEMPAS) test or when intense spherocytosis is present.<sup>177</sup> In the sucrose hemolysis test, PNH red cells are lysed by C' components nonspecifically deposited on surfaces in solutions of low ionic strength. This test produces greater degrees of hemolysis than the acidified serum test, and values of 5% hemolysis or less are considered nonspecific and nondiagnostic.<sup>176</sup> These tests are complementary and should be performed in parallel if there is a high suspicion of PNH. Although the sucrose hemolysis test is more sensitive, it may fail to detect PNH in some patients whose cells do not exhibit increased sensitivity to C5-C9 MAC and whose acidified serum tests give positive results.<sup>176</sup>

### Immunophenotyping

Monoclonal antibodies have been developed to DAF (CD55) and to several other determinants on PIG-anchored proteins. These include MIRL (CD59), Fc $\gamma$ RIII (CD16), and CD48.<sup>178,179</sup> PIG-anchored proteins are expressed on a portion of PNH B cells, and a panel of monoclonal antibodies that detect CD55, CD59, and CD48 can be used to test for PNH.<sup>179</sup> Unlike traditional serologic tests, immunophenotyping may be applied to patients with PNH who develop aplastic anemia or are otherwise so heavily transfused as to have a low percentage of native PNH red cells. A rapid microtyping card test based on antibodies to CD55 and CD59 has been developed.<sup>180</sup> An improved method for the detection of PNH cells uses the selective binding of the protein aerolysin to GPI anchors; this is an important adjunct because no single monoclonal antibody can be used with confidence to diagnose PNH.<sup>181,182</sup>

### Pharmacologic and Immunotherapy

Treatment of PNH is determined by categorization of the disorder as a hypoplastic or classical form of PNH. Patients in the marrow failure group are managed as hypoplastic or aplastic anemia patients, depending upon the degree of aplasia. Hypoplastic variants require attention to correcting the cytopenias, while aplastic variants are treated with allogeneic stem cell transplants and/or immunosuppressive therapy. Patients with the classical form of PNH previously required allogeneic stem cell transplantation for attempted cure of the disorder. Eculizumab, a humanized monoclonal antibody against C5 that inhibits terminal complement activation,<sup>183</sup> is newly available for treatment of PNH. It is highly effective in reducing hemolysis and transfusional needs, in reducing the incidence of thrombosis, and in improving the quality of life in patients with PNH. A reduction in the levels of free hemoglobin reduces the nitric oxide consumption in PNH and helps eliminate the common symptoms of esophageal spasm and erectile dysfunction that complicate the disorder. Patients require vaccination against *Neisseria meningitidis* because of the increased risk of meningococcal infection with blockade of the terminal complement components.<sup>184,185</sup>

Hematinics

Chronic hemolysis in PNH often produces iron and folic acid deficiency, which may worsen anemia. Patients with PNH should receive supplemental folic acid. Iron therapy carries some risk of exacerbating hemolysis because of production of a cohort of C'-sensitive red cells.<sup>186</sup> Administration of oral iron is usually not accompanied by severe acute hemolysis and may be sufficient to offset urinary losses. However, when iron loss is more severe, some patients lose as much as 20mg/day,<sup>186</sup> and parenteral iron administration can become necessary. A severe acute hemolytic response to iron therapy often can be prevented by corticosteroid administration<sup>186</sup> (Table 22-5).

Androgens

A minority of patients with PNH respond to treatment with androgens.<sup>187</sup> These drugs may function by decreasing hemolysis or by increasing red cell production. Methyltestosterone, parenteral preparations, and synthetic steroids (including danazol) all have been effective in some patients but they have serious side effects, including cholestatic jaundice and peliosis hepatis, and predispose to progressive hepatic venous thrombosis. Because the response to androgens cannot be predicted, a trial of fluoxymesterone (10 to 30mg/day) or oxymetholone (10 to 50mg/day) is worthwhile, but these drugs should be discontinued if no response has occurred in 6 to 8 weeks.<sup>187</sup>

Corticosteroids

Steroids suppress hemolysis in the majority of patients with PNH. The onset of action generally occurs within hours, and 57% to 67% of patients respond to therapy with moderate-dose alternate-day oral prednisone.<sup>187,188</sup> The mechanism of steroid action is uncertain. Steroids may reduce C' activation by the alternate pathway, but red cells of patients with PNH who are taking prednisone are no less sensitive to C'-mediated lysis in standard in-vitro tests. Generally,

Table 22-5. Management of Paroxysmal Nocturnal Hemoglobinuria

| Agent or Therapy | Considerations                                                                                                                                                                                               |
|------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Hematinics       | Folic acid supplementation: <i>cautious</i> iron replacement                                                                                                                                                 |
| Androgens        | Minority of patients have dramatic reduction in anemia                                                                                                                                                       |
| Corticosteroids  | One-half to two-thirds of patients benefit from alternate-day therapy; heparin is used for acute episodes but may sometimes increase hemolysis; thrombolytic agents may be useful in hepatic vein thrombosis |
| Immunotherapy    | Eculizumab decreases hemolysis, lessens nitric oxide-related symptoms, and reduces incidence of thrombosis                                                                                                   |
| Transfusions     | For refractory symptomatic anemia or to abort or avert an acute hemolytic crisis; washed or frozen deglycerolized cells should be used                                                                       |

prednisone doses of 20 to 60mg/day are required to suppress hemolysis. Corticosteroids may be given daily for a limited time to achieve an immediate effect. However, their side effects, particularly predisposition to infection in patients already compromised by granulocytopenia, can be toxic. Corticosteroids should be prescribed for prolonged periods only on an alternate-day schedule and should be discontinued if they are ineffective after a trial of 2 to 4 weeks.

Splenectomy

There are potential hazards of surgical procedures in patients with PNH but, with careful attention to anesthetic and surgical technique, surgery can be accomplished with safety.<sup>189</sup> Splenectomy is usually not useful in PNH. In some patients, however, splenectomy reduces the anemia associated with PNH. This procedure is worth considering in patients with myelofibrosis-associated PNH.

Erythropoietin and Cytokines

Biologic agents have been used in a few patients with PNH. Although erythropoietin levels are usually elevated in patients with PNH, chronic anemia in patients with PNH sometimes responds to erythropoietin at doses between 50 and 500 U/kg given three times weekly.<sup>190</sup> Filgrastim (granulocyte colony-stimulating factor) administration led to recovery or protection from infection of two patients with PNH subject to repeated bacterial infection, and granulocyte colony-stimulating factor administration produced increased expression of PIG-anchored FcγRIII expression on their leukocytes.<sup>191</sup> The use of these agents in the routine care of patients with PNH remains to be defined but offers the hope of decreased demand for transfusion therapy and better outcomes to infectious episodes.

Marrow Transplantation

Clinical cures of PNH by allogeneic or syngeneic marrow transplantation have been increasingly reported, and expression of normal levels of PIG-anchored proteins on circulating blood cells of a transplant recipient with PNH has been directly demonstrated.<sup>192</sup> Allogeneic or syngeneic transplantation seems to be very effective for patients with PNH in whom aplastic anemia has supervened. Allogeneic transplants can restore normal marrow function in about 50% of patients with PNH.<sup>193</sup> The recent demonstration of a population of normal (DAF+ and CD59+) primitive (CD34+ and CD38+) cells in the marrow of patients with PNH suggests the possibility of selecting normal stem cells for autologous transplantation.

Anticoagulants and Thrombolytic Agents

Patients with PNH have a marked tendency for repeated venous thromboses,<sup>171</sup> requiring aggressive use of anticoagulants. Warfarin should be given as soon as such a complication is recognized. Heparin therapy is required for hepatic venous thrombosis and has been used without incident in many patients with PNH, although heparin does precipitate hemolytic episodes in some individuals.<sup>187</sup> Low-molecular-weight heparin may be more useful
