for both the inhibition of hemolysis and the prevention of thrombosis in PNH.<sup>194</sup> Plasminolytic therapy has been used successfully to treat hepatic venous thrombosis<sup>195</sup>; its efficacy is related to the acuteness or sub-acuteness of the thrombosis and when the lysis is attempted. Previous recommendations of restricting its use to within 2 or 3 days after the thrombotic event have now been extended to as long as 2 to 3 weeks with some success.<sup>196</sup>

## Transfusion

### Indications

Red cell transfusions are sometimes required for relief of symptoms in PNH when hemolysis produces anemia that cannot be corrected by the therapeutic maneuvers discussed above. Additionally, hypertransfusion to a cell volume of 35% to 40% can abort acute hemolytic crises refractory to corticosteroids.<sup>187</sup>

## Choice of Blood Components

### Red Cells

Transfusion of whole blood to patients with PNH can initiate hemolysis and worsen anemia. Infused plasma can increase C' levels, whereas whole blood and red cells contain white cell fragments that can be immunogenic and result in C' activation.<sup>197</sup> Therefore, washed cells have been recommended and many transfusion services follow this practice. Sirchia and Zanella<sup>198</sup> have presented evidence that white cell fragments are the element most likely to initiate hemolysis during transfusion of patients with PNH, and they advocate the use of blood components that have undergone leukocyte reduction by filtration.

It seems clear that many patients with PNH tolerate infusion of whole blood or red cells without ill effects, but the proportion of patients with PNH who may experience increased hemolysis is not clear. The use of blood components that have been leukocyte reduced by filtration seems to be safer, and the use of washed or frozen deglycerolized cells avoids the problem altogether.

### Platelet Concentrates

Thrombocytopenia is common in patients with PNH and can be severe (platelet count less than 20,000/ $\mu$ L) enough to require platelet transfusion for surgery or for bleeding after trauma. Platelet preparations should be leukocyte reduced by filtration. The possibility of a hemolytic episode should be anticipated but can be treated with corticosteroids or hypertransfusion. Patients with PNH who receive many transfusions of non-leukocyte-reduced RBCs are at risk of becoming alloimmunized and may become refractory to platelet transfusion, in which case HLA-matched or crossmatched platelets may be required.

## Special Situations

### Pregnancy

Many successful pregnancies have occurred in women with PNH. Two-thirds have a successful outcome, but maternal death occurs in approximately 10% of PNH-affected pregnancies. Mothers often experience accelerated hemolysis and venous thrombosis.<sup>199</sup> Increased red cell transfusion is usually necessary, and

many authors advocate prophylaxis against venous thrombosis in patients who are bedridden and possibly also in the peripartum period.<sup>200</sup> Because of multiple maternal red cell transfusions, hemolytic disease of the fetus and newborn is frequent.<sup>201</sup>

### Extensive Elective Surgery

When extensive surgery is planned for a patient with PNH, the possibility of severe hemolysis should be anticipated. An exchange transfusion can be performed before the operation. The precaution prevents hemolysis and provides the surgeon and anesthetist with a more stable patient.<sup>189</sup>

### Disseminated Intravascular Coagulation

Disseminated intravascular coagulation seems to be a rare direct complication of PNH.<sup>202</sup> When asymptomatic, it has been monitored carefully<sup>202</sup> or treated with blood component support. Additional special measures have not been required on account of PNH, and cryoprecipitate and platelet concentrates have been tolerated without accelerated hemolysis being noted.

### Myelofibrosis

As many as 50% of patients with primary myelofibrosis exhibit red cell membrane defects of PNH and some suffer from thrombotic complications.<sup>203</sup> These patients have marrow failure contributing to their anemia, in addition to hemolysis, and sometimes have substantial transfusion requirements. Contrary to the usual finding of iron deficiency, such patients can develop transfusion-related hemosiderosis.

### Acute Leukemia

Paroxysmal nocturnal hemoglobinuria evolves into acute myelocytic leukemia (AML) in 2% to 4% of patients.<sup>204</sup> Leukemia apparently develops in the PNH clone, and there is cytogenetic evidence of clonal evolution.<sup>205</sup> Complete remissions can be induced with antileukemic therapy, and in these patients there has been no evidence of PNH during remission.<sup>206</sup> Reports of patients with PNH who develop AML do not indicate increased complications referable to the PNH defect, despite the need for intensive transfusion support. In fact, in one patient who did not undergo induction chemotherapy for AML, complications of PNH decreased during the course of the leukemia.<sup>207</sup>

### Aplastic Anemia

Paroxysmal nocturnal hemoglobinuria may evolve from or into aplastic anemia.<sup>208</sup> Development of this complication is compatible with prolonged survival with treatment similar to that prescribed for uncomplicated cases of PNH.<sup>209</sup> Aplastic anemia associated with PNH may be successfully treated by marrow transplantation.

---

## Summary

Autoimmune hemolytic anemia is divided into warm and cold autoantibody types and may be idiopathic (primary) or associated

with another disease (secondary). It also may be drug induced. The DAT is an important laboratory marker but may produce negative results in patients with anemia and positive results in patients without anemia. Transfusion frequently requires autoadsorption studies. Glucocorticoids and splenectomy are primary treatments, although immunosuppressive drugs and other treatments are also used. The cold autoantibody type of AIHA is either acute or chronic cold hemagglutinin disease or PCH. Drug-induced hemolytic anemia involves drug adsorption, a drug-dependent antibody, or autoantibody induction mechanisms.

Paroxysmal nocturnal hemoglobinuria is an uncommonly diagnosed hemolytic anemia that arises from a somatic mutation of pluripotent hematopoietic stem cells. Hemolysis results from increased sensitivity to C' produced by deficiency of the PIG-anchored proteins, including DAF and MIRL, in the red cell membrane. The acidified serum test, the sucrose hemolysis test, and immunophenotyping of blood cells are used for diagnosis. Various therapies including immunotherapy with eculizumab and marrow transplantation have been successfully used in PNH. The disorder is protean in its manifestations with hemolysis, thrombosis, infection, smooth muscle dystonias, aplastic anemia, and leukemia as part of its natural history.

### General Tests to Investigate Thrombocytopenia

Thrombocytopenia can be caused by platelet underproduction, sequestration, hemodilution, or destruction. This chapter explores the problem of immune platelet destruction. Immune thrombocytopenia is characterized by a shortened platelet life span caused by platelet-antibody interactions. Several indirect clues suggest a shortened life span, such as a rapid decrease in platelet count or severe thrombocytopenia in a patient with normal megakaryocyte numbers. Radioactive markers sometimes are needed to establish directly the existence of a shortened platelet survival time. An additional role for impaired thrombopoiesis is recognized increasingly in the pathogenesis of autoimmune thrombocytopenia.

### Complete Blood Cell Count and Blood Film

Platelets usually are quantitated during a complete blood cell count with a particle counter. A normal platelet count usually is 150,000 to 400,000/ $\mu$ L, although the reference range may be lower in Mediterranean populations (125,000 to 300,000/ $\mu$ L) that have larger-sized platelets. The platelet count usually remains fairly stable throughout a normal human life span.<sup>1</sup> An exception occurs during pregnancy, when the platelet count decreases somewhat, perhaps the result of increased plasma volume (hemodilution). An elevated platelet count also is normal 10 to 14 days after a major surgical procedure (postoperative thrombocytosis, 250,000 to 1,000,000/ $\mu$ L) before return to preoperative baseline by 3 weeks after the operation.<sup>2,3</sup> Thus, a platelet count of only 190,000/ $\mu$ L 10 days after an operation on a patient with dyspnea who had received postoperative heparin prophylaxis could represent pulmonary embolism complicating heparin-induced thrombocytopenia (HIT).

A useful general rule is that isolated thrombocytopenia usually is caused by increased platelet destruction, whereas bicytopenia or pancytopenia usually is attributable to marrow dysfunction,

hypersplenism, or hemodilution. Isolated, severe thrombocytopenia (platelet count less than 20,000/ $\mu$ L) often indicates platelet destruction by autoantibodies, alloantibodies, or drug-dependent immunoglobulin G (IgG) antibodies. Such severe thrombocytopenia, however, occasionally occurs in patients with HIT<sup>4</sup> or septicemia, although platelet count nadirs are typically more than 20,000/ $\mu$ L in these two disorders characterized by in-vivo platelet activation caused by heparin-dependent IgG antibodies or thrombin, respectively. Examining the blood film is important to exclude pseudothrombocytopenia (spurious thrombocytopenia resulting from antibodies that cause ex-vivo platelet agglutination) and to suggest various nonimmune causes of thrombocytopenia, such as toxic leukocytes indicating infection or fragmented red cells suggesting microangiopathic hemolysis. In contrast, immune thrombocytopenia usually is characterized by reduction in platelet numbers with otherwise unremarkable morphologic features, unless the thrombocytopenia is secondary to a disorder such as lymphoma.

### Platelet Size, Platelet RNA, and Plasma Glycocalicin

A particle counter also is used to determine average platelet size, or mean platelet volume (MPV), which usually ranges from 7.0 to 10.5 fL. Disorders of increased platelet destruction usually are characterized by large platelets, and MPV ranges from 10 to 15 fL. Normal-sized or small platelets are common in disorders of underproduction or sequestration of platelets.

Young platelets contain residual amounts of RNA, which can be detected by means of flow cytometric analysis of platelets labeled with either thiazole orange or auramine-O. However, such quantitation of reticulated platelets has not gained the acceptance that red cell reticulocyte assays have. One problem is that thiazole orange also labels platelet-dense granules nonspecifically.

Levels of glycocalicin [a soluble proteolytic product of platelet glycoprotein Ib (GPIb)] are increased in patients with increased platelet destruction. Because of factors such as platelet count, renal function, disease-related proteolysis, and technical considerations, this assay is used predominantly for research.<sup>5</sup>

## Marrow Examination

Disorders of increased platelet destruction are characterized by normal or increased numbers of megakaryocytes in the marrow. Sometimes examination of the marrow yields enough information to determine the cause of the thrombocytopenia, such as myelodysplasia or megakaryoblastic anemia.

## Measurement of Platelet Life Span

Measurement of the life span of platelets is the definitive test for classifying the cause of thrombocytopenia. Indium-111 is the radiolabel of choice because of its higher labeling efficiency and efficient range of  $\gamma$  emissions. Indium-111 is not released from platelets by platelet autoantibodies. Three patterns of platelet survival can be observed, as follows: 1) normal platelet recovery (60% to 75%) and a normal survival time (7 to 10 days) characterize thrombocytopenia caused by underproduction; 2) a markedly reduced platelet life span (sometimes only hours) is found in patients with thrombocytopenia caused by increased platelet destruction; and 3) reduced platelet recovery (as low as 10% to 30%) with a normal or near-normal platelet survival time confirms the diagnosis of thrombocytopenia caused by increased platelet sequestration (hypersplenism). Platelet life span studies are not often performed, however, because physicians usually infer the mechanism of the thrombocytopenia from the clinical situation.

## Platelet-Antibody Assays

There are two broad categories of platelet-antibody assays—classical platelet-associated IgG assays and assays that identify the protein target of the antibody (protein-specific assays).

### Classical Platelet-Associated Immunoglobulin G Assays

Measurement of platelet-associated IgG (PAIgG) has been widely available for 25 years. Unfortunately, these assays have limited diagnostic usefulness. A positive assay result does not differentiate immune from nonimmune thrombocytopenia.<sup>6</sup> These assays can detect either surface-associated immunoglobulin or complement by means of direct binding of a labeled anti-immunoglobulin (and/or anticomplement) probe, or total PAIgG measured after platelet lysis.

#### Direct Binding Assays for Platelet Surface Immunoglobulin G

In direct binding assays, binding of a labeled anti-immunoglobulin probe to the platelet surface is quantitated. The anti-immunoglobulin probe is labeled with radioisotope, fluorescent marker, or an enzyme. The labeled probe (eg, anti-IgG, anti-IgM, or anticomplement) is incubated with washed test platelets, unbound probe is washed away, and the amount bound to the platelets is measured.<sup>6</sup> Although these assays are simple, a disadvantage is that platelet membranes nonspecifically adsorb proteins, including the labeled probe. However, there is a more fundamental problem: even monoclonal anti-immunoglobulin

probes, despite their low nonspecific binding to platelet membranes, cannot differentiate immune from nonimmune thrombocytopenic disorders.<sup>6</sup> This type of assay can be diagnostically useful, however, in special situations, such as detecting a drug-dependent increase in platelet surface-bound IgG in the presence of patient serum.<sup>7</sup>

### Total Platelet-Associated Immunoglobulin G

The total amount of IgG, from both the interior and the surface of platelets, can be measured as total PAIgG.<sup>6</sup> The test platelets are washed and counted, and the platelet membranes are lysed. The total amount of PAIgG in soluble form can be measured with any technique used to measure fluid-phase IgG, such as nephelometry or immunoradiometric assay. However, the limited diagnostic value of this assay is not surprising, given that less than 1% of PAIgG is bound to the platelet surface, indicating that the majority of IgG measured is nonspecific and stored internally.

### Protein-Specific Platelet-Antibody Assays

The diagnostic usefulness of platelet-antibody assays has increased dramatically with the introduction of various protein-specific assays that help identify the platelet protein target of antibodies with either monoclonal antibodies or electrophoretic techniques.

### Monoclonal Antibody Assays

Various monoclonal antibody-based assays can be used to detect platelet antibodies. Perhaps most widely used is the monoclonal antibody immobilization of platelet antigen (MAIPA) assay. An improved modified MAIPA assay<sup>8</sup> is shown in Fig 23-1(A). A technically simpler assay is the antigen capture enzyme immunoassay, in which platelet glycoprotein monoclonal antibodies interact with detergent-solubilized platelet samples [Fig 23-1(B)], rather than intact platelets.<sup>7,9</sup>

Simplicity and relatively high diagnostic specificity are advantages of these assays, especially the antigen capture assay. In addition to investigation of autoimmune thrombocytopenia, these assays can be adapted for study of alloimmune disorders with a panel of platelet glycoproteins of known alloimmune phenotype, or for study of drug-induced thrombocytopenia through demonstration of drug-dependent binding of antibody to platelet glycoproteins.<sup>7</sup> A disadvantage, however, is that they detect antibodies that bind to platelet proteins captured with the specific monoclonal antibody, so a large number of different monoclonal reagents are needed. These assays also can give false-negative results if the patient antibody binds to the same epitope recognized by the monoclonal antibody. Some human sera contain antibodies that recognize murine IgG, which is why the modified MAIPA and antigen capture assays are preferred to the original MAIPA.<sup>8</sup>

### Immunoprecipitation

Immunoprecipitation is performed by incubating patient serum or plasma with platelets labeled with iodine-125 or tagged with nonradioactive biotin.<sup>10</sup> The proteins are then solubilized by the addition of detergent, and the antibody-protein complex is

**Figure 23-1.** Modified monoclonal antibody immobilization of platelet antigen (MAIPA) assay and antigen capture assay. “Direct” versions of both assays are shown, that is, the patient’s platelets are tested for the presence of platelet glycoprotein (GP)-bound autoantibodies. (In indirect assays, the patient’s serum or plasma is added to target platelets to detect the presence of serum or plasma platelet glycoprotein antibodies.) (A) In the MAIPA assay, the antihuman GP monoclonal antibodies (MoAbs) are added to washed intact patient platelets

before detergent lysis.<sup>8</sup> (B) In the antigen capture assay, the patient’s platelets are washed, then lysed, and only later is GP MoAb added.<sup>9</sup> However, both assays resemble each other in the final stages (steps 4 and 5). A relative advantage of the antigen capture assay is that the platelet lysate can be stored and the assay performed later using any MoAb of choice, making this a technically simpler and more versatile assay. OD = optical density.

precipitated by addition of an anti-immunoglobulin bound to a solid phase (eg, immobilized staphylococcal protein A). The labeled protein-antibody complexes are washed, and the platelet proteins are separated by denaturing gel electrophoresis and detected by autoradiography or use of enzyme-conjugated streptavidin. The target antigen is identified according to its electrophoretic mobility. Either the patient’s platelets are used (direct immunoprecipitation), or patient serum or plasma is mixed with target platelets (indirect immunoprecipitation).

Immunoprecipitation offers advantages over immunoblotting because the antibody reacts with native, rather than denatured, platelet proteins. In particular, this technique has allowed detection of clinically significant antibodies against previously unrecognized platelet proteins, such as anti-HPA-15 (anti-Gov) on CD109, a 175-kD glycosylphosphatidylinositol (GPI)-anchored protein.<sup>11</sup> The main disadvantage of immunoprecipitation is

technical difficulty. In addition, not all platelet proteins are optimally labeled (eg, GPVI).

### Immunoblotting (Western Blotting)

In immunoblotting, patient serum is allowed to interact with platelet proteins that have been electrophoretically separated and then immobilized onto a solid phase (nitrocellulose paper). The test serum is added and binding of patient antibody to specific protein bands is detected with labeled anti-immunoglobulin. Although immunoblotting offers the advantage of simplicity and the opportunity to store the immobilized proteins for long periods, a major disadvantage is that protein antigens are denatured in this method. This can destroy some platelet antigens (eg, HPA-5 and -15) and may modify or expose epitopes to which normal sera can react (eg, vinculin, talin), making interpretation difficult.<sup>11,12</sup>

**Figure 23-2.** Operating characteristics of various platelet-antibody assays. The operating characteristics (sensitivity-specificity trade-offs at various diagnostic cutoffs between positive and negative results) show that assays for heparin-induced thrombocytopenia (HIT) are diagnostically useful (high sensitivity and specificity).<sup>2,13,14</sup> The data for the HIT assays show two diagnostic cutoffs (20% and 50% serotonin release) for the serotonin release assay (SRA), and one diagnostic cutoff (0.45 optical density unit) for the platelet factor 4/heparin enzyme immunoassay (EIA, performed with serum at 1/50 dilution). In contrast, the modified monoclonal antibody immobilization of platelet antigen (MAIPA) assay and antigen capture (AC) tests have moderate usefulness for diagnosis of autoimmune thrombocytopenia (high specificity but low to moderate sensitivity).<sup>9</sup> Conventional assays for platelet-associated immunoglobulin G (PAIgG) have minimal diagnostic value;<sup>6</sup> that is, sensitivity is similar to 1 – specificity. Open symbols = diagnostic cutoff actually used for each assay. The data used for the MAIPA, AC, and PAIgG assays are from published sources.<sup>6,9</sup> Used with permission from Warkentin.<sup>13</sup>

### Tests for Heparin-Induced Thrombocytopenia

Special tests are required to detect the antibodies that cause HIT. These assays are classified as platelet activation or platelet factor 4 (PF4)-dependent antigen assays.<sup>13,14</sup>

#### Platelet Activation Assays

Heparin-induced thrombocytopenia antibodies have potent heparin-dependent, platelet-activating properties. Aggregation of platelets (prepared as citrate-anticoagulated platelet-rich plasma) by patient plasma detected with conventional platelet aggregometry once was widely used for HIT; however, the sensitivity of this assay is relatively low for detecting HIT antibodies. In contrast, assays performed with washed platelets that have been resuspended in calcium-containing buffer, such as the platelet serotonin release assay (SRA) or heparin-induced platelet activation assay, are both sensitive and specific for detecting clinically significant HIT antibodies.<sup>13,14</sup> However, these assays are not widely available because they are technically demanding, require careful platelet donor selection, and require a panel of strong and weak positive serum controls. Heparin-induced thrombocytopenia antibodies have a characteristic activation profile: platelet activation at therapeutic, but not high, heparin concentrations and inhibition of activation by Fc receptor-blocking monoclonal antibodies.

#### Platelet Factor 4/Heparin Enzyme Immunoassay

In 1992, Amiral et al<sup>15</sup> identified PF4/heparin complexes as the antigen of HIT. Both commercial and in-house antigen assays based on enzyme immunoassay (EIA) methods have since become available.

An intriguing feature of the HIT antigen is that certain polyanions other than heparin render PF4 antigenic. This is the basis of the PF4-polyvinylsulfonate EIA for PF4/heparin antibodies.<sup>16</sup>

#### Diagnostic Usefulness of Platelet-Antibody Assays

Figure 23-2 compares the operating characteristics (sensitivity-specificity trade-offs) for three types of platelet-antibody assays. Classical PAIgG assays provide limited diagnostic information,<sup>6</sup> whereas the newer protein-specific platelet-antibody assays have moderate sensitivity and relatively high specificity for immune thrombocytopenia.<sup>9</sup> Both the antigen and washed-platelet activation assays are useful for diagnosis of HIT.<sup>13,14</sup>

### Platelet Genotyping

Serologic assays are generally reliable for detecting platelet alloantibodies. However, a disadvantage of antibody-based analysis is that there may not be sufficient platelets available from a patient with severe thrombocytopenia [eg, posttransfusion purpura (PTP)] to allow determination of the reciprocal platelet alloantigen phenotype.<sup>17</sup> Molecular techniques provide a reliable alternative to serologic phenotyping. Genomic DNA is used to determine the corresponding platelet alloantigen *genotype* and is readily available from a number of sources. Molecular techniques are useful in the evaluation of suspected neonatal alloimmune thrombocytopenia (NAIT). Analysis of fetal cells (obtained by amniocentesis, chorionic villus sampling, or sampling of fetal blood) can determine whether a fetus is at risk for

this complication. Small amounts of tissue can be studied (eg, 5 to 10 mL of amniotic fluid), because the technique of polymerase chain reaction (PCR) greatly amplifies the DNA. The possibility of significant maternal DNA contamination of a fetal sample can be assessed with the forensic technique of variable-number tandem repeat analysis of the sample.<sup>18</sup>

### Polymerase Chain Reaction and Restriction Fragment Length Polymorphism

For all platelet alloantigen polymorphisms but one (HPA-4), the single-base substitution responsible for the change in the expressed amino acid is associated with a restriction endonuclease recognition site.<sup>17</sup> Accordingly, restriction fragment length polymorphism (RFLP) analysis was the first genotyping assay developed to identify platelet alloantigens. In the PCR-RFLP method, a section of DNA that encompasses the polymorphism is amplified using a pair of sense/antisense primers. When the amplified fragment is subjected to restriction enzyme digestion and separated by means of agarose gel electrophoresis, the position and number of fragments indicate the platelet antigen genotype. One limitation is the possibility that another polymorphism within the amplified fragment could confound the genotyping by interfering with the restriction enzyme, as has been shown for the *Msp* I site for HPA-1a/1b.<sup>19</sup>

### Allele-Specific Polymerase Chain Reaction

Because PCR-RFLP is a comparatively labor-intensive technique, an alternative is widely used. In allele- or sequence-specific PCR (SSP-PCR), one of the primers is specific for the particular allele to be amplified.<sup>20</sup> When the allelic polymorphism is positioned at the 3' end of the oligonucleotide primer, efficient amplification occurs only when the primer is 100% complementary to the genomic sequence. *Taq* polymerase is used for the PCR because this enzyme does not repair single-base mismatches at the 3' end of the primers that occur when the mismatch is present. Thus, each allele-specific primer with a common universal primer will amplify the DNA only if the allele is present. The advantage of this method is that the PCR product is visualized directly in agarose gels to determine the genotype. Appropriate controls must be included in the assay, including additional primers to amplify a ubiquitous gene (eg, human growth hormone) to ensure that all assay constituents are working properly.

### Real-Time Polymerase Chain Reaction

A modification of SSP-PCR is real-time PCR. Real-time PCR has improved both the speed and accuracy of genotyping.<sup>21</sup> The use of specifically designed hybridization probes tagged with fluorescent dyes for the PCR allow direct determination of the platelet genotype without gel electrophoresis or restriction enzymes, and in a single reaction. One hybridization probe, the donor, is tagged with a dye (fluorescein) and emits light at a specific wavelength when excited by a light source. The other probe, the acceptor, is tagged with a different dye. It straddles the single nucleotide polymorphism of interest and is 100% homologous to one of the platelet alleles. The acceptor probe usually is one nucleotide away from the donor probe in a head-to-tail arrangement; that is, the

dyes are juxtaposed. The energy emitted by the dye of the donor probe is transferred to the adjacent dye of the acceptor probe, which emits light at a different wavelength. The intensity of the second light emitted is proportional to the amount of double-stranded DNA present. Unbound donor probe in the mixture can be excited but cannot transfer energy to the acceptor probe. At the end of the PCR, the platelet genotype is determined by means of melting curve analysis. Because the acceptor probe straddles the polymorphism and is 100% homologous to one of the alleles, the melting curve has a different temperature midpoint ( $T_m$ ) depending on whether a mismatch is present. The acceptor probe can have as much as 5°C to 8°C difference in  $T_m$  between the two platelet alleles. In all, three melting curves are seen, one for each polymorphism, and a composite melting curve when the heterozygous situation is present.<sup>21</sup> The advantage of fluorescence-based real-time PCR with melting curve analysis is that the PCR product is measured directly and no further manipulation is required. Any additional polymorphism in the region of the acceptor probe is detected in the melting curve analysis. Rapid thermal cycling and DNA extraction permits determination of a platelet genotype within 2 hours of specimen collection.

## Pathophysiology of Immune Platelet Destruction

Immune thrombocytopenia results from antibody-mediated platelet destruction. The IgG-sensitized platelets are phagocytosed by monocytes and macrophages of the reticuloendothelial system. Reticuloendothelial cells are located throughout the body but are concentrated in the spleen, liver, lungs, and marrow. Pathogenic antibodies bind to platelets via their Fab termini, usually against specific autoantigen or alloantigen epitopes. Sometimes the target antigen is induced by a drug or drug metabolite. The result is a ternary complex that involves IgG, drug, and a specific region on a platelet glycoprotein. Heparin-induced thrombocytopenia is an exception to these generalizations: although HIT antibodies bind to PF4/heparin complexes via the Fab terminus, the Fc moiety of IgG interacts with platelet FcγIIa receptors, resulting in platelet activation.<sup>4</sup>

The rate of platelet destruction is determined by the quantity and subclass distribution of IgG on the platelet, the amount of complement, and the efficiency of reticuloendothelial clearance. The severity of thrombocytopenia reflects the balance between the rate of platelet destruction and the compensatory marrow thrombopoiesis.

---

## Idiopathic (Immune) Thrombocytopenic Purpura

Immune thrombocytopenic purpura (ITP), also known as primary autoimmune thrombocytopenic purpura, is a common disorder characterized by increased platelet destruction and impaired platelet production. It is primarily a diagnosis of exclusion, defined as isolated thrombocytopenia with no other

clinically apparent cause such as human immunodeficiency virus (HIV) infection, systemic lupus erythematosus (SLE), drug-induced thrombocytopenia, alloimmune thrombocytopenia, lymphoproliferative disorders, myelodysplasia, hypogammaglobulinemia, splenomegaly, or familial thrombocytopenia.<sup>22</sup> Although platelet-antibody assays allow detection of platelet GP-reactive autoantibodies in up to 75% of patients with ITP, the false-negative rate (at least 25%) means that a negative test does not exclude the diagnosis of ITP.<sup>9,23</sup>

### Pathogenesis

Over 50 years ago, Harrington et al<sup>24</sup> showed that ITP plasma infused into healthy volunteers caused acute severe thrombocytopenia. The platelet-destroying plasma factor was later shown to be IgG, although in some patients, IgM and IgA antibodies may be pathogenic. The immune target of the autoantibodies usually is one of the two major platelet glycoprotein complexes, with GPIIb/IIIa implicated more often than GPIb/IX.<sup>25</sup> Other less common autoantigen targets include GPIa/IIa and, possibly, non-protein targets such as glycosphingolipids. The autoantibodies bind to platelets by way of their Fab terminus and cause premature platelet destruction via Fc receptor (Fc $\gamma$ R)-mediated phagocytosis by macrophages in the spleen and other reticuloendothelial tissues. Platelet autoantibodies can also cause binding of complement *in vitro*; however, *in-vivo* complement-mediated platelet lysis has not been proven. Another proposed mechanism of platelet destruction is direct platelet lysis by T cells.<sup>26</sup>

Platelet production is also impaired in ITP. Platelet turnover is lower than expected, as shown by radiolabeled autologous platelet studies.<sup>27</sup> Further, levels of thrombopoietin (TPO), the constitutively expressed, principal thrombopoiesis regulatory hormone, are lower in ITP compared with other thrombocytopenic disorders such as aplastic anemia.<sup>28</sup> An increased megakaryocyte mass may account for the relative TPO deficiency, because these cells bind free TPO; conversely, platelet underproduction may result from megakaryocyte injury caused by autoantibodies.<sup>29</sup>

A fundamental research problem in ITP is to understand the relation between pathogenic platelet-reactive autoantibodies and measured PAIgG. Doubt regarding the pathogenic significance of elevated PAIgG levels was raised by the observation that even nonimmunoglobulin proteins, such as albumin, are elevated on platelets of patients with ITP.<sup>30</sup> Results of subsequent investigations suggested that elevated PAIgG and albumin levels in ITP and other disorders with increased platelet turnover are caused by increased endocytosis of these plasma proteins into platelet  $\alpha$  granules, which occurs either in megakaryocytes or mature platelets.<sup>31,32</sup> Electron microscopic examination and immunogold labeling of IgG show increased amounts of IgG within  $\alpha$  granules, as well as the open canalicular system and platelet surface, of patients with ITP.<sup>33</sup> Newer assays that detect glycoprotein-specific antibodies are more informative.<sup>23</sup>

The cause of autoantibody formation in ITP is not known. Light-chain and immunoglobulin subclass restriction of

platelet-reactive antibodies suggests an oligoclonal origin of autoantibodies in chronic ITP.<sup>34</sup> Further, the autoepitopes involved may be fairly narrow in scope. Autoantibodies are produced by B lymphocytes, and the loss of T-cell tolerance to platelet proteins is a key feature.

### Clinical and Laboratory Features

Patients are arbitrarily considered to have chronic ITP when thrombocytopenia has lasted more than 6 months. Although chronic ITP can occur at any age and in both sexes, women between 30 and 50 years of age are affected most often (female to male ratio, approximately 3:1). This condition usually is asymptomatic, or the symptoms and signs are limited to bleeding. If clinical evaluation reveals weight loss, fever, lymphadenopathy, hepatomegaly, or splenomegaly, other diagnoses should be considered. Some physicians perform routine screening for thyroid disease,<sup>22</sup> because both hyper- and hypothyroidism are associated with ITP.

The onset of bleeding symptoms is typically insidious. Mucocutaneous bleeding is the hallmark of ITP and manifests as purpura (petechiae, ecchymosis), epistaxis, menorrhagia, oral mucosal bleeding, and gastrointestinal bleeding. Aspirin ingestion can cause bleeding in a patient who otherwise has no symptoms. Immune thrombocytopenic purpura is rarely life-threatening; for example, in a pooled analysis of ITP patients with persistent low platelet counts (less than 30,000/ $\mu$ L), the rate of fatal bleeding (usually from intracranial hemorrhage) was estimated at 0.02 to 0.04 case per patient-year, but was highest (approximately 0.13 case per patient-year) among patients over 60 years of age.<sup>35</sup> On the other hand, many patients even with severe thrombocytopenia have minimal or no bleeding, possibly because of the presence of small numbers of young, reticulated platelets with enhanced  $\alpha$ -granule release to platelet agonists.<sup>36</sup> Often, morbidity is attributable to the treatments and not the disease itself.<sup>37</sup>

The complete blood count usually reveals isolated thrombocytopenia, although microcytic anemia can indicate iron deficiency in patients with chronic bleeding. The MPV usually is increased, although some patients with severe ITP can have a normal or even low MPV. The marrow examination shows normal or increased megakaryocyte numbers, although diagnostic marrow examinations are generally needed only for elderly patients in whom myelodysplasia is common. The bleeding time usually is elevated only when the platelet count is less than 30,000/ $\mu$ L. An elevated bleeding time with a high platelet count is rarely caused by autoantibodies that interfere with platelet glycoprotein function. About 15% to 25% of patients with otherwise typical ITP have a positive result of an antinuclear antibody test, usually low titer. These patients generally do not have a different clinical outcome than do patients with negative antinuclear antibody results.<sup>38</sup> Although platelet autoantibodies are generally not needed to diagnose ITP, direct assays that detect glycoprotein-specific platelet autoantibodies on the platelet surface are more sensitive than indirect assays using patient serum or plasma (~75% vs 50% sensitivity, respectively).<sup>23</sup>

## Treatment Overview

The principles of treatment of adults with ITP are based on the following considerations:

1. Most patients with ITP have hyperfunctional platelets associated with an increased MPV. Thus, many patients do not need treatment despite moderate or even severe thrombocytopenia.
2. The goal of treatment is to achieve a safe platelet count, not necessarily a normal count. The presence of petechiae is helpful in assessing the need for treatment of a patient with minimal bleeding. Prophylactic platelet transfusions are rarely indicated in the management of ITP. Although a transient increase in platelet count usually can be achieved,<sup>39</sup> the benefits of a short-lived increase in a chronic disorder are doubtful. However, platelet transfusions are indicated in the care of patients with life-threatening bleeding (see later).
3. Most adults have chronic ITP; the rate of spontaneous remission is estimated to be only 5%.<sup>22</sup> Thus, the risks of treatment must be balanced against the risks of life-threatening bleeding. Most adults are not cured by a prolonged course of prednisone but often develop significant morbidity from this agent. Splenectomy offers a good chance for a long-term cure and avoids the long-term toxicity of medical therapy.
4. Treatment with corticosteroids and splenectomy fail in approximately 10% to 15% of patients. For these patients, numerous alternative treatments are available, including intravenous immune globulin (IVIG), intravenous Rh Immune Globulin (WinRho, Cangene, Winnipeg, Canada or Rhophylac, ZLB Bioplasma AG, Berne Switzerland), rituximab, danazol, vinca alkaloids, cyclophosphamide, azathioprine, and cyclosporine, among others. Recently, TPO agonists have also been shown to be effective in early clinical trials.
5. Drugs that interfere with platelet function—particularly aspirin, nonsteroidal antiinflammatory agents, and alcohol—should be avoided.

## First-Line Therapy

### Corticosteroids

Corticosteroids improve platelet survival in ITP by reducing both reticuloendothelial phagocytic activity and synthesis of pathogenic autoantibodies.

The standard initial dosage of prednisone is 1 mg/kg/day, usually given until the platelet count has increased to safe values. Regardless of the response, tapering usually is started on Day 14 of therapy, if not sooner. Two prospective studies<sup>40,41</sup> compared conventional and lower-dose prednisone therapy (1 mg/kg/day vs 0.25 mg/kg/day in one trial; 1.5 mg/kg/day vs 0.5 mg/kg/day in the other), and in neither study was there a significant difference in remission at 6-month follow-up evaluation. In the larger study,<sup>41</sup> however, the higher-dose regimen showed a trend to a higher rate of complete remission (46% vs 35%) as well as higher platelet counts at 14-day follow-up evaluation (77% vs 51% having a platelet count greater than 50,000/ $\mu$ L).

For patients with newly diagnosed ITP, very large doses of corticosteroids have been used with the hope of achieving durable

remissions. Initial treatment with high-dose pulse methylprednisolone (starting at 30 mg/kg/day intravenously) resulted in better short-term platelet count responses compared with conventional doses, but long-term responses were not improved.<sup>42,43</sup> In one study ( $n = 125$ ), 84% of patients with acute ITP treated with a single course of high-dose dexamethasone (40 mg/day for 4 days) achieved a platelet count response (to greater than 50,000/ $\mu$ L) and of those, 50% had a response that lasted from 2 to 5 years.<sup>44</sup> In another study ( $n = 37$ ), six courses of monthly high-dose dexamethasone resulted in an overall response rate of 83.8%, and a sustained response of 64.9% after 2 years.<sup>45</sup> However, repeated cycles of high-dose dexamethasone were often poorly tolerated.

In patients with chronic ITP, responses with high-dose dexamethasone are variable. In one study, all 10 treated patients achieved a response that lasted 6 months following six cycles of high-dose dexamethasone (40 mg/day for 4 days).<sup>46</sup> However, other subsequent studies were less encouraging. Using the same regimen, Stasi et al<sup>47</sup> reported that 13 of 32 patients (40.6%) had transient responses only, and in the study by Warner et al<sup>48</sup> none of nine patients responded, and five could not tolerate the treatment.

At least two-thirds of patients attain safe platelet counts (minimum, 30,000/ $\mu$ L) within 1 to 2 weeks of receiving corticosteroids. Most responders achieve platelet counts greater than 100,000 to 150,000/ $\mu$ L. However, ITP in adults usually is a chronic disorder, and most patients have a relapse of thrombocytopenia, either during tapering of prednisone, or within months after stopping the drug.<sup>49</sup>

Overall, approximately 50% of patients have a platelet count above 50,000/ $\mu$ L after stopping prednisone.<sup>40,41,50,51</sup> Patients with shorter duration of bleeding symptoms are more likely to respond favorably.<sup>51</sup> For patients who suffer relapse of thrombocytopenia after initial complete remission, an additional course of prednisone can be effective.<sup>50</sup>

Results of studies with longer follow-up periods indicate that the continuing risk of relapse among adult patients with initial complete remission is substantial. For example, one study<sup>50</sup> showed that only 29% of adult patients who entered complete remission remained in remission 4 years later. In summary, only approximately 10% to 15% of adult patients with ITP have a durable remission following corticosteroid therapy. Consequently, most need either long-term medical treatment or splenectomy.

Adverse effects of prednisone occur in 5% to 20% of patients and include facial swelling, weight gain, and behavioral changes.<sup>22,51</sup> Less common (1% to 5%) but important complications include infection, myopathy, hyperglycemia, psychosis, hypertension, hypokalemia, and osteoporosis. Osteonecrosis, most commonly involving the femoral head, occurs as a late side effect in approximately 5% of patients who undergo prolonged therapy. This complication sometimes occurs after intensive short-term corticosteroid therapy.<sup>52</sup>

### Intravenous Immune Globulin

High-dose IVIG has been used to manage ITP since 1981.<sup>53,54</sup> Prepared by means of ethanol precipitation of pooled plasma

followed by a technique to minimize IgG self-aggregation, monomeric IgG is stabilized with sugar. Thus, more than 95% of IVIG consists of monomeric IgG. The IgG aggregates, IgA, and other contaminants constitute a negligible fraction. The IgG possesses both the Fab and Fc activities required for antigen neutralization and reticuloendothelial cell interaction, respectively, and has the expected half-life and subclass distribution of human IgG.

Reticuloendothelial blockade is the principal mechanism of action of IVIG. Treatment with high-dose IVIG increases serum IgG concentration two- to fourfold, a level that blocks clearance of radiolabeled, IgG-sensitized red cells. Monomeric IgG is in equilibrium with the Fc receptors on the reticuloendothelial cells, and even though the binding affinity for monomeric IgG is low, the high plasma IgG concentration results in high receptor occupancy. However, this reticuloendothelial blockade theory cannot explain the occasional long-term response to IVIG treatment, nor can it account for the observation that Fc-depleted immunoglobulin preparations can be effective in the management of ITP. Thus, other mechanisms of IVIG have been proposed, including the reduction of antibody synthesis; IgG molecules against the Fab regions of pathogenic autoantibodies ("antiidiotypic antibodies")<sup>55</sup>; cytokine-induced pro- or anti-inflammatory effects<sup>56</sup>; up- or downregulation of various FcγRs; or the formation of soluble immune complexes. In a mouse model of ITP, the inhibitory IgG receptor, FcγRIIB, was required for IVIG to cause an elevation in platelet count,<sup>57</sup> and the transfer of IVIG-primed dendritic cells has been shown to recapitulate the effect of IVIG.<sup>58</sup>

The use of IVIG is indicated for patients with ITP with bleeding or for whom an invasive procedure is planned, because it is more effective than corticosteroids at raising the platelet count quickly. A French study of 122 adults with ITP showed that IVIG (0.7 g/kg/day for 3 days) raised the platelet count to over 50,000/μL within 5 days more frequently than did corticosteroids (methylprednisolone, 15 mg/kg/day for 3 days).<sup>59</sup> However, the clinical impact of these observations can be debated.

The usual dose of IVIG is 2 g/kg, given either as 0.4 g/kg for 5 consecutive days or as 1 g/kg over 2 days. One trial showed no difference between one and two doses of 1 g/kg.<sup>60</sup> Thus, one approach is to give 1 g/kg as a single dose and to repeat the dose 2 days later if no significant platelet count increase has occurred.<sup>61</sup> This may avoid unnecessary use of a second dose. To minimize acute side effects, the infusion is given over at least 4 to 8 hours. There is no evidence to suggest that any one preparation of IVIG is superior.

IVIG increases the platelet count to greater than 50,000/μL in approximately 80% of adult patients with chronic ITP, often within 1 to 3 days following start of treatment. In more than half of responders, platelet counts become normal. Unfortunately, responses are usually transient, and tachyphylaxis is common. Platelet counts peak 5 to 10 days after treatment and return to baseline within 2 to 6 weeks.

Although long-lasting complete remission after a single course of IVIG for chronic ITP in adults is uncommon, repeated

treatments separated by a few weeks result in complete or partial remission without need for further IVIG in up to one-third of patients.<sup>60</sup> Of the remaining patients, approximately one-half continue to respond to ongoing maintenance therapy, and one-half experience refractoriness. However, the high cost and time requirement often preclude the use of maintenance IVIG.

IVIG is generally regarded as being safe, although important adverse events are described.<sup>62</sup> Common but mild side effects, which occur among 15% to 75% of patients, include headache, backache, nausea, flushing, and fever.<sup>63</sup> These can be controlled by temporarily stopping or reducing the rate of infusion. Premedication with acetaminophen, antihistamine, or corticosteroids can be helpful. Chest pain, hypertension, hypotension, bronchospasm, and laryngeal edema are uncommon, and other rare side effects include hemolysis caused by ABO alloantibodies within the IVIG, acute renal failure, and aseptic meningitis.<sup>22</sup> Administration of high-dose IVIG can be complicated by thrombotic events, including myocardial infarction, stroke, and deep venous thrombosis (DVT), particularly in elderly patients.<sup>64</sup> Because IVIG is prepared from pooled plasma from thousands of donors, infection transmission is theoretically possible. Transfusion-related acute lung injury following IVIG also has been described.<sup>65</sup>

### Intravenous Rh Immune Globulin

Like IVIG, the mechanism of action of intravenous RhIG is believed to be reticuloendothelial blockade, which probably occurs through occupancy of the reticuloendothelial cell FcγRs by IgG-sensitized red cells. The result is reduced platelet clearance. Thus, the therapy is only effective in D-positive individuals. Further support for this mechanism of action is the observation that plasma containing high-titer anti-c also can increase the platelet count of patients with ITP whose red cells bear this Rh alloantigen. Intravenous RhIG usually is ineffective in the treatment of patients who have undergone splenectomy.<sup>66</sup> Cytokine/chemokine secretion by reticuloendothelial cells may also be an important mechanism for the platelet count rise following treatment with RhIG.<sup>67</sup>

Initially, lower doses of intravenous RhIG were used, but doses of 75 μg/kg have been shown to produce a more rapid increase in platelet count with a longer duration of response.<sup>68</sup> The likelihood of a platelet count response following 75 μg/kg is similar to that of IVIG<sup>69</sup>; likewise, the increase in platelet count usually is transient (2 to 4 weeks), although long-term remissions sometimes occur. The peak platelet count tends to be lower with intravenous RhIG than with IVIG, but the time to reach peak platelet count often is longer; therefore, a greater interval between maintenance injections may be possible with RhIG.<sup>70</sup> Some patients who do not respond to IVIG respond to intravenous RhIG, and vice versa. Costs associated with use of RhIG in the United States are approximately 35% to 60% less than the costs of IVIG.<sup>71</sup>

A clinically important adverse effect of intravenous RhIG is alloimmune hemolysis. Usually, only a minor decrease in

hemoglobin level occurs (less than 20 g/L), although a positive direct antiglobulin test is universal. However, in at least 1 in 1000 recipients, life-threatening acute intravascular hemolysis results, necessitating transfusion or even hemodialysis.<sup>72</sup> Such patients have usually received the US Food and Drug Administration (FDA)-approved dose (50 µg/kg), and the explanation for the severe hemolysis is unknown. Another rare complication is disseminated intravascular coagulation (DIC), with some fatal outcomes reported.<sup>73</sup> Although current intravenous RhIG preparations are considered pathogen-free, the theoretical risk of transmitting infection is illustrated by the epidemic of hepatitis C during 1978 and 1979 in Ireland. It affected young mothers who received perinatal RhIG contaminated with this virus from a single infected donor.<sup>74</sup> Current availability of solvent/detergent-treated RhIG should make the risk of infection negligible. Table 23-1 compares IVIG and intravenous RhIG.

Splenectomy

Splenectomy is frequently successful, because the spleen is the major site of both autoantibody production and platelet destruction. Complete remission occurs in approximately 75% of patients within 4 to 6 weeks after splenectomy.<sup>75</sup> In complete responders, normal platelet counts are reached within 7 days in 90% and within 6 weeks in 98% of patients; spontaneous remission is encountered rarely thereafter. In a further

Table 23-1. Comparison of High-Dose IVIG and Intravenous RhIG for Management of Immune Thrombocytopenic Purpura

| Characteristic                              | High-Dose IVIG                                                                                                    | Intravenous RhIG                                                                                |

IVIG = intravenous immune globulin; RhIG = Rh immune globulin; DIC = disseminated intravascular coagulation; ITP = immune thrombocytopenic purpura.

5% to 10% of patients, partial remission is achieved. In a systematic review of the efficacy of splenectomy for patients with ITP, younger age was an independent predictor of response to splenectomy<sup>75</sup>; however, other investigators have shown that response to IVIG<sup>76–78</sup> and splenic clearance of platelets (determined by radionuclide platelet imaging techniques)<sup>79</sup> are good predictors of response to splenectomy. The risk of relapse after a complete remission following splenectomy is low (approximately 10% to 15% at 10 years).

Perioperative management of splenectomy involves 1) optimization of the platelet count before surgery; 2) vaccination to minimize the risk of overwhelming postsplenectomy infection; and 3) prevention of thromboembolism. Adequate perioperative hemostasis usually can be achieved with preoperative high-dose IVIG or corticosteroids. Sometimes despite these measures, patients have thrombocytopenia at splenectomy. However, most patients do not have excessive bleeding; therefore, platelet transfusions should be reserved for perioperative bleeding.

Laparoscopic splenectomy is an increasingly popular surgical approach, with outcomes similar to open splenectomy.<sup>80,81</sup> A concern is that residual spleen tissue (accessory spleens) may be missed more frequently than with open splenectomy; however, this did not occur in a recent large cohort study.<sup>81</sup>

The presence of residual accessory spleen should be considered when splenectomy fails, or when patients relapse months or years after surgery.<sup>82</sup> Postsplenectomy blood film changes (eg, Howell-Jolly bodies) do not necessarily eliminate the possibility of a residual accessory spleen. Approximately 10% to 50% of patients with postsplenectomy relapse have accessory spleens detected with sensitive radionuclide imaging, such as heat-damaged red cells labeled with technetium-99m or platelets labeled with indium-111; however, a durable platelet count response following accessory splenectomy performed because of postsplenectomy relapse of ITP is expected in less than 50% of patients.

Perioperative morbidity after splenectomy is less than 10%. The most frequent complications are pleuropulmonary (pneumonia, subphrenic abscess, pleural effusion) in 4% of patients, major bleeding in 1.5%, and thromboembolism in 1%. Morbidity is probably even lower when laparoscopic splenectomy is performed by an experienced surgeon. Overall mortality is approximately 1% following laparotomy and 0.2% following laparoscopic splenectomy.<sup>75</sup>

The major long-term risk is overwhelming postsplenectomy infection. In a pooled analysis of 19,680 splenectomized patients from 78 studies, the incidence of postsplenectomy septicemia and/or meningitis (median follow-up, 6.9 years) was 3.2%, with a 44% case-fatality rate (overall infection-associated mortality rate, 1.4%).<sup>83</sup> The incidence of septicemia/meningitis and infection-associated mortality was 2.1% and 1.2%, respectively, among the 484-patient subgroup splenectomized because of ITP.<sup>83</sup> To reduce this risk, all patients should be vaccinated with polyvalent pneumococcal vaccine, quadrivalent meningococcal polysaccharide vaccine, and *Haemophilus influenzae* type b vaccine, preferably at least 2 weeks before splenectomy.<sup>84</sup>

Postoperative thromboembolism is the most common cause of postoperative mortality; thus, for patients with delayed postoperative mobilization, prophylactic low-molecular-weight (LMW) heparin should be considered when the platelet count is recovering.

### Long-Term Management: Second-Line Therapy

About 10% to 15% of patients with ITP do not attain a durable response despite prednisone and splenectomy. The large number of therapies that have been used for these treatment failures attests to the difficulty in caring for such patients. In a systematic review, rituximab, azathioprine, and cyclophosphamide had the most reported complete responses in such refractory patients.<sup>85</sup>

#### Rituximab

Rituximab is a chimeric monoclonal anti-CD20 currently indicated for the treatment of lymphoma and rheumatoid arthritis. The Fab portion binds to CD20 on B lymphocytes, which results in Fc $\gamma$ R-mediated B-cell lysis by complement-dependent<sup>86</sup> and antibody-dependent pathways.<sup>87-89</sup> In ITP, rituximab depletes CD20-positive B cells, which are responsible for platelet autoantibody production. Rituximab-coated B cells may also cause reticuloendothelial blockade, possibly accounting for the rapid response to treatment observed in some patients.<sup>90</sup> Recently, platelet count responses to rituximab have been correlated with the normalization of T-cell abnormalities in ITP patients, suggesting that rituximab may be more effective at an early stage of ITP, when T-cell expansion is still dependent on B-cell co-stimulation.<sup>91</sup>

A systematic review<sup>92</sup> of the literature described outcomes in adults who had ITP for 1 to 360 months (half after splenectomy). A complete response to rituximab (platelet count greater than 150,000/ $\mu$ L) was seen in 43.6% of patients (95% CI, 29.5% to 57.7%) and an overall response (platelet count greater than 50,000/ $\mu$ L) in 62.5% (95% CI, 52.6% to 72.5%). Responses lasted a median of 10 months. Approximately one-third of patients treated with rituximab may achieve a durable remission.<sup>93</sup> Results with rituximab in children are less encouraging. In a prospective single-arm study of 36 children with chronic ITP treated with rituximab, 11 (30.6%) achieved a platelet count of 50,000/ $\mu$ L or greater for 4 consecutive weeks.<sup>94</sup>

Rituximab is generally well tolerated. However, infusional side effects, including chills, blood pressure fluctuations, and respiratory complaints, occur in approximately 20% of patients with ITP. Serum sickness has also been reported.<sup>94</sup> In 2006, the FDA issued a safety alert following two fatal cases of progressive multifocal leukoencephalopathy (a rare neurologic syndrome caused by JC virus reactivation) among patients with SLE treated with rituximab.<sup>95</sup>

#### Danazol

Danazol is an attenuated androgen with mild virilizing effects that can be used to treat men and nonpregnant women with ITP. Its mechanism of action is to decrease Fc $\gamma$ R numbers and the rate of Fc $\gamma$ R-mediated clearance of IgG-sensitized cells. Danazol decreases the number of monocyte IgG Fc receptors.<sup>96</sup> Usually, 400 to 800 mg is administered daily in divided doses, although

some physicians use low doses (50 mg/day). A response usually occurs within 2 months, although when low doses are used, as long as 6 months may be needed.

Danazol appears to produce a sustained increase in platelet count in approximately 30% to 40% of treated patients. The response rate may be higher among patients with associated rheumatologic disorders.<sup>97</sup> Danazol must be continued to maintain the platelet count response, although attempts at dose reduction should be made.

Danazol is generally well tolerated. The most frequent adverse effects are mild virilization, fluid retention, nausea, amenorrhea, and liver dysfunction. Peliosis of the liver and spleen, headaches, increased fibrinolysis, and idiosyncratic thrombocytopenia are rare side effects. Fetal damage precludes use during pregnancy.

#### Vinca Alkaloids

Vinca alkaloids (vincristine, vinblastine) can produce generally short-lived increases in platelet count in approximately 65% of patients.<sup>98</sup> These drugs bind to platelet microtubules and so might work by being delivered to, and thereby inhibiting, reticuloendothelial macrophages. Repeated doses of vinca alkaloids are rarely used to treat patients with chronic ITP, mostly because of dose-dependent neuropathy.

#### Immunosuppressive Agents

Cyclophosphamide, azathioprine, mycophenylate, and cyclosporine are immunosuppressive agents that have been used to treat patients with refractory ITP. Cyclophosphamide is an alkylating agent given in doses of 1 to 2 mg/kg/day, although high-dose cyclophosphamide has been used in combination with autologous stem cell transplantation.<sup>99</sup> Azathioprine and mycophenylate are purine antimetabolites that inhibit lymphocyte proliferation. Cyclosporine is a calcineurin inhibitor that selectively blocks T-cell-dependent biosynthesis of lymphokines, particularly interleukin-2, at the level of messenger RNA transcription.

These drugs, alone or in combination, have shown moderate success, with up to two-thirds of patients exhibiting a platelet count response.<sup>85,100,101</sup> However, only 20% to 30% have responses that persist after stopping the drug(s). Responses may occur as early as 2 weeks and as late as 3 months after initiation of treatment.

Leukopenia is a limiting side effect of azathioprine and occasionally mycophenylate, and the concern over leukemic transformation has limited use of cyclophosphamide.<sup>102</sup> Animal studies suggest that intermittent cyclophosphamide may be less leukemogenic than daily administration. Cyclophosphamide also can cause hemorrhagic cystitis and hepatic toxicity. Cyclosporine is associated with hypertension and renal failure in some patients.

#### *Helicobacter pylori* Eradication

Molecular mimicry between microbial antigens and platelet antigens is the proposed mechanism of ITP in the setting of *H. pylori* infection.<sup>103</sup> *H. pylori* can be successfully eradicated in 87% of patients with a 1- to 2-week course of antibiotics and proton

pump inhibitors, with some long-term remissions of concomitant ITP reported. Further, in a recent meta-analysis of 788 patients (half of whom had received prior treatment with corticosteroids, immunosuppressive agents, or splenectomy), *H. pylori* treatment and eradication were each associated with platelet counts that were 34,000/ $\mu$ L and 52,000/ $\mu$ L higher, respectively, than untreated and noneradicated controls.<sup>104</sup> Although this meta-analysis helps to support a pathogenic role for *H. pylori* infection in ITP, the conflicting results among individual studies remain unexplained.

### Thrombopoietin Agonists

The recent success of TPO agonists in patients with ITP has reinforced the concept of platelet underproduction as an important mechanism of thrombocytopenia in ITP. TPO agonists activate the c-Mpl receptor on megakaryocytes, thereby stimulating platelet production. Unlike recombinant TPO, these molecules do not resemble endogenous TPO, and thus do not stimulate formation of TPO-reactive autoantibodies. Subcutaneous and oral preparations have been developed, with both showing promising results in Phase I and II studies.<sup>105,106</sup> A platelet count increase during continuing TPO agonist administration is achieved in 60% to 75% of patients. Mild-to-moderate increase in marrow reticulin (but without collagen fibrosis and with normal cytogenetic findings) was observed in two patients.<sup>105</sup>

The precise role for TPO agonists in the treatment of ITP is still uncertain, and full reports of Phase III trials are anticipated. These agents may be most appropriate for refractory patients after splenectomy or to prepare for an invasive procedure. The potential to spare patients the need for splenectomy is also under investigation.

### Other Treatments

Other agents that have been used for patients with refractory ITP include colchicine, dapsone, interferon- $\alpha$ , protein A immunoadsorption, and plasmapheresis. Interferon- $\alpha$ -2b may be effective for patients with hepatitis C-associated thrombocytopenia.<sup>107</sup> Blocking monoclonal antibodies against the Fc $\gamma$ R<sup>108</sup> and against CD40 ligand (CD154)<sup>109</sup> have also shown promise in selected patients with refractory disease.

### Special Treatment Situations

#### Emergency Treatment of a Bleeding Patient

Any patient with ITP who has life-threatening bleeding needs immediate platelet transfusion (5 to 10  $\times 10^{11}$  platelets, or approximately 5 to 10 units). The patient then should receive IVIG (1 g/kg) over 4 to 6 hours to block the reticuloendothelial system, and additional platelet transfusions as required.<sup>110</sup> Some physicians use continuous infusions of IVIG and platelets for this situation.<sup>111</sup> Other treatments (eg, corticosteroids) to achieve longer-term control of thrombocytopenia should be started simultaneously.

#### Preparation for Invasive Procedures

High-dose IVIG usually is the treatment of choice for severely thrombocytopenic patients with ITP who need urgent surgery

or an invasive procedure. Prophylactic platelet transfusion should be administered only when maximal hemostasis is required, because transfusion-induced platelet count increments are usually transient. For situations in which at least 2 or 3 days are available before the planned procedure, less expensive and equally effective options include corticosteroids or intravenous RhIG.

### Immune Thrombocytopenic Purpura in Pregnancy

Thrombocytopenia during pregnancy usually is not caused by ITP. Rather, a benign condition known as *gestational thrombocytopenia* is more common, occurring in approximately 5% of pregnancies at term. In this condition, maternal platelet counts do not fall below 70,000/ $\mu$ L.<sup>112</sup> Newborns of mothers with incidental thrombocytopenia are not at increased risk of neonatal thrombocytopenia.<sup>113</sup> The second most likely cause of thrombocytopenia is pregnancy-related disorders [eg, preeclampsia and syndrome of hemolysis, elevated liver enzymes, and low platelet count (HELLP syndrome)]. Preeclampsia occurs in approximately 10% of pregnancies and causes thrombocytopenia in one-fourth of affected mothers. Preeclampsia is associated with increased maternal and fetal morbidity and mortality. Secondary causes of immune thrombocytopenia that can occur in young women, such as SLE or HIV infection, should also be considered in the appropriate clinical context.

ITP in pregnancy is an important disorder because of the treatment implications for the mother and the possibility of fetal or neonatal thrombocytopenia caused by transplacental passage of IgG platelet autoantibodies. In the past, infants of mothers with ITP were delivered by cesarean section; however, today, this procedure is not routinely recommended, for two reasons. First, the frequency of severe fetal thrombocytopenia (platelet count less than 20,000/ $\mu$ L) is low (approximately 4%).<sup>114</sup> Second, there is no evidence that cesarean section leads to less intracranial bleeding compared with vaginal delivery.

Many pregnant women with ITP do not need specific treatment, unless the platelet count decreases below 20,000/ $\mu$ L or there is evidence of impaired hemostasis. The two preferred treatment options are intermittent high-dose IVIG and low-dose prednisone; however, IVIG is generally the treatment of choice (1 g/kg every 2 to 4 weeks) because side effects are more common with prednisone and include teratogenicity (first trimester) and preeclampsia (second and third trimesters). At delivery, thrombocytopenic patients should not be subjected to epidural analgesia. Platelet transfusions are almost never needed at delivery. In the largest cohort of infants born to mothers with ITP (119 pregnancies in 97 women), 10% of infants had a platelet count below 50,000/ $\mu$ L at birth, 15% required hemostatic treatments, and 1% died.<sup>115</sup>

There are no good predictors of fetal thrombocytopenia, not even the severity of maternal thrombocytopenia (indeed, women cured of ITP by splenectomy can bear infants with passive autoimmune thrombocytopenia). Results of maternal platelet-antibody tests also are unhelpful. Although it is

possible to determine the fetal platelet count by fetal cord sampling (cordocentesis), this procedure causes morbidity or mortality in 1% to 2% of fetuses sampled. Consequently, this procedure is generally discouraged.

At the authors' facility, pregnant patients with ITP are followed with platelet counts every few weeks. Testing for antiphospholipid antibodies (lupus anticoagulant and anticardiolipin antibodies) is performed because this can be an indication for treatment, especially if previous miscarriages have occurred.<sup>116</sup> If therapy for maternal thrombocytopenia is needed, IVIG is preferred. Splenectomy is rarely indicated for severe, refractory thrombocytopenia in pregnancy.<sup>22</sup>

Unless cesarean section is needed for obstetric indications, spontaneous vaginal delivery is recommended for mothers with ITP. An immediate fetal umbilical vein platelet count is obtained at delivery. Relatively severe neonatal thrombocytopenia (platelet count less than 50,000/ $\mu$ L) should be aggressively managed with IVIG or corticosteroids. It is important to recognize that the platelet count of a newborn infant with passive autoimmune thrombocytopenia may decrease for up to 5 days after delivery,<sup>117</sup> possibly because of the recruitment of reticuloendothelial cells within the lung. A daily platelet count should be obtained until the platelet count normalizes.

### Acute Immune Thrombocytopenic Purpura of Childhood

Acute ITP of childhood is a relatively common, generally self-limited, immune thrombocytopenic disorder with a peak incidence between 2 and 6 years of age. Boys and girls are equally affected, except for infants, in which males predominate.<sup>118</sup> Most children (80% to 90%) with acute ITP recover completely within 6 months; the others have persistent thrombocytopenia. Acute ITP of childhood likely is a transient autoimmune disorder.<sup>119</sup>

The typical clinical manifestations are bleeding and bruising following a viral infection. The mortality is approximately 0.4% and most deaths are caused by intracranial hemorrhage. Laboratory abnormalities include isolated thrombocytopenia and normal or increased MPV. A marrow examination usually is not performed on a child with typical clinical features of ITP, but is indicated for unexpected clinical or laboratory findings. Normal or increased numbers of megakaryocytes are observed. Sometimes, morphologically distinct lymphoid cells, called *hematogones*, constitute up to one half of the marrow cells and may cause confusion with acute leukemia.<sup>120</sup> These nonneoplastic cells have the surface immunophenotypic profile of immature lymphocytes.

Acute ITP in children usually is a benign disease. Although rare, intracranial hemorrhage is the most feared complication. Clinical trials have focused on the time to increase the platelet count to safe levels as a surrogate endpoint for avoiding intracranial hemorrhage.

In a meta-analysis of six randomized trials ( $n = 410$  children), IVIG was associated with a more rapid platelet count increase compared with corticosteroids.<sup>121</sup> On the basis of these results, high-dose IVIG is generally recommended for initial treatment of severe acute ITP in children. Oral prednisone or an additional dose of IVIG is added if the platelet count remains below 20,000/ $\mu$ L by 48 hours. It appears that lower doses of IVIG (eg, 250 to 500 mg/kg/day for 2 days rather than the standard 1 g/kg/day) may also be effective.<sup>122</sup>

High-dose corticosteroid therapy (eg, intravenous methylprednisolone at 30 mg/kg/day for 3 days; or oral methylprednisolone 30 to 50 mg/kg/day for 7 days) also rapidly increases the platelet count in children with acute severe ITP.<sup>123</sup> Combined treatment with IVIG and pulse methylprednisolone may be indicated for those children felt to be at very high risk of intracranial hemorrhage.<sup>124</sup>

### Chronic Immune Thrombocytopenic Purpura of Childhood

Approximately 10% to 20% of children with ITP eventually have chronic ITP, defined as a platelet count less than 100,000/ $\mu$ L for more than 6 months. As many as one-third of children who meet this definition can still enter late spontaneous remission, sometimes as long as 5 to 10 years after diagnosis. Chronic ITP in children resembles adult chronic ITP.

Some patients have no symptoms despite marked thrombocytopenia. These children generally do not need treatment. For children with symptoms, options include long-term or intermittent administration of corticosteroids, maintenance IVIG or RhIG, splenectomy, vinca alkaloids, and immunosuppressive agents.<sup>125</sup>

Intravenous immune globulin (2 g/kg over 2 to 5 days) increases the platelet count of most children with chronic ITP<sup>53,125</sup> and repeated courses of IVIG have been used to defer or avoid splenectomy. This practice also appears to be cost-effective.<sup>126</sup> Unfortunately, approximately 25% of patients become refractory. Low-dose, alternate-day corticosteroid therapy may improve the results with maintenance IVIG.

Intravenous RhIG is effective in increasing the platelet count of most Rh-positive children with chronic ITP<sup>70,127</sup> and, at a dose of 75  $\mu$ g/kg, appears to be as effective as IVIG.<sup>69</sup> The benefit is transient and the median duration of benefit is approximately 3 weeks. RhIG can also be considered splenectomy-sparing in some patients.<sup>127</sup> However, RhIG is generally ineffective following splenectomy.<sup>127</sup>

Splenectomy is sometimes performed in children with chronic ITP who cannot be maintained on low-dose maintenance glucocorticoids, IVIG, or RhIG therapy. Because of the high probability of a cure (approximately 70%), some physicians perform splenectomy before instituting potentially toxic immunosuppressive therapy. However, in general, splenectomy is avoided in children, especially young children, because of the

high risk of postsplenectomy sepsis, the possibility of late spontaneous remissions, and the efficacy of intermittent maintenance therapy with IVIG or RhIG. Patients must receive polyvalent pneumococcal, meningococcal, and *H. influenzae* type b vaccination, at least 2 weeks before the splenectomy.<sup>84</sup>

Results of use of immunosuppressive agents (azathioprine or cyclophosphamide) and vinca alkaloids to treat children with chronic ITP are variable and based on uncontrolled studies.<sup>125</sup> Pulse corticosteroids have been used in children, although few durable remissions occur. In one study, three of seven children achieved a platelet count above 50,000/ $\mu$ L 6 months after receiving high-dose dexamethasone. One child had a response that was maintained to 1 year.<sup>128</sup> Children with chronic ITP refractory to splenectomy occasionally obtain benefit from cyclosporine. Danazol can be tried in the adolescent patient. About one-third of pediatric patients with chronic ITP responded to rituximab in one study.<sup>94</sup>

## Secondary Immune Thrombocytopenic Purpura

### Systemic Lupus Erythematosus and Antiphospholipid Antibody Syndromes

SLE and antiphospholipid antibody syndrome (APLAS) are autoimmune disorders complicated by thrombocytopenia in 15% to 25% of patients. Mechanisms of thrombocytopenia include platelet glycoprotein-reactive autoantibodies,  $\beta_2$ -glycoprotein 1-containing and other platelet-reactive immune complexes, and hypersplenism, among others. Whether antibody-induced platelet activation in vivo contributes to thrombosis in SLE or APLAS is uncertain.

Various thrombocytopenic syndromes occur. Sometimes the thrombocytopenia is chronic, resembling ITP, and is the predominant clinical manifestation of SLE or APLAS.<sup>129</sup> Sometimes, patients with even mild thrombocytopenia have platelet dysfunction and a prolonged bleeding time. Thrombocytopenia complicated by antiphospholipid antibodies carries increased risk of thrombosis, rather than bleeding.<sup>130</sup> These patients often have livedo reticularis or acrocyanosis that can progress to digital necrosis.<sup>131</sup> Acute, severe thrombocytopenia can be prominent in patients with severe multisystem exacerbation of SLE<sup>129</sup> or the catastrophic APLAS.<sup>132</sup> In rare instances, patients with SLE have an illness that closely resembles thrombotic thrombocytopenic purpura (TTP) or hemolytic uremic syndrome (HUS). These patients may require plasma exchange.<sup>133</sup>

Thrombocytopenia associated with SLE is managed similarly to ITP, except that danazol should be tried before splenectomy. Antiplatelet agents are recommended in patients with APLAS as soon as a hemostatic platelet count is achieved; in patients who have thrombotic complications, full-dose anticoagulation is required. Corticosteroids are used as initial therapy, although thrombocytopenia may recur during tapering of prednisone. Steroid maintenance should be considered especially if this

treatment controls other aspects of SLE. The role of corticosteroids in APLAS-associated thrombocytopenia is less clear. Some patients develop progressive ischemic necrosis of digits during corticosteroid therapy.<sup>134</sup>

Splenectomy is probably as effective in achieving platelet count remission in SLE and APLAS as it is in ITP.<sup>135</sup> Some physicians first try danazol (an attenuated androgen) for several weeks or months in doses of 200 to 1200 mg/day<sup>97</sup> before splenectomy. For patients with disease that is refractory to danazol and splenectomy, more aggressive therapies such as high-dose IVIG, rituximab, azathioprine, mycophenylate, intermittent pulse cyclophosphamide,<sup>136</sup> plasmapheresis synchronized with pulse intravenous cyclophosphamide,<sup>137</sup> and cyclosporine<sup>138</sup> can be tried.

### HIV-Associated Immune Thrombocytopenic Purpura

Thrombocytopenia occurs in approximately 10% to 15% of persons with asymptomatic HIV infection and 30% to 40% of patients with AIDS. Besides immune platelet destruction, there are many other ways that infection with HIV can cause thrombocytopenia,<sup>139</sup> including impaired platelet production secondary to HIV infection of megakaryocytes, drug-induced myelosuppression (commonly, zidovudine, ganciclovir, and trimethoprim/sulfamethoxazole), HIV-associated thrombotic microangiopathy, hypersplenism, and marrow infiltration by tumor or opportunistic infections. Platelet kinetic studies have shown a complex interaction of impaired platelet production, increased platelet destruction, and predominant splenic platelet sequestration and destruction.<sup>140</sup>

Immune platelet destruction may be related to antibodies that cross-react with polymorphic regions on HIV-1 proteins and GPIIb/IIIa or GPIb/IX complexes.<sup>141</sup> Immune complexes containing IgM anti-idiotypic antibodies against anti-GPIIIa may explain the paradox of high levels of platelet-bound IgG and IgM but low levels of serum platelet-reactive antibodies in HIV-associated ITP.<sup>142</sup>

The occurrence of isolated immune thrombocytopenia does not necessarily indicate an increased risk of progression to a more advanced stage of HIV infection. Particularly in children, patients with HIV-associated thrombocytopenia may not even have helper-T-cell lymphopenia. Sometimes thrombocytopenia resolves spontaneously.

Anti-HIV therapy, as with zidovudine, often increases the platelet count in patients with HIV-associated thrombocytopenia.<sup>143</sup> For patients whose condition is refractory to zidovudine, interferon- $\alpha$  has been reported to be effective. Highly active antiretroviral therapy, typically consisting of two nucleoside analogs in conjunction with an HIV protease inhibitor or a nonnucleoside reverse transcriptase inhibitor, has improved survival among patients with HIV infection. Such regimens also increase the platelet count of patients with thrombocytopenia in inverse proportion to the reduction in HIV viral load.<sup>144</sup>

Many patients have no or minimal bleeding and do not need specific therapy for HIV-associated thrombocytopenia. For patients with symptomatic thrombocytopenia, however, the treatment approach is similar to therapy for classical ITP,<sup>54,70,145</sup> although intravenous RhIG may be somewhat more effective than IVIG in some patients with HIV-associated ITP.<sup>146</sup> Splenectomy appears to be at least as effective in achieving long-term remission of HIV-associated thrombocytopenia as it is in the management of primary ITP.<sup>147</sup> Splenectomy also does not accelerate, and may even reduce, the rate of progression to AIDS among persons with HIV infection.

### Neoplasia-Associated Immune Thrombocytopenic Purpura

Immune thrombocytopenia can precede or accompany neoplastic disorders, especially lymphoproliferative syndromes.<sup>148</sup> Decreased platelet survival and the presence of platelet-reactive autoantibodies<sup>149</sup> have been found. In general, the thrombocytopenia represents less of a risk to the patient than does the underlying malignant disease; thus, the first step is management of the underlying disorder. Sometimes thrombocytopenia resolves as the tumor responds to treatment, but at other times, it necessitates therapy similar to chronic ITP (corticosteroids, splenectomy, etc). In one study, 30% of patients with ITP and Hodgkin disease responded to corticosteroids, whereas 75% benefited from splenectomy.<sup>148</sup>

### Transplantation-Associated Immune Thrombocytopenic Purpura

Severe persistent thrombocytopenia despite recovery of red and white cells is relatively common after allogeneic or autologous hematopoietic stem cell transplantation (HSCT). Autoimmune thrombocytopenia has been implicated in some patients. Late-onset thrombocytopenia following HSCT or solid-organ transplantation that responds to glucocorticoids, IVIG, and splenectomy also has been attributed to autoimmune and even alloimmune thrombocytopenia.<sup>150</sup> However, in any consideration of immune-mediated thrombocytopenia, more common explanations for thrombocytopenia should be suspected including infection, organ rejection, and drugs (eg, vancomycin,<sup>151</sup> azathioprine, sulfamethoxazole-trimethoprim, etc). Approximately 2% of recipients of solid-organ transplants have microangiopathic hemolysis within the first year after transplantation.<sup>152</sup>

## Drug-Induced Immune Thrombocytopenia

Drugs can produce several immune-mediated thrombocytopenic disorders<sup>4,153–156</sup> (Table 23-2). The most common is HIT, which paradoxically is associated with increased risk of thrombosis but not bleeding. In contrast, many other drugs in rare instances cause severe thrombocytopenia and bleeding, a

syndrome called *drug-induced immune thrombocytopenic purpura* (DITP) to emphasize its clinical resemblance to acute ITP. Some drugs cause atypical clinical signs and symptoms (eg, abciximab-induced thrombocytopenia) or trigger an illness that resembles TTP or HUS.

### Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia is a relatively common, IgG-mediated, adverse reaction to heparin that has a strong association with venous and arterial thrombosis.<sup>2-4,157</sup> Heparin-induced thrombocytopenia can be considered a clinicopathologic syndrome; that is, the diagnosis is made most reliably on both clinical and serologic grounds.<sup>158,159</sup> Thus, HIT antibody formation without thrombocytopenia or other abnormalities is not HIT, whereas HIT antibody formation accompanied by an otherwise unexplained 50% or greater postoperative decrease in platelet count (even if the platelet count remains greater than 150,000/ $\mu$ L)<sup>3</sup> or complicated by necrotizing skin lesions at heparin injection sites<sup>157</sup> are examples of HIT syndrome. Indeed, the thrombocytopenia usually is much less severe in HIT<sup>4</sup> than in DITP<sup>160</sup> or GPIIb/IIIa antagonist-induced thrombocytopenia<sup>161</sup> (Fig 23-3). Another contrast from DITP is that even when severe thrombocytopenia occurs in HIT, petechiae and other types of bleeding typically are not observed.<sup>157,162</sup> Indeed, even the one characteristic (although uncommon) hemorrhagic complication of HIT—bilateral adrenal hemorrhage—is caused by thrombosis (adrenal vein thrombosis leading to hemorrhagic necrosis).<sup>157</sup> HIT is an antibody-mediated disorder, and a minimum of 5 days is required for an immunizing exposure to heparin to generate sufficient levels of antibodies to cause thrombocytopenia.<sup>157</sup> Sometimes, onset of thrombocytopenia and thrombosis begins after all heparin has been stopped (“delayed-onset HIT”).

The target antigen recognized by HIT antibodies consists of a multimolecular complex between PF4 (a platelet  $\alpha$ -granule protein of the CXC family of chemokines) and heparin.<sup>15</sup> The HIT antibodies bind to one or more PF4 regions that have undergone conformational modification through binding to heparin. The formation of the antigen is somewhat nonspecific, because PF4 can be rendered antigenic by binding to certain other polyanions, such as pentosan polysulfate or polyvinylsulfonate.<sup>16</sup> At least 12 to 14 saccharide units are needed for heparin to form the antigen complex with PF4. This may explain why LMW heparin preparations are less immunogenic than unfractionated heparin and are less likely to cause HIT.<sup>2,3</sup> Although LMW heparin sometimes causes HIT, it is likely that very small heparin preparations (eg, fondaparinux, a synthetic anti-Factor Xa-binding pentasaccharide) or specially engineered heparins (eg, highly-sulfated heparin moieties bridged with nonsulfated spacer regions) cause HIT rarely, if at all.<sup>163</sup>

Figure 23-4 illustrates several possible mechanisms to explain the intense thrombin generation that occurs in HIT.<sup>164,165</sup> These

MMR = measles-mumps-rubella; ITP = immune thrombocytopenic purpura; TTP = thrombotic thrombocytopenic purpura; HUS = hemolytic uremic syndrome.

include the formation of procoagulant, platelet-derived micro-particles<sup>166</sup> that result from cell signaling triggered by clustering of platelet Fc $\gamma$ Rs. Recent data suggest that in-situ formation of IgG-PF4/heparin complexes on the platelet surface leads to platelet activation.<sup>167</sup> In-vivo platelet activation is suggested by expression of P-selectin by circulating platelets in HIT as well as by increased levels of circulating microparticles. Tissue factor expression by endothelium or monocytes activated by HIT antibodies that recognize PF4 bound to surface glycosaminoglycans are other possible procoagulant events.

Marked in-vivo thrombin generation helps explain several clinical features of HIT, including its association with venous and arterial thrombosis (hypercoagulable state), the occurrence of decompensated DIC with low fibrinogen levels in approximately 10% of patients, and the potential for DVT to progress to venous limb gangrene, particularly in patients treated with warfarin.<sup>165</sup> This last syndrome results from impaired procoagulant-anticoagulant balance: warfarin-induced protein C depletion leads to microvascular thrombosis caused by ongoing intense thrombin generation. Patients with warfarin-induced venous gangrene

typically have a supratherapeutic international normalized ratio (INR), usually more than 4.0. The explanation is a concomitant severe decrease in Factor VII that parallels the decrease in protein C. The importance of in-vivo thrombin generation in HIT provides a rationale for current consensus recommendations that an agent that reduces thrombin generation or directly inactivates thrombin be used for the management of this syndrome.<sup>158,159</sup>

The frequency of HIT varies among different patient populations. Medical patients appear to develop HIT less often than do surgical patients, and female gender is a minor risk factor for HIT.<sup>168</sup> The frequency of HIT can be as high as 5% when multiple risk factors are present (thromboprophylaxis with unfractionated heparin administered for 2 weeks to a female patient following major surgery), whereas the risk is very low or negligible in other settings (eg, administration of LMW heparin during pregnancy).<sup>2,3,169</sup>

**Iceberg Model of HIT**

Figure 23-5 illustrates the relation between clinical HIT and detectability of PF4/heparin antibodies either by washed platelet

**Figure 23-3.** Platelet count nadirs ( $\log_{10}$  scale) and clinical profile of classic drug-induced immune thrombocytopenic purpura (DITP) and heparin-induced thrombocytopenia (HIT). Classic DITP (eg, caused by quinine, vancomycin, or glycoprotein IIb/IIIa antagonists, among many others) typically produces severe thrombocytopenia (platelet count nadir,  $\sim 10,000/\mu\text{L}$ ) and associated mucocutaneous bleeding. In contrast, HIT typically results in mild to moderate thrombocytopenia (median platelet count nadir,  $\sim 60,000/\mu\text{L}$ ) and associated venous or arterial thrombosis. Note that the relative heights of the two peaks are not drawn to scale; HIT is much more common than all other causes of DITP combined. (Used with permission from Warkentin.<sup>4</sup>)

**Figure 23-4.** Pathogenesis of heparin-induced thrombocytopenia. Two explanations for thrombosis in HIT are presented. Activation of platelets by platelet factor 4 (PF4)/heparin IgG antibodies leads to formation of procoagulant, platelet-derived microparticles. Together with neutralization of heparin by PF4 released from activated platelets, there results a marked increase in thrombin generation. Such a “hypercoagulability state” is characterized by an increased risk of venous and arterial thrombosis, as well as predisposition to warfarin-associated microvascular thrombosis (eg, venous limb gangrene). However, it is also possible that other unique pathogenetic mechanisms operative in HIT explain unusual thromboses, such as arterial “white clots.” For example, HIT antibodies have been shown to activate endothelium and monocytes (leading to cell surface tissue factor expression), although this stimulation may be large indirect through poorly defined mechanisms involving platelet activation and, possibly, formation of platelet-derived microparticles. Further, aggregates of platelets and polymorphonuclear (PMN) leukocytes have been described in HIT. To what extent these cooperative interactions between platelets, microparticles, PMN leukocytes, monocytes, and endothelium lead to arterial or venous thrombotic events in HIT, either in large or small vessels, remains unclear. (Used with permission from Warkentin.<sup>164</sup>)

**Figure 23-5.** This “iceberg” model depicts several features of HIT, including the hierarchy of sensitivity and specificity of three different types of assays: 1) platelet activation assay that utilizes washed platelets, eg, platelet serotonin-release assay (SRA); 2) PF4/heparin enzyme immunoassay that detects IgG antibodies (EIA-IgG); and 3) commercial EIA that detects IgG, IgM, and/or IgA antibodies. Clinical HIT occurs in either of the top two levels of the iceberg (HIT and thrombosis;

thrombocytopenia). Subclinical seroconversion indicates formation of antibodies in the absence of developing clinical HIT. The relative proportion of patients who form antibodies vs those who do not form antibodies differs in various clinical situations. Various serologic, platelet, and macrophage characteristics that determine the pathogenicity of PF4/heparin-reactive antibodies are shown on the left. (Modified with permission from Warkentin, Cook.<sup>170</sup>)

activation assay or PF4-dependent EIA.<sup>170</sup> The key concept is that whereas both types of assay have high sensitivity for diagnosis of clinical HIT, the former assay has greater diagnostic specificity. It is estimated that substantial overdiagnosis (~100%) of HIT will result<sup>171</sup> if a positive EIA of any magnitude is considered diagnostic of HIT irrespective of the patient’s clinical likelihood of HIT, as judged using a clinical scoring system (the 4T’s)<sup>172</sup> and the gold standard assay (platelet SRA).

### Management of Heparin-Induced Thrombocytopenia-Associated Thrombosis

Results of prospective and retrospective studies<sup>2,3,162,172</sup> indicate that approximately 50% to 75% of patients with HIT have new, progressive, or recurrent thrombosis. Thus, the need for an alternative anticoagulant is a common issue in the care of these patients.

*Danaparoid sodium* (Orgaran, Schering-Plough, Kenilworth, NJ) is a mixture of anticoagulant glycosaminoglycans with predominant anti-Factor Xa activity that decreases thrombin generation in patients with HIT.<sup>173</sup> A randomized trial showed a higher thrombosis resolution rate among patients treated with danaparoid and warfarin than among those treated with dextran and warfarin, especially for patients with severe thrombosis (92% vs 33%;  $p < 0.001$ ).<sup>174</sup> Although some HIT sera show in-vitro

cross-reactivity with danaparoid (ie, enhanced platelet activation in the presence of danaparoid), this effect is usually weak; moreover, platelet-activating effects of many HIT sera are inhibited by danaparoid at therapeutic concentrations.<sup>174</sup> Because in-vitro cross-reactivity is not predictive of adverse outcome,<sup>174</sup> danaparoid should be given without preceding in-vitro testing for cross-reactivity.<sup>159</sup> The success rate is high (approximately 85% to 90%), as defined by platelet count recovery without new thrombosis.<sup>159,174,175</sup> The anticoagulant effect of danaparoid is monitored with a chromogenic anti-Factor Xa assay, which must be performed using a standard curve prepared with danaparoid. The target range is generally 0.5 to 0.8 anti-Factor Xa U/mL, although levels of 1.0 U/mL or higher are used by some in the treatment of patients with severe thrombosis. Recommended therapeutic dosing includes an initial intravenous bolus followed by continuous infusion (usually 200 U/hour with monitoring of anti-Factor Xa levels, if available). Danaparoid does not interfere with INR measurements. This is an advantage in the care of patients with venous thromboembolism in whom overlapping warfarin anticoagulation usually is performed after resolution of thrombocytopenia. Danaparoid is approved therapy for HIT in the European Union, Canada, and elsewhere, but is neither approved for HIT management nor currently available in the United States.

*Lepirudin* (Refludan, Bayer HealthCare, Leverkusen, Germany) is a hirudin derivative manufactured by means of recombinant technology. Two prospective cohort studies<sup>176,177</sup> of lepirudin with a prespecified dosing schedule for the management of HIT-associated thrombosis (with historical controls for comparison) led to approval of this agent in the United States, Canada, and the European Union for treatment of patients with HIT-associated thrombosis. Meta-analysis<sup>178</sup> of these two studies showed that a subtherapeutic activated partial thromboplastin time (aPTT) ratio ( $<1.5$ ) was associated with increased risk of thrombosis, whereas a therapeutic aPTT ratio above the therapeutic range ( $>2.5$ ) was associated with increased bleeding without further reduction in antithrombotic efficacy. However, even for patients within the target therapeutic range, the risk of bleeding was significantly greater than among historical controls (relative risk approximately 3). Current dosing recommendations<sup>159</sup> are considerably lower than that recommended by the manufacturer, in keeping with postapproval studies indicating that the approved dosing regimen is too high.<sup>179,180</sup>

The anticoagulant effect of lepirudin is usually monitored with the aPTT. Lepirudin is renally excreted, and ideally should not be used to treat patients with renal failure because there is substantial risk of overdosing, and no antidote exists. The half-life of lepirudin is short (approximately 1.3 hours) in patients with normal renal function. A high proportion of patients develop hirudin antibodies, which occasionally results in a paradoxical increase in the anticoagulant effects of the drug (perhaps via reduced renal clearance). Thus, ongoing aPTT monitoring is recommended during lepirudin treatment, even if initial anticoagulation is stable. Fatal anaphylactoid reactions have been reported following use of an intravenous bolus, particularly in patients sensitized because of recent exposure to hirudin.<sup>159</sup>

*Argatroban* (Novastan, GlaxoSmithKline, Middlesex, United Kingdom) is a small-molecule, direct thrombin inhibitor approved in the United States for the management and prevention of HIT-associated thrombosis.<sup>159,181</sup> Advantages of argatroban include its short half-life (40–50 minutes) as well as its hepatic route of metabolism. No dose adjustments are needed for patients with moderate renal failure, although dose reduction is needed in the presence of hepatic insufficiency. Anticoagulant monitoring is usually performed using the aPTT. Argatroban also prolongs the INR, which complicates the transition from argatroban to warfarin therapy. It is important to postpone introduction of warfarin until the thrombocytopenia has substantially recovered (platelet count at least 150,000/ $\mu$ L).<sup>159</sup>

There are several important contraindications to therapy for acute HIT, including warfarin monotherapy, LMW heparin, and prophylactic platelet transfusion.<sup>159</sup> Warfarin therapy can lead to acute depletion of protein C, which can cause microvascular thrombosis in HIT, and lead to venous limb gangrene.<sup>165</sup> However, once thrombocytopenia has resolved, it is reasonable to overlap warfarin cautiously with one of the agents that can reduce thrombin generation in HIT (danaparoid, lepirudin, argatroban). Use of LMW heparin is contraindicated because of a

high chance of treatment failure (approximately 50% of patients have further thrombocytopenia or thrombosis).<sup>159</sup> Prophylactic platelet transfusion is relatively contraindicated because even patients with severe thrombocytopenia do not usually have evidence of hemostatic dysfunction, such as petechiae, and platelet transfusions may contribute to increase risk of thrombosis.<sup>159</sup>

### Management of Isolated Heparin-Induced Thrombocytopenia

Isolated HIT is defined as HIT that is recognized because of thrombocytopenia without evidence of HIT-associated thrombosis.<sup>162</sup> Unfortunately, simply stopping administration of heparin or substituting warfarin for heparin is inadequate treatment for these patients. In a large retrospective cohort study,<sup>162</sup> the risk of thrombosis among these patients was approximately 10% at 2 days, 40% at 7 days, and 53% at 30-day follow-up evaluations. Other investigators<sup>182</sup> with a similar approach subsequently found a 38% rate of thrombotic events despite stopping administration of heparin. The frequency of thrombosis surprisingly was not any lower in the subgroup of patients for whom heparin was stopped fairly promptly ( $<48$  hours) after the onset of thrombocytopenia than it was among patients with later cessation of heparin (45 vs 34%;  $p = 0.26$ ).

For patients strongly suspected (or confirmed) to have isolated HIT, the authors discontinue heparin, start administration of an alternative rapidly acting anticoagulant, and screen for subclinical DVT by means of compression ultrasonography (approximately 50% of patients are shown to have DVT with this approach).<sup>159</sup> Whether or not thrombosis is found, a therapeutic dose of anticoagulant is given to these patients. This is because prophylactic-dose anticoagulation appears to have a higher failure rate than does therapeutic-dose anticoagulation.<sup>175</sup> Further, argatroban was approved in therapeutic doses for prevention of thrombosis in the care of patients with HIT.<sup>181</sup> After platelet count recovery, the absence of venous thrombosis is confirmed before discharge. For patients found at initial or follow-up imaging to have venous thrombosis, overlapping warfarin anticoagulation is usually begun for longer-term antithrombotic control.

### Reexposure to Heparin in a Patient with a History of Heparin-Induced Thrombocytopenia

Patients who have circulating HIT antibodies can have an abrupt decrease in platelet count if heparin is administered. However, the risk of such abrupt-onset HIT on reexposure to heparin is restricted to the first few months after use of heparin. This is because HIT antibodies begin to decline after heparin is discontinued, and usually they are no longer detectable by the 3-month follow-up evaluation.<sup>183</sup> Under exceptional circumstances (eg, need to perform heart or vascular surgery), it is recommended to readminister heparin to a patient with previous HIT, provided that HIT antibodies are no longer detectable with a sensitive and reliable assay (eg, platelet SRA or PF4-dependent EIA).<sup>159,183</sup> Such patients often do not form HIT antibodies after the brief reexposure to heparin, and if they do, these antibodies are not

formed before Day 5. Nevertheless, it seems prudent to limit the heparin reexposure to the operation itself and to use an alternative anticoagulant for perioperative anticoagulation.

### Typical Drug-Induced Immune Thrombocytopenia

The clinical criteria supporting a diagnosis of DITP are 1) thrombocytopenia occurs during drug treatment and is corrected completely after discontinuation of the drug; 2) the implicated drug was the only one used when thrombocytopenia occurred, or platelet count recovery occurred or persisted despite continuation or reintroduction of the other drugs used; 3) other causes of thrombocytopenia are excluded; and 4) reexposure to the implicated agent resulted in recurrent thrombocytopenia.<sup>154</sup> For reasons of patient safety, drug reexposure is rarely performed deliberately, but sometimes the outcome of unintentional reexposure can provide important diagnostic information (eg, recurrent thrombocytopenia following ingestion of tonic water suggests quinine-induced thrombocytopenia). Meeting all four criteria provides definite evidence of causation, whereas meeting the first three criteria suggests a probable cause.<sup>154</sup>

Drug-induced immune-mediated thrombocytopenia typically begins abruptly and is severe, most patients having a platelet count less than 20,000/ $\mu$ L.<sup>4,156,160</sup> Although the interval between starting the drug and development of thrombocytopenia usually is 1 or 2 weeks, occasionally it can be several months or even longer after administration of the drug is started. Sometimes, thrombocytopenia persists for several weeks even after the drug is stopped, possibly because some of the IgG antibodies formed have drug-independent platelet reactivity.

Although many dozens of drugs have been suspected as causing DITP, convincing evidence to support a causal relation exists for relatively few drugs.<sup>153-156</sup> Supporting evidence for the drugs claimed to cause DITP is available (<http://moon.ouhsc.edu/jgeorge>). The risk of DITP is approximately 1 case in 1000 for quinine, and 1 in 25,000 for sulfamethoxazole-trimethoprim.<sup>184</sup> Quinine is present in certain beverages (eg, tonic water) and consequently patients may not be aware of exposure.

The pathogenesis of DITP involves formation of a ternary complex involving a platelet glycoprotein (usually, the GPIIb/IIIa complex, less often GPIb/IX), drug (or drug metabolite), and the Fab terminus of IgG.<sup>7,151,185</sup> Such a mechanism has been invoked for quinine, quinidine, sulfonamide, rifampin, vancomycin,<sup>151</sup> and pentamidine, among others. Unlike the mechanism of HIT, platelet Fc $\gamma$ Rs are not involved. Further, the drug does not function as a hapten; that is, drug-dependent IgG does not bind to platelets that have been washed after pretreatment with the implicated drug.<sup>156</sup> Limited evidence of a hapten mechanism of DITP has been suggested only for penicillin; that is, penicillin-dependent IgG binds to platelets that have been washed after pretreatment with penicillin. A recently proposed model suggests that drug-dependent antibodies are derived from a pool of naturally occurring antibodies with weak affinity for self antigens residing on platelet membrane glycoproteins; certain drugs are able to affect both antibody and antigen in such a way that their

interaction is greatly enhanced, provided that B cells expressing such antibodies are induced to produce these.<sup>156,186</sup>

In a case of suspected DITP, as many drugs as possible should be discontinued. If further drug treatment is necessary, an immunologically non-cross-reactive substitute should be prescribed. Platelet transfusions should be given to patients with life-threatening bleeding or who are judged to be at high risk of bleeding (eg, severe thrombocytopenia plus “wet purpura”). High-dose IVIG, 1 g/kg given over 6 to 8 hours for 2 consecutive days, may be of value, but can be ineffective if the relevant drug is not discontinued.<sup>151</sup> Corticosteroids are relatively ineffective in the management of this condition.<sup>160</sup>

### Atypical Drug-Induced Immune Thrombocytopenic Purpura

#### Glycoprotein IIb/IIIa Antagonist-Induced Thrombocytopenia

Thrombocytopenia is a relatively common side effect of the three approved GPIIb/IIIa antagonists—abciximab, tirofiban, and eptifibatide.<sup>161</sup> Often the thrombocytopenia begins within hours of a first exposure; this is caused by naturally occurring antibodies.<sup>187</sup> In other patients, the thrombocytopenia begins about 1 week after initial—or abruptly upon repeat—drug administration; this clinical presentation reflects drug-induced antibody formation.<sup>188</sup>

Abciximab (c7E3, ReoPro, Eli Lilly, Indianapolis, IN) is a humanized chimeric Fab fragment of a murine monoclonal antibody specific for an epitope on GPIIIa. It is used to prevent restenosis after coronary angioplasty. Approximately 0.5% of patients have moderate or severe thrombocytopenia within several hours of treatment with this drug.<sup>161</sup> Although approximately 20% of the normal population have antibodies that react against the papain cleavage site in abciximab, the remainder (1.6% overall) react against murine sequences incorporated into abciximab that confer specificity for GPIIb/IIIa. It is this latter group of antibodies that evinces pathogenicity. Perhaps surprisingly, given the degree of thrombocytopenia and use of a major platelet glycoprotein inhibitor, most patients do not have petechiae or bleeding<sup>161</sup> (although fatal bleeding episodes have been reported). Treatment with platelet transfusions and, perhaps, IVIG may benefit bleeding patients.

For approximately one-third of patients with apparent abciximab-associated thrombocytopenia, examination of the blood film shows platelet clumping. This finding suggests pseudothrombocytopenia (ex-vivo platelet clumping) caused by abciximab.<sup>189</sup> Such patients are not at risk for bleeding and do not need treatment.

Tirofiban and eptifibatide are synthetic compounds that mimic or contain the RGD (arg-gly-aspartic acid) peptide and bind tightly to the RGD recognition site in GPIIb/IIIa.<sup>161</sup> As with abciximab, the frequency of naturally occurring antibodies (approximately 1% to 2%) correlates roughly with their risk of inducing abrupt-onset thrombocytopenia upon first exposure. Delayed-onset thrombocytopenia beginning about 1 week after exposure has also been reported.

### Drug-Induced Autoimmune Thrombocytopenia

Approximately 1% to 3% of patients treated with gold have thrombocytopenia that sometimes persists for weeks or months despite stopping the drug; thus the disorder resembles chronic ITP.<sup>190</sup> It remains uncertain whether this is true drug-induced autoimmune thrombocytopenia or is caused by gold-dependent IgG antibodies that are slowly released from tissues. Procainamide,  $\alpha$ -methyl dopa, sulphonamide antibiotics, and interferons alfa and beta also may cause autoimmune thrombocytopenia.<sup>156,191</sup> In extremely rare instances, measles-mumps-rubella vaccination causes an acute ITP-like illness in which anti-GPIIb/IIIa IgG is formed.<sup>192</sup>

### Drug-Induced Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

In rare instances, drugs cause a thrombotic microangiopathy that closely resembles TTP or HUS. Paradoxically, such platelet-mediated thrombotic disorders can even be caused by the antiplatelet agents ticlopidine<sup>193</sup> and clopidogrel.<sup>194</sup> Ticlopidine-induced TTP is estimated to occur in 1 in 2000 to 5000 patients who receive this drug after coronary stenting. The characteristic onset is between 1 and 8 weeks after administration of the drug is started. Clopidogrel-induced TTP occurs in approximately 1 in 20,000 recipients, generally within the first 2 weeks of treatment. Autoantibodies to von Willebrand factor-cleaving metalloproteinase have been identified in these patients and may contribute to the pathogenesis.<sup>195</sup>

Other drugs that cause an illness that resembles HUS include quinine,<sup>196</sup> antineoplastic chemotherapy (eg, gemcitabine, mitomycin C, cisplatin, bleomycin), immunosuppressive agents [eg, cyclosporin, FK506 (tacrolimus)], and miscellaneous drugs (penicillamine, penicillin). Because some of the medical conditions leading to use of these drugs can be associated with microangiopathic blood film changes (neoplasia, organ rejection, graft-vs-host disease, vasculitis), causal relationships to the various drugs listed can be problematic.

The mortality of drug-induced TTP is high. Early recognition and discontinuation of the drug are essential. Response to plasma exchange has been observed. Many physicians would also give corticosteroids, although the efficacy remains unproven. Specific therapy for drug-induced HUS (dialysis, plasmapheresis, corticosteroids) is individualized depending on the clinical situation. The prognosis is poor for drug-induced TTP in the setting of HSCT.

## Alloimmune Thrombocytopenia

Alloantigens are genetically determined molecular variations of proteins or carbohydrates that can be recognized immunologically by some healthy persons. Exposure to alloantigens occurs during pregnancy, transfusion, or transplantation. If alloantibodies form against platelet alloantigens, alloimmune thrombocytopenia can result from platelet clearance mediated by the reticuloendothelial system. Five alloimmune thrombocytopenic disorders have been described (Table 23-3),<sup>197</sup> the most common being NAIT.

**Table 23-3.** The Five Alloimmune Thrombocytopenic Syndromes<sup>197</sup>

#### Classical alloimmune thrombocytopenic syndromes

- Neonatal alloimmune thrombocytopenia
- Posttransfusion purpura

#### Other alloimmune thrombocytopenic syndromes

- Passive alloimmune thrombocytopenia
- Transplantation-associated alloimmune thrombocytopenia
- Platelet transfusion refractoriness

### Alloantigens

More than 20 platelet alloantigens have been identified.<sup>197-203</sup> Table 23-4 classifies the platelet alloantigens by glycoprotein localization and gene frequency, the latter divided into public and private (or low frequency, arbitrarily less than 0.02). More than one-half of the alloantigens that have been identified are located on one of the two glycoproteins that constitute the GPIIb/IIIa complex (platelet fibrinogen receptor). One of these alloantigens, HPA-1a (PI<sup>A1</sup>), is located on GPIIIa. It is responsible for most alloimmune thrombocytopenia in populations of European ancestry, including almost all patients with severe alloimmune thrombocytopenia. The other major platelet glycoprotein complex (GPIb/IX, von Willebrand factor-binding complex) is rarely implicated in alloimmune thrombocytopenia. However, the GPIa/IIa complex (platelet collagen receptor), which bears the HPA-5a/5b (Br<sup>a/b</sup>; Za<sup>a/b</sup>) alloantigen system, is a relatively common cause of moderately severe alloimmune thrombocytopenia.<sup>204</sup> The HPA-15a/15b (Gov<sup>a/b</sup>) alloantigen system has been shown to be a relatively common cause of alloimmune thrombocytopenia that, like HPA-5a/5b, tends not to be severe.<sup>205</sup>

### Immunogenetics and Frequency of Alloimmune Thrombocytopenia

The HPA-1a alloantigen is far more immunogenic than its corresponding allele, HPA-1b. For example, consider the frequency of NAIT caused by either anti-HPA-1a or anti-HPA-1b alloantibodies in relation to the genotype frequency of HPA-1a (0.85) and HPA-1b (0.15). Thus, a homozygous HPA-1bb (PI<sup>A1</sup>-negative) female, representing approximately 2% ( $0.15 \times 0.15$ ) of the population, would have an 85% probability of being exposed to the HPA-1a alloantigen during pregnancy. In contrast, a homozygous HPA-1aa female, representing approximately 72% ( $0.85 \times 0.85$ ) of the population, would have a 15% probability of being exposed to the HPA-1b alloantigen during pregnancy. Thus, if both alloantigens were equally immunogenic, one would expect anti-HPA-1b to occur approximately six times more often than anti-HPA-1a:  $(0.72 \times 0.15)/(0.02 \times 0.85) = 6.4$ . However, the opposite is actually observed: anti-HPA-1a is far more common than anti-HPA-1b (Table 23-5).<sup>204,206</sup> In a study of 348 cases of suspected NAIT,<sup>204</sup> only one case caused by anti-HPA-1b was found, compared with 144 cases of proven or suspected NAIT secondary to anti-HPA-1a. Thus, the observed ratio of NAIT caused by anti-HPA-1a/anti-HPA-1b (1:144, or

**Table 23-4.** Platelet Antigens Classified According to Glycoprotein Location and Gene Frequency\*

<sup>†</sup>Percentage of pregnancies at theoretic risk of NAIT for a given target alloantigen is determined as follows:  $x(1 - x)^2 \times 100$ , where  $x$  is the gene frequency of the target alloantigen. Note the lack of correlation between the theoretical and observed risk for NAIT.

<sup>‡</sup>Data are from Mueller-Eckhardt et al.<sup>204</sup> and represent serologic investigations using a defined protocol over an 18-month period ending June 30, 1988.

<sup>§</sup>For comparison, the serologic findings for cases of PTP are shown for which only one platelet alloantigen specificity was identified (from January 1990 to August 2006 at the BloodCenter of Wisconsin).<sup>206</sup>

NAIT = neonatal alloimmune thrombocytopenia; PTP = posttransfusion purpura.

are much more likely to generate an alloimmune response when GPIIIa bears the leucine<sup>33</sup> substitution that determines the HPA-1a phenotype.

Overall, on the basis of the observed allelic frequencies, the expected theoretical ratio of NAIT for anti-HPA-5b, compared with anti-HPA-5a, should be approximately 8 (Table 23-5). A similar ratio (47:3, or 15.7) has been observed. However, although the expected and observed ratios are similar (contrast the HPA-1a/1b system), a role for immunogenetics and alloimmunization exists also for the HPA-5a/5b system.<sup>209</sup>

### Severity of Alloimmune Thrombocytopenia

In general, the severity of thrombocytopenia is greater for alloimmune thrombocytopenia that involves the GPIIb/IIIa complex, compared with the GPIa/IIa complex (Table 23-6<sup>197,204,206,210</sup>). Because there are approximately 20 times more GPIIb/IIIa molecules compared with GPIa/IIa complexes (40,000 vs 2000), this suggests that greater numbers of alloantibodies binding to the more numerous GPIIb/IIIa receptors results in greater platelet destruction.

### Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia is a transient but potentially life-threatening thrombocytopenic disorder limited to fetal and neonatal life. It is caused by maternal IgG alloantibodies that cross the placenta and cause premature destruction of platelets bearing paternally derived platelet alloantigens (analogous to

\*Data from Warkentin & Smith<sup>197</sup> and Brunner-Bolliger et al.<sup>210</sup>

The data show that alloimmune thrombocytopenic syndromes that involve GPIIb/IIIa are more likely to cause severe thrombocytopenia than are those involving GPIa/IIa. The data are combined for alloimmune thrombocytopenic syndromes involving either allele of the HPA-3ab and HPA-4ab alloantigen systems, whereas the data are shown separately for the alleles of the HPA-1ab and HPA-5ab systems.

NAIT = neonatal alloimmune thrombocytopenia; PTP = posttransfusion purpura; PAT = passive alloimmune thrombocytopenia; TAT = transplantation-associated alloimmune thrombocytopenia.

hemolytic disease of the fetus and newborn). Neonatal alloimmune thrombocytopenia occurs in approximately 1 to 1.5 per 1000 live births.<sup>211</sup>

Approximately 75% of cases in a population of European ancestry are caused by fetomaternal incompatibility for the platelet-specific alloantigen HPA-1a, and 20% by HPA-5b.<sup>204</sup> Other alloantigens implicated in NAIT, including private alloantigens identified in only one or a few families [eg, HPA-6b (Tu<sup>a</sup>/Ca), HPA-7b (Mo<sup>a</sup>)], are shown in Table 23-4. In east Asian populations, anti-HPA-4b (Pen<sup>b</sup>) is more common than anti-HPA-1a. Although HLA or ABO alloantibodies have been claimed to cause NAIT, in most cases, undetected platelet-specific alloantibodies or another diagnosis caused the thrombocytopenia.<sup>212</sup>

The typical clinical presentation of NAIT is isolated severe thrombocytopenia in an otherwise healthy neonate, especially if fetomaternal incompatibility involves an alloantigen on the GPIIb/IIIa complex (Table 23-6). Petechiae are found in 90%; gastrointestinal tract hemorrhage in 30%; and hemoptysis, hematuria, and retinal bleeding in fewer than 10% of patients. Approximately 15% have intracranial hemorrhage.<sup>204</sup> The thrombocytopenia usually resolves within 1 to 3 weeks. Serious sequelae of fetal and neonatal intracranial bleeding include hydrocephalus, porencephalic cysts, and epilepsy. First-born offspring constitute approximately one-half of patients. This suggests that unlike the situation for hemolytic disease of the

fetus and newborn, sensitization can occur early during the first pregnancy.<sup>204</sup> Subsequently affected siblings usually have thrombocytopenia to a similar or greater extent, an observation used to emphasize preventive treatment in subsequent pregnancies.

Laboratory investigation of possible NAIT involves three steps. First, there must be a high index of suspicion: isolated thrombocytopenia in an otherwise well infant should be assumed to indicate NAIT until proved otherwise. The second step is to type maternal and paternal platelets to determine whether they are incompatible for a major platelet alloantigen. Commonly, the mother lacks certain platelet alloantigens that often are associated with alloimmune thrombocytopenia; for example, maternal homozygous HPA-1bb (PI<sup>A1</sup>-negative) status confers risk of NAIT caused by anti-HPA-1a. The third step is to determine whether the mother has platelet alloantibodies in her serum. Sometimes, no alloantibodies can be detected in maternal serum despite severe neonatal thrombocytopenia. Indeed, for approximately one-fourth of HPA-1bb mothers with infants believed to have had NAIT, anti-HPA-1a cannot be detected.<sup>204</sup> The potential for low-incidence platelet-specific alloantigens to explain fetomaternal incompatibility means that maternal serum should be tested against paternal platelets whenever possible. There remains debate as to whether the titer of alloantibodies predicts severity of fetal thrombocytopenia.

### Neonatal Treatment

The optimal treatment of a neonate in whom NAIT is suspected because of severe thrombocytopenia is to increase the platelet count urgently to safe levels, even before serologic confirmation of the diagnosis. In some centers (eg, National Blood Service in the United Kingdom), HPA-1bb and HPA-5bb platelets can be obtained upon request. These should be effective for more than 95% of patients.<sup>213</sup> When matched platelets are not available, washed and irradiated maternal platelets should be given to the neonate. These platelets are obtained by apheresis, and are washed to remove the maternal alloantibodies. Irradiation is performed to prevent graft-vs-host disease caused by maternal lymphocytes. In an emergency, immediate administration of whole-blood-derived platelets obtained from random donors may be of benefit to a bleeding infant.<sup>214</sup> Giving high-dose IVIG to the neonate increases the platelet count of approximately 65% of patients.<sup>215</sup> This treatment should be combined with maternally derived platelets. Corticosteroids are not recommended.

### Prenatal Management

About one-half of the time, NAIT is suspected during the prenatal period, usually because the mother previously bore an affected infant, although the diagnosis sometimes is suggested in utero when fetal ultrasonography shows cerebral hemorrhage, hydrocephalus, or hydrops fetalis. One tenet of management is that thrombocytopenia in a subsequently affected offspring is generally as severe as, or more severe than, a previously affected sibling. Neonatal alloimmune thrombocytopenia caused by anti-HPA-1a is more likely to cause fetal morbidity and mortality than

that caused by anti-HPA-5b and usually requires more aggressive treatment. When the father is known to be heterozygous for the implicated alloantigen (a situation that occurs approximately 25% and 20% of the time for NAIT involving the HPA-1a/1b and HPA-5a/5b systems, respectively), prenatal fetal typing (usually performed with genetic methods) is important, because it identifies the infant who is homozygous for the maternal antigen and is not at risk, obviating further treatment. For pregnancies at risk, general advice to the mother includes avoiding aspirin and nonsteroidal antiinflammatory medications.

Two general approaches have been taken to manage pregnancies at high risk of severe NAIT<sup>213,216</sup>: regular administration of high-dose IVIG, repeated in-utero platelet transfusions, or both. The initial step is to obtain a fetal platelet count by means of percutaneous umbilical blood sampling, generally starting at 20 to 24 weeks of gestation. Because of the risk of fetal exsanguination, maternal platelets should be on hand for transfusion if the fetal platelet count is shown to be less than 50,000/ $\mu$ L.<sup>216</sup> Intravenous immune globulin is given at a dosage of 1 g/kg/week starting within 1 week of documentation of fetal thrombocytopenia. Fetal blood sampling is repeated 4 to 6 weeks later; if no response is seen, glucocorticoid salvage treatment (prednisone, 60 mg/day) is started.<sup>216</sup> However, not all fetuses respond to this approach.

Another approach, which has been used in certain European centers, involves regular intrauterine platelet transfusions by means of percutaneous umbilical blood sampling, including a short time before delivery. This approach has led to good outcomes in situations in which previous siblings were severely affected.<sup>217</sup> However, each fetal platelet transfusion carries risk of hemorrhage and death<sup>218</sup> that likely depends on the experience of the fetomaternal unit. There is no consensus on which approach is preferred.

Regardless of the antenatal management, there is consensus that delivery should be by means of elective cesarean section, performed as soon as fetal maturity is documented. The major reason for this mode of delivery is that it allows an organized, multidisciplinary approach to the peripartum care of the newborn. This approach includes urgent determination of the cord platelet count, provision of washed, irradiated maternal platelets (or antigen-negative platelets) and, usually, the use of high-dose IVIG (1 g/kg/day for 2 consecutive days) to treat severe neonatal thrombocytopenia.

### Posttransfusion Purpura

Posttransfusion purpura is a very rare disorder that typically manifests as severe thrombocytopenia and bleeding that begin 5 to 10 days after blood transfusion—usually Red Blood Cells (RBCs)—in a patient previously sensitized by pregnancy or transfusion.<sup>206</sup> In 85% to 95% of cases, women are affected; the median age is 52 years. The observation that previous blood transfusions can be sensitizing explains why, on occasion, males develop PTP. Sometimes the presumably sensitizing transfusion occurs only a few weeks earlier; consequently, PTP can present after just a few weeks of intermittent transfusions.<sup>206</sup>

Although thrombocytopenia usually lasts 1 to 4 weeks, the duration can be as short as 3 days<sup>219</sup> to as long as 4 months

or more. The platelet count usually is less than 10,000/ $\mu$ L (Table 23-6). Mucocutaneous bleeding (wet purpura, petechiae, epistaxis, gastrointestinal, urinary tract) is common, and approximately 5% to 10% of patients die, usually because of intracranial hemorrhage. Because effective treatments are available (see below), it is important to diagnose PTP promptly to minimize morbidity and mortality. Diagnostic confusion with HIT can result because both syndromes can present 5 to 10 days following surgery, and sometimes PF4/heparin antibodies are present because of concomitant exposure to heparin.<sup>220,221</sup>

### Pathogenesis

Almost invariably, high-titer, platelet-specific alloantibodies are found in the patient's serum or plasma. Anti-HPA-1a is detected in 60% of cases, although several other platelet alloantigens have been implicated [HPA-1b, -2b, -3a, -3b, -4b, -5a, -5b, -15b, and the isoantigen CD-36 (Nak<sup>a</sup>)].<sup>206</sup> More than one specificity is observed in approximately 15% of cases. As in NAIT, the HLA-DRB3\*0101 antigen is found in most HPA-1a-negative patients with PTP.

Although platelet-specific alloantibodies are causative, the pathogenesis of PTP remains obscure, and the conundrum is why autologous platelets are destroyed. The currently favored hypothesis is that PTP represents a situation in which alloantibodies resulting from reexposure to an incompatible platelet alloantigen evince autospecificity ("pseudospecificity"). Although the platelet-specific alloantibodies are detectable for years following an episode of PTP, the autoreactive (or panreactive) antibodies are detectable only during the acute (thrombocytopenic) phase of PTP. In keeping with this view, Taaning and Tønnesen<sup>222</sup> reported that panreactive GPIIb/IIIa antibodies are readily detected during, but not after, an episode of PTP. Kiefel et al<sup>223</sup> reported that antibody with allospecificity for HPA-1a, but not for HPA-1b, could be eluted from both autologous and donor HPA-1bb platelets that had been sensitized with acute phase serum from a PTP patient, suggesting that use of adsorption/elution methods may help distinguish a reactivity profile of PTP sera from that seen with NAIT. One report<sup>224</sup> suggests that such alloantibodies with autoreactivity could arise spontaneously, because a woman with HPA-1bb platelets and no history of blood transfusion developed "ITP" with antibodies showing specificity for HPA-1a. Cure of the thrombocytopenia by splenectomy was accompanied by disappearance of the HPA-1a-like antibodies. Studies by another group of investigators<sup>225</sup> indicate that two distinct types of antibodies—some with alloreactivity and others with autoreactivity—develop during the acute phase of PTP.

### Treatment

High-dose IVIG is the treatment of choice for PTP. More than 90% of patients respond, attaining a platelet count greater than 100,000/ $\mu$ L in an average of 4 days.<sup>226</sup> Although some physicians also give corticosteroids, this agent probably does not influence the course of disease and should be considered adjunctive rather than primary therapy. In rare instances, splenectomy may be

considered for a patient refractory to IVIG, corticosteroids, and compatible platelet transfusion.<sup>227</sup>

Whole-blood-derived (unselected) platelets—which are likely to bear the HPA-1a antigen—are usually destroyed quickly, and can cause febrile or even anaphylactoid reactions. Antigen-negative platelets are the preferred component; however, the efficacy of HPA-1a-negative platelet transfusions (for patients with PTP caused by anti-HPA-1a) is also uncertain. Some reports indicate lack of benefit.<sup>228</sup> RBC units should be washed<sup>229</sup> or filtered<sup>228</sup> before administration to remove platelet antigens. Only four patients are known to have developed recurrent PTP with subsequent transfusions.<sup>206</sup> Accordingly, for a patient who has recovered from PTP, future precautions usually include avoidance of incompatible blood components (only autologous, washed, or platelet alloantigen-compatible RBCs are given, or platelet alloantigen-compatible plasma or platelet products are given). However, PTP recurrence is uncommon even if incompatible blood is given, possibly because residual high-titer platelet alloantibodies immediately clear the alloantigens. Patients with a history of PTP must not donate blood because their plasma can trigger passive alloimmune thrombocytopenia.

### Passive Alloimmune Thrombocytopenia

Passive alloimmune thrombocytopenia is characterized by abrupt onset of thrombocytopenia within a few hours after transfusion of a blood component.<sup>197</sup> It is caused by the passive transfer of platelet-reactive alloantibodies in the component that rapidly clear the incompatible recipient platelets. Protein-specific platelet-antibody studies confirm that the alloantibodies bind to the recipient's platelets. However, although the alloantibody can be detected in the donor's plasma, it may not be detectable in the recipient's plasma. This finding suggests that almost 100% of the transfused alloantibody binds soon after transfusion.<sup>210,230</sup> Only two alloantigens (HPA-1a and -5b) have been implicated in this syndrome.<sup>197,210,230</sup> In general, the severity of bleeding parallels the degree of thrombocytopenia; thus, spontaneous mucocutaneous bleeding usually occurs only in patients with severe thrombocytopenia caused by anti-HPA-1a. The duration of thrombocytopenia is generally less than 1 week. It is important to investigate suspected passive alloimmune thrombocytopenia, because the risk that numerous recipients can develop this syndrome means that the implicated blood donor must not donate blood in the future.

### Transplantation-Associated Alloimmune Thrombocytopenia

In rare instances, alloimmune mechanisms explain thrombocytopenia that occurs in the setting of HSCT or transplantation of solid organs.

### Hematopoietic Transplantation

Panzer et al<sup>231</sup> reported a 32-year-old man with chronic myeloid leukemia who had severe thrombocytopenia (platelet count, 17,000/ $\mu$ L) beginning 18 months after allogeneic marrow transplantation from his HLA-matched sister. High-dose IVIG gave

transient increases in platelet count, and persisting remission followed splenectomy. Antibodies with HPA-1a specificity were eluted from the patient's platelets. This led to further investigations, which showed that a small number of residual, non-neoplastic lymphoid cells of host origin produced anti-HPA-1a against the HPA-1a-positive platelets formed by donor-derived megakaryocytes. Thus, host-vs-donor alloimmune thrombocytopenia resulted from mixed chimerism, in which residual host lymphoid cells derived from the HPA-1a-negative individual developed an alloimmune response against platelets derived from the engrafted HPA-1a-positive marrow.

A similar situation attributable to anti-HPA-5b after allogeneic marrow transplantation for chronic myeloid leukemia has been reported.<sup>232</sup> However, in this patient, HPA-5b alloantibodies were detectable both before and after transplantation, and the early posttransplantation thrombocytopenia gradually improved as elutable anti-HPA-5b became more difficult to detect.

Alloimmune thrombocytopenia may have played a role in two cases with transfusion-refractory thrombocytopenia associated with a rise in titer of anti-HPA-1a (compared with the pretransplantation state) that developed following autologous HSCT performed for metastatic carcinoma of the breast. However, these reports are not conclusive, because it is difficult to distinguish a PTP-like illness (which implies destruction of engrafted autologous donor marrow-derived platelets) from typical posttransplantation platelet transfusion refractoriness.<sup>233</sup>

### Solid-Organ Transplantation

In rare instances, immunocompetent lymphoid cells within a transplanted solid organ cause alloimmune thrombocytopenia in the recipient of the organ. A dramatic scenario was reported by West et al.<sup>234</sup> All three organ recipients (two of a kidney, one of a liver) had severe thrombocytopenia and bleeding within 5 to 8 days after transplantation from a multiparous female organ donor with normal platelet counts. The two recipients of renal transplants had thrombocytopenia refractory to high-dose IVIG and platelet transfusions. One of these patients died, but the other recovered after splenectomy performed 50 days after transplantation. The liver transplant recipient had organ rejection, which was accompanied by correction of the platelet count when he received a new liver allograft. HPA-1a alloantibodies were detected in the organ donor and posttransplant (but not pretransplant) recipient serum. These cases illustrate that passenger immunocompetent lymphoid cells occasionally induce severe alloimmune thrombocytopenia when introduced into an alloincompatible environment.

### Platelet Transfusion Refractoriness

Platelet transfusion refractoriness, which is failure to achieve the expected platelet increment after two consecutive platelet transfusion episodes, has several explanations (Table 23-7). Nonimmune, patient-dependent factors are probably the most important, which means that poor platelet count recoveries can persist even when HLA alloimmunization is prevented with

**Table 23-7.** General Causes of Platelet Transfusion Refractoriness, Listed in Probable Descending Order of Frequency\*

- 
- Nonimmune mechanisms
  - Septicemia, fever, disseminated intravascular coagulation, amphotericin B therapy, hypersplenism, fixed platelet count requirements in severe thrombocytopenia
  - Platelet-nonspecific alloantibodies
    - HLA alloantibodies
    - ABO alloantibodies
  - Platelet-specific alloantibodies
  - Drug-dependent antibodies (eg, vancomycin)
  - Platelet-reactive antibodies
-

leukocyte-reduced blood components<sup>235</sup> and when HLA- or ABO-compatible platelets are given.

There is anecdotal evidence that platelet-specific alloantibodies sometimes cause refractoriness. However, prospective studies have shown that this is a relatively infrequent occurrence. For example, Novotny et al<sup>236</sup> found that even when HLA alloantibody formation was largely prevented with blood components filtered before storage, platelet-specific alloantibodies at most explained 4 of 79 (5%) of cases of refractoriness. There are occasions, however, on which the transfusion service needs to provide HLA- and platelet-specific antigen-compatible platelet products to manage certain of these patients.<sup>237</sup>

---

## Summary

A variety of platelet-antibody and other assays have improved the ability of the clinician to make an accurate diagnosis of immune thrombocytopenia in many diverse clinical settings that can involve pathogenic autoantibodies, alloantibodies, and drug-dependent antibodies. The treatment decisions that arise depend upon several relevant factors, including the nature of the specific diagnosis, the expected prognosis, and the presence of clinically evident bleeding or thrombosis.

<sup>3</sup> Hamilton Professor of Hematology, Director, Division of Hematology, Oncology, and Blood and Marrow Transplantation, and Professor of Medicine, Department of Internal Medicine, Carver College of Medicine, University of Iowa, Iowa City, Iowa, USA

Acquired disorders of hemostasis may occur in association with specific clinical conditions or may arise spontaneously in otherwise healthy patients. Unlike inherited coagulation disorders, acquired coagulation disorders are often diagnosed in adult patients, although they may present at any age. Bleeding symptoms can vary from mild bruising and mucosal bleeding to prolonged postoperative bleeding and severe hemorrhage. If the patient does not have a history of significant hemostatic challenge such as surgery or trauma, it may be difficult to distinguish an acquired coagulation defect from an undiagnosed congenital disorder such as mild hemophilia or von Willebrand disease. Management of acute bleeding in patients with acquired coagulation disorders requires prompt recognition of the specific hemostatic defect to guide therapy. The initial laboratory evaluation should usually include the prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin time, fibrinogen level, and platelet count. In most patients, the bleeding time test is not recommended, because it is not informative about the risk of bleeding or the proper treatment. Automated hemostatic assays, including use of the platelet function analyzer (PFA-100, Dade Behring, Deerfield, IL) and thromboelastography, are receiving increasing attention as potentially more informative alternatives to the bleeding time test.<sup>1,2</sup>

The acquired coagulation defects discussed in this chapter, and their characteristic effects on laboratory tests of hemostasis, are summarized in Table 24-1. Congenital disorders of coagulation are considered in Chapter 28, and hemostatic support in the perioperative setting and solid organ transplantation are reviewed in Chapters 38 and 40, respectively.

## Liver Disease

### Pathophysiology

Liver disease and liver transplantation are associated with multiple hemostatic defects, including quantitative and qualitative abnormalities of coagulation factors, thrombocytopenia, and platelet dysfunction. The liver produces most of the soluble components of the coagulation pathways and many of the regulatory proteins, including Factors II, V, VII, IX, X, XI, XII, and XIII, as well as prekallikrein, high-molecular-weight kininogen, plasminogen,  $\alpha_2$ -macroglobulin, antiplastins, antithrombin, thrombin activatable fibrinolysis inhibitor, tissue factor pathway inhibitor, ADAMTS13 metalloprotease, protein C, and protein S.<sup>3,4</sup> Factor VIII, the factor that is deficient in patients with classical hemophilia, is also produced by the liver. However, plasma levels of Factor VIII are determined by release of von Willebrand factor (vWF) from endothelium; therefore, levels may be elevated, rather than decreased, in patients with liver disease. The liver also plays a key role in clearance of activated coagulation factors and fibrinolytic fragments that interfere with hemostatic mechanisms. Significant liver dysfunction can, therefore, lead to bleeding from impaired biosynthesis of multiple hemostatic factors combined with failed clearance of inhibitory factors.

In both acute and chronic liver disease, the extent of hepatocellular damage generally correlates with the magnitude of the hemostatic defect, as assessed by laboratory tests and clinical bleeding. In acute hepatitis, plasma levels of the vitamin-K-dependent Factors II, VII, IX, and X are quantitatively decreased. Deficiency of Factor VII usually precedes that of other factors because of its short (6-hour) biological half-life. Levels of Factor IX tend to be less depressed than other vitamin-K-dependent factors. Levels of Factor V are variably decreased in acute hepatitis and are often decreased in chronic liver disease. Levels of fibrinogen are usually elevated in acute hepatitis as part of the acute phase response. In chronic hepatitis, levels of fibrinogen are typically

**Table 24-1.** Laboratory Tests of Hemostasis in Patients with Acquired Coagulation Defects

| Disorder or Therapy                            | PT  | aPTT | TT | Fibrinogen | Platelet Count |
|------------------------------------------------|-----|------|----|------------|----------------|
| Liver disease                                  | ↑   | (↑)  | ↑  | (↓)        | (↓)            |

| Fibrinolytic therapy                           | ↑   | ↑    | ↑  | ↓          | N              |

PT = prothrombin time; aPTT = activated partial thromboplastin time; TT = thrombin time. Test results are indicated as normal (N), increased (↑), or decreased (↓). Parentheses indicate a mild or variable effect.

normal or mildly decreased, with levels less than 100 mg/dL indicative of end-stage liver disease and poor prognosis.

Biosynthesis of dysfunctional hemostatic proteins also contributes to the bleeding diathesis of liver disease. Impaired vitamin K utilization results in the production of dysfunctional, noncarboxylated vitamin-K-dependent factors. Production of abnormal fibrinogens (dysfibrinogenemia) and accumulation of fibrin degradation products (FDPs) can impair coagulation. Dysfibrinogenemia caused by abnormal posttranslational processing of fibrinogen is common in chronic active hepatitis and cirrhosis. The abnormal fibrinogens have been shown to have antithrombin activity and to impair fibrin polymerization, which may result in the formation of fibrin clots with impaired stability. Elevated FDP levels are caused by disseminated intravascular coagulation (DIC) and impaired hepatic clearance of FDPs.

Thrombocytopenia and platelet dysfunction are important components of the hemostatic deficit in liver disease. In chronic liver disease, portal hypertension with resultant splenomegaly and sequestration of platelets is the primary cause of thrombocytopenia. In acute viral hepatitis thrombocytopenia is usually modest, although platelet-dependent hemostatic mechanisms may be defective even when the platelet count is normal.

### Laboratory Features

The PT is the most sensitive laboratory screening test for coagulation defects in liver disease. The PT is particularly sensitive to decreased levels of Factor VII because of its short half-life. Factor VII is a reliable indicator of hepatic synthesis of vitamin-K-dependent hemostatic factors. The aPTT and thrombin time are also prolonged because of deficiencies of multiple coagulation factors and the inhibitory effects of dysfunctional fibrinogens and FDPs. When the thrombin time is prolonged, despite normal levels of fibrinogen and minor elevations of FDPs, dysfibrinogenemia should be suspected. In acute hepatitis, the fibrinogen level is usually normal, but may be

elevated when there is an acute phase response. A significant decline in plasma fibrinogen occurs only when acute liver disease is severe.

Prolonged clotting times usually correct to normal when the patient's plasma is mixed 1:1 with normal plasma. Levels of individual vitamin-K-dependent coagulation factors, as well as the non-vitamin-K-dependent Factor V, are often decreased in liver disease. In contrast, levels of Factor VIII are typically normal or elevated. It is usually not necessary to measure coagulation factors in patients with liver disease. However, measurement of Factors V, VII, and VIII can be useful in some patients to help distinguish between vitamin K deficiency (in which Factor VII is decreased and Factors V and VIII are normal), synthetic liver dysfunction (in which Factors V and VII are decreased and Factor VIII is normal or elevated), and consumption of coagulation factors (in which all three factors are generally decreased).

### Management of Bleeding

Bleeding associated with severe liver disease is a major clinical challenge requiring surgical, pharmacologic, and transfusion support. Because the hemostatic defect invariably includes deficiency of coagulation factors, often with coexisting thrombocytopenia, transfusion of plasma and platelets are the mainstay of therapy. Plasma or platelets may be transfused to treat active bleeding when the international normalized ratio (INR) is greater than 1.5 or the platelet count is below 50,000/μL, respectively. The utility of transfusion of plasma when the INR is more modestly elevated (ie, between 1.1 and 1.4) is uncertain.<sup>5</sup> The INR is a very poor predictor of bleeding in conjunction with surgical procedures, and the prophylactic transfusion of plasma to correct modest elevations of the INR before procedures has not been demonstrated to have a significant impact on clinical outcomes.<sup>5</sup> The prophylactic transfusion of plasma to correct modest elevations of the INR or in advance of minor procedures should be discouraged.

In bleeding patients, a typical initial dose of plasma is 15 mL/kg, with doses ranging up to 30 mL/kg in severe liver disease. The hemostatic benefit of plasma transfusion is often quite transient, necessitating frequent dosing, which can cause volume overload. The PT is used to monitor efficacy and to determine requirements for repeated administration. The PT may remain prolonged by up to 3 seconds despite hemostatically adequate levels of vitamin-K-dependent factors. It is often difficult to correct such mild elevations of the PT, and attempts to do so may consume large quantities of plasma without success. This difficulty may be related to the short half-life of Factor VII, the poor recovery of Factor IX from transfused plasma, and the loss of transfused clotting factors into third space fluid. Prolongation of the PT by more than 6 seconds often indicates that multiple factors are deficient.

Fibrinogen levels are seldom decreased enough from liver dysfunction to cause major bleeding. However, severe hypofibrinogenemia (fibrinogen level less than 100 mg/mL) in a patient with active bleeding should be treated with cryoprecipitate. Each unit of cryoprecipitate contains 150 mg to 250 mg of fibrinogen. A typical initial dose of 10 to 15 units should increase the plasma concentration of fibrinogen by 50 to 75 mg/dL. In Europe, fibrinogen concentrates fractionated from plasma and treated to inactivate or remove virus are available for this purpose.

An actively bleeding patient with a platelet count below 50,000/ $\mu$ L generally should be treated with transfusion of platelets. As with transfused plasma, multiple physiologic factors often diminish the recovery of transfused platelets. Although liver disease can cause qualitative platelet dysfunction, the therapeutic role of platelet transfusion in the absence of thrombocytopenia is unproven.<sup>3</sup>

Vitamin K should be administered to most patients with coagulopathy and liver disease, but its effectiveness is often poor; even if the PT is shortened, clinical bleeding may persist. Desmopressin acetate (DDAVP), which stimulates release of vWF (and possibly Factor VIII) from endothelial cells, is sometimes used. However, Factor VIII and vWF are often elevated in liver disease, so the value of DDAVP is uncertain and has not been rigorously tested.<sup>6</sup>

An evolving approach to the rapid treatment of the coagulopathy of liver disease is the use of recombinant activated Factor VII (rFVIIa).<sup>7</sup> Doses of rFVIIa ranging from 5 to 120  $\mu$ g/kg have been used before liver biopsy, with prompt normalization of the PT occurring in most patients. However, in this and several other settings of hemostatic challenge in liver disease, normalization of the PT associated with the use of rFVIIa has not been demonstrated to prevent bleeding or improve clinical outcomes. Thus, the utility of rFVIIa in treating the coagulopathy of liver disease remains unproven.

Prothrombin complex concentrates, which contain vitamin-K-dependent coagulation factors, are gaining renewed interest for treating the coagulopathy of liver disease.<sup>8</sup> Older prothrombin complex concentrates were occasionally associated with serious thromboembolic complications, but newer formulations appear to be safer and have been used successfully to rapidly reverse the coagulopathy of liver disease.

---

## Vitamin K Deficiency

### Pathophysiology

Vitamin K comprises a group of fat-soluble vitamins that are available from many dietary sources and from gastrointestinal flora. Because there are two independent sources of vitamin K, deficiency solely from inadequate dietary absorption or inadequate production by gastrointestinal flora is rare. Deficiency usually arises from disruption of both sources.

Vitamin K is a coenzyme in the hepatocellular pathway that synthesizes coagulation Factors II, VII, IX, and X, as well as the regulatory factors protein C, protein S, and protein Z. Vitamin K is required for the  $\gamma$ -carboxylation of several amino terminal glutamyl residues during posttranslational processing. The carboxylated glutamyl residues provide negative charge densities that allow formation of ionic bridges between the factors and phospholipid surfaces and also facilitate protein-protein interactions between coagulation factors. The ability of the vitamin-K-dependent clotting factors to assemble on anionic phospholipid surfaces, such as platelet membranes, is essential for normal hemostasis. In conditions of vitamin K deficiency, plasma levels of vitamin-K-dependent coagulation factors are quantitatively decreased, and production of dysfunctional noncarboxylated factors further contributes to impaired hemostasis.

---

## Hemorrhagic Disease of the Newborn

Hemorrhagic disease of the newborn is a postnatal bleeding disorder caused by inadequate production of vitamin-K-dependent coagulation factors. A transient physiologic decrease in coagulation factors normally occurs during the newborn period because of synthetic limitations of the immature liver. With maternal or newborn vitamin K deficiency, plasma concentrations of vitamin-K-dependent factors can decline to levels that are inadequate to maintain hemostasis. Bleeding in hemorrhagic disease of the newborn can be severe and can include melena, intracranial hemorrhage, bleeding from circumcision, generalized ecchymosis, and intramuscular hemorrhage. Factors that predispose to hemorrhagic disease of the newborn include prematurity, delayed bacterial colonization of the gut, liver disease, inadequate maternal or infant vitamin K intake, and prenatal exposure to warfarin or anticonvulsant drugs. Because breast milk is a poor source of vitamin K, postnatal deficiency of vitamin K tends to be more severe in breast-fed infants who do not receive vitamin K supplementation.

The PT is prolonged in hemorrhagic disease of the newborn, and levels of all of the vitamin-K-dependent factors are decreased. Levels of fibrinogen and Factors V and VIII are usually normal, as is the platelet count. Treatment relies on administration of vitamin K<sub>1</sub> (phytonadione). Intramuscular injection of 0.5 to 1 mg of vitamin K<sub>1</sub> usually produces normal neonatal levels of vitamin-K-dependent factors within 24 hours. In cases of

severe hemorrhage, transfusion of plasma should be given along with vitamin K<sub>1</sub>. Treatment with vitamin K<sub>1</sub> may be less effective in premature infants because of liver immaturity. Caution should be used with administration of vitamin K<sub>1</sub> in very large doses, which can produce hemolysis, hyperbilirubinemia, and kernicterus.

Prophylactic administration of vitamin K<sub>1</sub> to newborns (1 mg parenterally or 2 mg orally) diminishes the transient decrease in vitamin-K-dependent factors and prevents hemorrhagic disease of the newborn. This practice is mandated by law in many countries, which accounts for the rarity of the disorder in the developed world.

### Other Causes of Vitamin K Deficiency

Malabsorption syndromes, including celiac disease, sprue, inflammatory bowel disease, and parasitic infestations, can impair absorption of dietary vitamin K. Absorption of vitamin K also can be impaired in severe biliary stasis or after ingestion of bile acid sequestering resins. Ingestion of high-dose aspirin, high-dose vitamin E, warfarin, or other anticoagulants is a common cause of vitamin K deficiency, either from decreased absorption, or vitamin K antagonism. Antibiotic therapy contributes to vitamin K deficiency by inhibiting the synthetic capacity of vitamin-K-producing bacteria. Certain antibiotics, such as cephalosporins that contain an N-methyl thiotetrazol ring, interfere directly with vitamin K activity. The combination of inadequate dietary intake of vitamin K and use of broad spectrum antibiotics is an insidious cause of vitamin K deficiency in hospitalized patients.

### Treatment

A single oral dose of 5 to 10 mg of vitamin K<sub>1</sub> usually restores adequate levels of vitamin-K-dependent coagulation factors within 24 hours. Larger doses may be required in patients with severe deficiency, particularly those associated with warfarin or other anticoagulants. In cases of ingestion of warfarin-like rodent poisons, doses of vitamin K<sub>1</sub> up to 100 mg daily (orally or intravenously) may be required because of the potency and extremely long biological half-lives of these poisons. If emergent reversal of the bleeding diathesis is required, transfusion of plasma (15 mL/kg) should raise levels of vitamin-K-dependent factors to 30% to 50% of normal. Both rFVIIa and prothrombin complex concentrates have been used successfully to urgently reverse the effects of vitamin K antagonists in small numbers of patients.<sup>9-11</sup> General guidelines for the reversal of warfarin anticoagulation are summarized below in the section on Antithrombotic Therapy.

## Disseminated Intravascular Coagulation

### Pathophysiology

DIC is a syndrome of diverse etiology that is characterized by pathologic activation of procoagulant and fibrinolytic pathways. Systemic activation of these pathways creates two seemingly

paradoxical clinical problems: tissue injury caused by disseminated microvascular thrombosis, and hemorrhage caused by consumption of coagulation factors and accelerated fibrinolysis. Some patients, such as those with DIC caused by meningococcemia, experience severe thrombosis of the skin and other organs but have little clinical evidence of bleeding. Other patients with DIC present with bleeding from surgical sites, severe ecchymosis, and diffuse oozing from phlebotomy sites and mucosal surfaces. Still other patients have clinical manifestations of both thrombosis and hemorrhage.

DIC is usually a secondary phenomenon, and the clinical entities that underlie its development are impressively diverse. They include obstetric accidents, intravascular hemolysis, sepsis, viral illnesses, crush injuries, burns, head injuries, autoimmune and inflammatory disorders, malignancies, toxins, and medications. The most common causes of DIC in the developed world are obstetric accidents and infection. Worldwide, venomous snake bite is estimated to be among the most common causes of DIC.

DIC often occurs in patients who have features of the systemic inflammatory response syndrome (SIRS). In SIRS, pathologic processes evoke the production of inflammatory mediators that stimulate expression of tissue factor and release of plasminogen activators from endothelial cells.<sup>12</sup> Tissue factor initiates coagulation pathways, leading to the production of thrombin, which in turn stimulates platelet aggregation, activation of coagulation Factors V and VIII, and cleavage of fibrinogen to form fibrin matrices. Generalized production of thrombin can lead to diffuse microvascular deposition of fibrin and subsequent organ failure. Thrombin is normally regulated by the thrombomodulin/protein C anticoagulant system, but this regulatory system is impaired in DIC because of downregulation of thrombomodulin and consumption of protein C. Plasminogen activators activate plasmin, which proteolytically cleaves both fibrin clots (fibrinolysis) and soluble fibrinogen (fibrinogenolysis). Generation of plasmin in the systemic circulation causes proteolytic consumption of fibrinogen and accumulation of FDPs, both of which contribute to bleeding in DIC.

Platelet activation and aggregation lead to thrombocytopenia and bleeding in DIC. Consumption of platelets in DIC can be extremely rapid, overwhelming the capacity of the marrow to replenish the circulating pool of platelets. In addition, partial activation of platelets and accumulation of FDPs may produce a functional defect in the platelets that remain in the circulation. Severe deficiency of the vWF-cleaving metalloprotease ADAMTS13 has been reported in DIC and may contribute to platelet microvascular thrombosis.<sup>13</sup>

### Clinical Features

DIC is a spectrum of disorders with acute and chronic manifestations. In fulminant acute DIC, thrombosis and hemorrhage often produce multi-organ failure manifested by renal, pulmonary, hepatic, cutaneous, and central nervous system dysfunction. Metabolic instability, hypotension, fever, proteinuria,

and hypoxia are common. Hematologic signs include generalized ecchymosis, petechiae, or skin necrosis, and bleeding from mucosal surfaces, venipuncture sites, and surgical sites. In DIC associated with meningococcemia, the appearance of rapidly progressing retiform skin lesions is a poor prognostic sign. The skin lesions in these patients are caused by widespread thrombosis of dermal and subdermal vessels. The thrombotic diathesis of DIC also can include significant large vessel thrombosis.

Chronic DIC reflects low-grade systemic activation of hemostatic pathways and is associated with underlying vascular disease, autoimmune disorders, chronic inflammatory disorders, malignancies, and chronic liver disease. Because hemostatic compensatory mechanisms usually keep pace with consumption, bleeding may be less prominent than thrombotic complications, except with severe thrombocytopenia. Clinical manifestations are variable and may include deep venous thrombosis or migratory thrombophlebitis as well as epistaxis and ecchymosis.

### Laboratory Features

Many laboratory tests have been developed to aid in the diagnosis of DIC. These tests include assays for activated coagulation factors, specific activation fragments of coagulation factors, complexes of hemostatic factors with inhibitors, fibrin monomer, and various products of fibrin degradation. Although these assays offer the potential to refine the diagnostic criteria and pathophysiologic understanding of DIC syndromes, a more commonly available set of laboratory tests suffices in most clinical circumstances.

The initial laboratory evaluation should include the PT, aPTT, platelet count, fibrinogen concentration, and a test for FDPs or D-dimer. Collectively, these assays reflect the degree of depletion of hemostatic factors and the extent of fibrinolytic activity. The PT and aPTT assess the collective function of coagulation factors and provide an indication of available hemostatic resources. A low or falling fibrinogen level in combination with other coagulation abnormalities is strong evidence for DIC. FDPs and D-dimer are almost always elevated in DIC because of accelerated fibrinolysis. FDP levels reflect both fibrinolysis and fibrinogenolysis, while D-dimer detects only fibrinolysis and is a more specific indicator of fibrin formation. FDPs and D-dimer do not distinguish between the systemic fibrinolysis of DIC and the localized fibrinolysis that occurs following trauma or surgical procedures. Thus these tests must be interpreted together with fibrinogen levels and other hemostatic assays.

In chronic DIC, consumption of coagulation factors is partially compensated by their increased hepatic synthesis. Levels of fibrinogen and Factor VIII are often elevated as acute phase reactants. The PT and aPTT are normal or shortened. Increased FDP and D-dimer levels are of particular value in the diagnosis of chronic DIC.

### Treatment

Treatment of DIC requires control of the triggering pathologic process. Management of bleeding and thrombosis is an

important adjunctive measure, and can provide time for definitive therapies, such as antimicrobial therapy, surgery, or cancer treatment, to become effective. Prevention of ischemic organ injury is of paramount concern. Other supportive measures may include volume expansion and correction of hypotension to improve microcirculation and optimize tissue oxygenation.

The use of heparin in DIC highlights the dilemma of a disorder that simultaneously produces bleeding and thrombosis. While it may be counterintuitive to consider using an anticoagulant in the face of pathologic bleeding, the devastating consequences of systemic thrombosis make heparin a rational treatment for DIC. Moreover, by slowing consumption of coagulation factors, heparin may paradoxically improve the bleeding diathesis. Heparin inhibits thrombin activity and slows the consumptive process while reducing microvascular fibrin deposition. Heparin has been found to prevent complications of DIC in certain syndromes such as DIC associated with acute promyelocytic leukemia or solid tumors, but its value in treating DIC in other clinical settings is less certain. The initial dose of heparin in DIC is usually relatively low (for example, 8 U/kg/hour by continuous intravenous infusion), and titrated according to the hemostatic response. Declining levels of FDPs and D-dimer, rising levels of fibrinogen, and shortening of the aPTT demonstrate the efficacy of heparin in slowing consumption of coagulation factors and decreasing fibrin formation.

Despite theoretical concerns about “feeding the fire” of thrombosis, transfusion of platelets, fibrinogen, and other coagulation factors can be lifesaving in some patients with severe bleeding caused by DIC. In patients with active bleeding or impending biopsy and laboratory evidence of severe consumption of fibrinogen (fibrinogen level less than 100 mg/dL) or other coagulation factors (PT greater than  $1.5 \times$  control value), transfusion of cryoprecipitate (0.2 unit/kg) or plasma (15 mL/kg) is indicated. It is important to remember that many patients who have definitive laboratory evidence of DIC may not have clinically significant thrombosis or hemorrhage. Such patients typically do not require any specific therapy other than treatment of the underlying process that is triggering DIC.

When bleeding associated with DIC is refractory to heparin and transfusion therapy, antifibrinolytic agents such as  $\epsilon$ -aminocaproic acid are occasionally used. In addition to stabilizing clots, antifibrinolytic agents also reduce FDP production. However, inhibition of fibrinolysis has the potential to exacerbate fibrin deposition, resulting in severe thrombotic complications. Therefore, antifibrinolytic agents should be reserved for life-threatening hemorrhage, and should be considered for use only in conjunction with heparin in the setting of DIC.

Potential newer therapeutic agents for DIC include antithrombin and activated protein C, as well as small molecules that directly inhibit thrombin or Factor Xa.<sup>14</sup> Antithrombin is a serine protease inhibitor that inactivates thrombin, Factor Xa, and other coagulation factors. Heparin is a cofactor for antithrombin, and if antithrombin becomes depleted in DIC, the effectiveness of heparin anticoagulation may be limited. Antithrombin has been reported to be beneficial as an adjunctive to heparin therapy in

DIC when its levels are depleted to less than 70% of normal.<sup>14,15</sup> Protein C is an anticoagulant agent that inhibits thrombin production by inactivating Factors Va and VIIIa. Protein C and activated protein C have shown efficacy in clinical trials of DIC associated with bacterial sepsis.<sup>16,17</sup> These new agents and others in development offer the promise of improved treatment of DIC in the future.<sup>14</sup>

## Coagulation Factor Inhibitors

Normal blood plasma contains several proteins that inhibit activated coagulation factors. These natural coagulation factor inhibitors include antithrombin, heparin cofactor II,  $\alpha_1$ -protease inhibitor,  $\alpha_2$ -macroglobulin, C1 inhibitor, plasminogen activator inhibitors, and tissue factor pathway inhibitor. They function to limit the extent of hemostatic and fibrinolytic reactions and thereby localize thrombi to sites of vascular injury.

In contrast to natural coagulation factor inhibitors, pathologic inhibitors are usually immunoglobulins that bind directly to coagulation factors and either inhibit their activity or increase their clearance. Pathologic inhibitors, also known as circulating anticoagulants, may occur as an immunologic response to coagulation factor therapy in patients with hereditary hemophilia, or may arise spontaneously as autoantibodies in patients without a history of abnormal hemostasis.<sup>18</sup> Patients who spontaneously develop inhibitors of coagulation Factor VIII often present with a severe bleeding diathesis, and are said to have “acquired hemophilia.” Spontaneous inhibitors of other coagulation factors are encountered less frequently, but also can cause abnormal bleeding. When a coagulation factor inhibitor is suspected, it is essential to distinguish between an inhibitor of a specific coagulation factor, which often causes bleeding, and a nonspecific inhibitor such as a lupus anticoagulant, which may predispose to thrombosis rather than bleeding.

### Factor VIII Inhibitors (Acquired Hemophilia)

Acquired hemophilia is a rare disorder that is caused by the spontaneous development of an autoantibody inhibitor of coagulation Factor VIII. The annual incidence has been estimated to be about one case per million.<sup>18</sup> Autoantibodies to Factor VIII occur mainly in adults; they may arise in the postpartum period or in association with immunologic disorders such as systemic lupus erythematosus, rheumatoid arthritis, inflammatory bowel disease, or lymphoproliferative disorders. Approximately 50% of cases occur in elderly patients without any underlying medical condition.

The characteristic clinical presentation of acquired hemophilia is the appearance of pathologic hemorrhage in a patient with no history of abnormal bleeding. Patients may present with rapidly enlarging ecchymosis, soft tissue hematoma, gross hematuria, hemarthrosis, or gastrointestinal bleeding. Bleeding is sometimes severe and life threatening. With no known history of a bleeding disorder, the presence of an inhibitor is often not

recognized before surgical procedures, and some patients are diagnosed only after experiencing excessive postoperative bleeding.<sup>18</sup>

The presence of a circulating inhibitor to Factor VIII can be readily detected in the hemostasis laboratory. Typically, the aPTT is prolonged, and it does not correct to the normal reference range when repeated on a 1:1 mixture of the patient's plasma with normal plasma. Occasionally, the 1:1 mixture must be incubated for up to 2 hours to allow the inhibitor to completely inactivate Factor VIII before the aPTT is performed. The PT is usually normal. The Factor VIII activity level is low (often less than 10% of normal), but levels of other coagulation factors (such as Factors IX, XI, and XII) are normal. If multiple coagulation factors are affected, a nonspecific inhibitor (lupus anticoagulant) should be suspected. The diagnosis of a specific Factor VIII inhibitor is confirmed by a quantitative assay of the inhibitor level (often expressed in “Bethesda units” or BU). One Bethesda unit is defined as the amount of inhibitor that neutralizes half the Factor VIII activity in a 1:1 mixture with normal plasma.

The natural history of acquired hemophilia is variable. In some cases, such as those that present in the postpartum period, the inhibitor disappears spontaneously within weeks to months.<sup>19</sup> In other cases, the inhibitor persists for many years. In patients with active bleeding, the immediate goal of treatment is to control acute hemorrhage (Table 24-2). Invasive procedures, intramuscular injections, and the use of antiplatelet agents should be avoided if possible. If the bleeding is mucosal, an antifibrinolytic agent such as  $\epsilon$ -aminocaproic acid should be given.

If the inhibitor level is low (less than 10 BU), large doses of human Factor VIII (starting dose of 100 to 150 U/kg, followed by continuous infusion of 10 U/kg/hour) can overwhelm the inhibitor. Many clinicians prefer to use recombinant human Factor VIII, rather than plasma-derived Factor VIII concentrates, to minimize exposure to multiple blood donors.<sup>18</sup> Factor VIII levels should be measured frequently to assess the response to

**Table 24-2.** Management of Acute Bleeding Episodes in Patients with Acquired Factor VIII Inhibitors

#### Low inhibitor level (<10 BU)

- Desmopressin acetate (DDAVP)
- Human Factor VIII concentrate
- Recombinant human Factor VIII

#### High inhibitor level (>10 BU)

- Recombinant human Factor VIIa
- Porcine Factor VIII concentrate
- Prothrombin complex concentrate
- Activated prothrombin complex concentrate
- Plasmapheresis or immunoabsorption, followed by human Factor VIII concentrate or recombinant human Factor VIII

#### Adjunctive measures

- Immobilization
- Compression
- Avoid aspirin and other antiplatelet agents
- $\epsilon$ -aminocaproic acid (if bleeding is mucosal)

treatment; the usual goal of Factor VIII replacement in a patient with active bleeding is to maintain a Factor VIII activity level that is greater than 50% of normal.

Patients with very low inhibitor levels (less than 3 BU) may respond to DDAVP, which acts by stimulating release of endogenous vWF and Factor VIII from endothelial storage sites. DDAVP is administered either intravenously or nasally, and can be repeated every 24 hours for up to 3 days. Side effects of DDAVP include fluid retention and hyponatremia; therefore, this drug should not be used in elderly patients with a history of cardiovascular disease. Repeated use of DDAVP for more than three doses may result in loss of its hemostatic effectiveness because of depletion of vWF from storage sites.<sup>6</sup>

If the inhibitor level is high (greater than 10 BU), the likelihood of achieving a therapeutic response to human Factor VIII is low, and alternative treatments should be considered. Plasmapheresis or immunoabsorption columns have been used to acutely decrease the plasma level of a circulating inhibitor to allow successful treatment with human Factor VIII.<sup>20</sup> Some patients respond well to porcine Factor VIII concentrate (starting dose of 50 to 100 U/kg), because most acquired inhibitors have low cross-reactivity with porcine Factor VIII. However, continuous or repeated use of porcine Factor VIII often results in the development of inhibitors of porcine Factor VIII, which limits therapeutic options for management of future episodes of bleeding. It is recommended, therefore, that use of this product be restricted to life- and limb-threatening emergencies. Other therapeutic options for the management of acute bleeding in patients with acquired hemophilia include rFVIIa, prothrombin complex concentrates, and activated prothrombin complex concentrates (also called Factor VIII inhibitor bypassing concentrates). These products contain activated coagulation factors that appear to bypass Factor-VIII-dependent clotting reactions. Because the goal of therapy is to bypass (rather than replace) Factor VIII, it is not necessary to measure Factor VIII levels when using these products. It is important to distinguish between prothrombin complex concentrates, which contain Factor VIII bypassing activity, and highly purified plasma-derived Factor IX concentrates or recombinant Factor IX (eg, BeneFIX, Wyeth BioPharma, Madison, NJ), which cannot be used to bypass Factor VIII inhibitors.

The long-term management of patients with acquired Factor VIII inhibitors should be directed toward eradication of the inhibitor. Although some inhibitors disappear spontaneously, even after many years, a trial of immunosuppressive therapy should be considered in most patients. Some patients respond to corticosteroids alone.<sup>18</sup> Other immunosuppressive treatments include cyclophosphamide, azathioprine, cyclosporin A, intravenous immunoglobulin, and rituximab.<sup>19</sup>

### Lupus Anticoagulants

Lupus anticoagulants are autoantibodies that nonspecifically inhibit phospholipid-dependent coagulation reactions *in vitro*. Although first recognized in patients with systemic lupus

erythematosus, nonspecific inhibitors are actually encountered more frequently in patients without lupus. Lupus anticoagulants are induced by certain medications, including procainamide, hydralazine, quinidine, and chlorpromazine, or may occur in association with human immunodeficiency virus infection. Lupus anticoagulants also arise spontaneously in patients who are otherwise healthy.

Lupus anticoagulants represent a subset of a larger group of “antiphospholipid” autoantibodies that recognize phospholipid-protein complexes. Antiphospholipid antibodies are usually either IgG or IgM; other immunoglobulin classes are rare. Lupus anticoagulants often prolong the aPTT, but rarely prolong the PT. The aPTT usually does not correct completely to normal when the patient’s plasma is mixed 1:1 with normal plasma, but correction in mixing studies can be observed with lupus anticoagulants of low titer or low avidity. Some lupus anticoagulants do not prolong either the aPTT or PT. Several alternative clotting assays, including the dilute Russell viper venom time and kaolin clotting time, have been developed as high-sensitivity screening tests for lupus anticoagulants. Regardless of whether the aPTT or one of the alternative assays is used to detect the lupus anticoagulant, a confirmatory test should be performed to establish that the inhibitor is phospholipid dependent.<sup>21</sup>

Paradoxically, although lupus anticoagulants prolong clotting times *in vitro*, they are often associated clinically with thrombosis rather than with bleeding. Thrombotic events in patients with lupus anticoagulants can be either venous (such as deep venous thrombosis and pulmonary embolism) or arterial (such as myocardial infarction, stroke, and peripheral arterial occlusion). A syndrome of severe microvascular thrombosis resulting in acute multi-organ failure (the “catastrophic antiphospholipid antibody syndrome”) has been described in some patients.<sup>22</sup> In addition to thrombosis, patients with lupus anticoagulants may experience pregnancy loss, thrombocytopenia, neurologic symptoms, and livedo reticularis. The mechanisms by which lupus anticoagulants predispose to these clinical conditions are incompletely understood, but may involve autoantibody-mediated activation of procoagulant cell surface receptors<sup>23</sup> or disruption of the anticoagulant properties of annexin A5.<sup>24</sup>

Individual patients with antiphospholipid antibodies usually have positive laboratory test results for lupus anticoagulants, anticardiolipin antibodies, anti- $\beta_2$ -glycoprotein I antibodies, or a combination. However, none of the currently available laboratory tests for antiphospholipid antibodies predict with certainty which patients have an increased risk for clinical complications, and it is likely that only a subset of individuals with abnormal test results are actually predisposed to thrombosis. Patients with lupus anticoagulants, either with or without anticardiolipin antibodies, have a higher risk for thrombotic complications than those with isolated anticardiolipin antibodies.<sup>25</sup> Women with persistence of antiphospholipid antibodies also have an increased risk for miscarriage and other complications of pregnancy.

Identification of a lupus anticoagulant in a bleeding patient is important for several reasons. First, because most lupus

anticoagulants do not cause a bleeding diathesis (with the rare exception of those associated with severe thrombocytopenia or hypoprothrombinemia; see below), a search for another abnormality of hemostasis should be undertaken. Second, recognition that prolongation of the aPTT is caused by a lupus anticoagulant may prevent inappropriate transfusion of plasma and other blood components. Third, all patients with lupus anticoagulants should be considered to be at high risk for thrombosis, particularly in the settings of surgery, trauma, or pregnancy.

Patients with lupus anticoagulants may have coexistent autoimmune thrombocytopenia. The thrombocytopenia is often mild, but can be associated with abnormal bleeding if the platelet count decreases to less than 50,000/ $\mu$ L. Another circumstance in which lupus anticoagulants are directly associated with increased risk of bleeding, rather than thrombosis, is the hypoprothrombinemia-lupus anticoagulant syndrome. Patients with this syndrome appear to have an autoantibody inhibitor that causes accelerated clearance of prothrombin from plasma.<sup>26</sup> The PT is typically prolonged out of proportion to the aPTT. The diagnosis can be confirmed by performing a specific assay for prothrombin (Factor II) activity or antigen. A prothrombin level below 20% of normal can produce severe hemorrhage. Treatment of bleeding in such patients is challenging. Transfusion of plasma may be ineffective. Treatment options for acute bleeding include intravenous IgG and rFVIIa.<sup>27,28</sup> Immunosuppressive therapy with corticosteroids, danazol, or rituximab may be effective for long-term management.<sup>29,30</sup>

In patients with venous or arterial thrombosis, anticoagulant therapy with heparin followed by long-term anticoagulation with warfarin is usually indicated. The presence of a lupus anticoagulant may interfere with monitoring of heparin using the aPTT, and alternative monitoring methods such as Factor Xa inhibition assays may be needed to measure the heparin level. Alternatively, fixed-dose low-molecular-weight (LMW) heparin can often be used without laboratory monitoring. Lupus anticoagulants also can influence the INR in patients who are treated with warfarin. In such patients, it may be necessary to monitor warfarin therapy by measuring the level of a specific vitamin-K-dependent factor (such as Factor II or X).<sup>31</sup>

### Acquired von Willebrand Syndrome

Acquired deficiency of vWF arises spontaneously in previously healthy individuals or occur in association with neoplastic, rheumatologic, or hematologic disorders. Up to 50% of patients have monoclonal gammopathies or lymphoproliferative disorders.<sup>32</sup> The clinical presentation of acquired von Willebrand syndrome is similar to that of congenital von Willebrand disease, except that it occurs in individuals with no personal or family history of abnormal bleeding. Symptoms vary from mild cutaneous and mucosal bleeding (ecchymosis, epistaxis, gingival hemorrhage, or menorrhagia) to severe, life-threatening hemorrhage. The diagnosis should be suspected in patients who have a prolonged bleeding time or a prolonged platelet function analyzer (PFA-100) closure time. The aPTT is either prolonged or normal.

Levels of vWF activity (ristocetin cofactor activity), vWF antigen, and Factor VIII are often depressed. Most cases are caused by autoantibody inhibitors of vWF. The inhibitors cause rapid clearance of vWF from the circulation, and inhibitory activity often cannot be demonstrated in the patient's plasma by mixing studies. Variant forms of acquired von Willebrand syndrome occur in some patients with solid tumors, particularly Wilms' tumor. In these patients, the deficiency of vWF is not mediated by autoantibodies, but is caused instead by absorption of vWF to malignant cells or cell products.<sup>33</sup> Selective loss of high-molecular-weight multimers of vWF can be seen in patients with aortic valve stenosis.<sup>34</sup>

Management of bleeding in patients with vWF inhibitors can be difficult. As in patients with other bleeding disorders, invasive procedures, intramuscular injections, and the use of antiplatelet agents should be avoided if possible. In patients with an underlying hematoproliferative disorder, treatment with chemotherapeutic or cytoreductive agents may lead to resolution of the long-term bleeding diathesis.<sup>32</sup> In patients with acute bleeding, therapeutic options include DDAVP or infusion of Factor VIII concentrates that contain large quantities of vWF [eg, Humate P (ZLB Behring, King of Prussia, PA); Koate-DVI (Bayer Corporation, West Haven, CT); Alphanate (Grifols, Los Angeles, CA)]. Although these partially purified Factor VIII concentrates are derived from pooled plasma, they are subjected to virus attenuation procedures during processing, so the risk of viral transmission is considered to be low. Highly purified Factor VIII concentrates or recombinant human Factor VIII cannot be used, because these products generally contain little or no vWF. Purified vWF concentrates are available in Europe. Cryoprecipitate can be given as a source of vWF, but its use is discouraged because of a greater risk of exposure to blood-borne pathogens. Replacement therapy may be only transiently effective, because of the short half-life of vWF caused by excessive clearance from the circulation. Antifibrinolytic agents such as  $\epsilon$ -aminocaproic acid may be beneficial, particularly in patients with mucosal bleeding. Treatment with rFVIIa may be efficacious in some patients with vWF inhibitors.<sup>35</sup> Administration of high-dose intravenous IgG (2 g/kg over 2 to 5 days) may result in a rapid increase in vWF levels. Repeated administration of intravenous IgG every 3 weeks may be effective in controlling chronic bleeding.<sup>36</sup>

### Inhibitors of Factor V

Autoantibody inhibitors of Factor V can arise in patients following surgery, transfusions, or antibiotic therapy. The majority of cases have been reported in patients who were exposed to topical hemostatic agents, such as bovine thrombin or fibrin sealant, that contain trace amounts of bovine Factor V. The inhibitor presumably arises as an alloantibody to bovine Factor V that cross-reacts with human Factor V.<sup>37</sup> Inhibitors to Factor V may occur after a single exposure to fibrin sealant, but reexposure appears to increase the likelihood of inhibitor development.<sup>38</sup> Typically, both the PT and aPTT are prolonged, and do

not correct to normal when performed on a 1:1 mixture of the patient's plasma with normal plasma. The thrombin time also is prolonged because of the presence of a coexisting inhibitor to bovine thrombin. The diagnosis can be confirmed by performing a quantitative assay of the Factor V inhibitor level. The clinical presentation is quite variable, ranging from apparently normal hemostasis to severe hemorrhage, possibly because of differential effects of the inhibitor on plasma and platelet pools of Factor V. Treatment options for acute bleeding are limited; some patients respond to transfusion of platelets, immunoadsorption, or plasmapheresis.<sup>39</sup> In a majority of patients, the inhibitor disappears within weeks to months, and immunosuppressive therapy does not appear to influence the time course of the disease.

Acquired Factor X Deficiency

Acquired deficiency of Factor X can occur in patients with primary (AL) amyloidosis. The deficiency arises from accelerated clearance of Factor X from the circulation resulting from adsorption of Factor X to amyloid fibrils.<sup>40</sup> Both the PT and the aPTT are prolonged, but unlike the situation in patients with circulating inhibitors, the PT and aPTT usually correct to normal when performed on a 1:1 mixture of the patient's plasma with normal plasma. The hemostatic defect in these patients is multifactorial; in addition to Factor X deficiency, patients with amyloidosis may have excessive fibrinolysis and amyloid infiltration of blood vessels. Management of bleeding in such patients is problematic. Replacement therapy in the form of plasma or prothrombin complex concentrate is often ineffective, and antifibrinolytic agents such as ε-aminocaproic acid are of limited benefit.

Other Coagulation Factor Inhibitors

Autoantibody inhibitors of other coagulation factors are rarely encountered. As with inhibitors of Factor V, inhibitors of prothrombin prolong both the PT and the aPTT. Inhibitors of Factors IX or XI prolong only the aPTT. Specific factor and inhibitor assays can be performed to distinguish the type of inhibitor present. Depending on the inhibitor, treatment options for bleeding episodes include plasma, prothrombin complex concentrates, Factor IX concentrates, or rFVIIa. Adjunctive treatment with antifibrinolytic agents such as ε-aminocaproic acid also may be beneficial.

Inhibitors of Factor XIII do not affect either the PT or aPTT; specific assays of fibrin stabilization (such as the urea clot lysis assay) are necessary to identify these inhibitors.<sup>41</sup> In patients with acute bleeding, large doses of cryoprecipitate or Factor XIII concentrate can be given to try to overwhelm the inhibitor, but this approach may have limited effectiveness.

Acquired Platelet Function Disorders

Acquired disorders of platelet function occur much more frequently than congenital platelet abnormalities. Acquired platelet dysfunction is caused by drugs such as aspirin, medical

conditions such as chronic renal insufficiency, or procedures such as cardiopulmonary bypass. The risk of bleeding in patients with acquired platelet dysfunction is variable and unpredictable, and abnormal bleeding generally occurs only in the presence of additional hemostatic defects. Signs of platelet dysfunction manifest typically as mucocutaneous bleeding with excessive bruising, gingival bleeding, or epistaxis. Diagnostic tests of platelet function include the bleeding time and the platelet function analyzer (PFA-100). Although useful as screening tests, these tests lack diagnostic specificity, and they cannot be used to predict bleeding risk. The bleeding time may be prolonged because of abnormalities of cutaneous connective tissue, and both the bleeding time and the PFA-100 test results may be abnormal in the presence of anemia (hematocrit less than 30%) or thrombocytopenia (platelet count less than 100,000/ $\mu$ L). Many medications can alter platelet function and lead to a delayed PFA-100 closure time or prolonged bleeding time, so a thorough medication history must be obtained before these tests are performed. Formal platelet aggregation testing may be useful in the evaluation of selected patients.

Drug-Induced Platelet Dysfunction

A large number of drugs and medications have been reported to impair platelet function (Table 24-3). Among the most frequently encountered are aspirin, nonsteroidal anti-inflammatory drugs, and antiplatelet agents such as ticlopidine, clopidogrel, and abciximab. The antiplatelet effects of aspirin are irreversible, so recovery of normal hemostasis relies on the release of new platelets into the circulation rather than the disappearance of the drug from the plasma. The ability of platelets to aggregate is partially restored within 4 to 5 days after aspirin ingestion is stopped, but platelet dysfunction may persist for up to 7 days after aspirin is discontinued.<sup>42</sup> If possible, aspirin should be discontinued 7 to 10 days before a surgical or endoscopic procedure, unless it has been prescribed for the secondary prevention of stroke or myocardial infarction.<sup>43</sup> Most other nonsteroidal anti-inflammatory drugs inhibit platelet reactivity in a reversible manner, and platelet function usually returns to normal within 24 hours after the

Table 24-3. Some Drugs that Cause Impairment of Platelet Function

|                                      |                      |
|--------------------------------------|----------------------|
| Aspirin                              | Nitroglycerin        |
| Nonsteroidal anti-inflammatory drugs | Isosorbide dinitrate |
| Ticlopidine                          | Nitroprusside        |
| Clopidogrel                          | Nitroglycerin        |
| Abciximab                            | Isosorbide dinitrate |
| Eptifibatide                         | Nitroprusside        |
| Tirofiban                            | Nitroglycerin        |
| $\beta$ -Lactam antibiotics          | Isosorbide dinitrate |
| Prostacyclin                         | Nitroprusside        |
| Dipyridamole                         | Nitroglycerin        |
| Dextrans                             |                      |

drug is discontinued. Nonsteroidal anti-inflammatory drugs that selectively inhibit cyclooxygenase-2, such as celecoxib, appear to have very little effect on platelets and can be used to treat pain in patients with preexisting bleeding disorders such as hemophilia. The risk of clinical bleeding caused by aspirin or other nonsteroidal anti-inflammatory agents is generally low, and platelet transfusions should not be given prophylactically. However, ingestion of these drugs can increase the risk for serious bleeding in patients who also have additional hemorrhagic risk factors. If severe hemorrhage caused by defective platelet function is suspected, transfusion of platelets can rapidly restore normal hemostasis.

The thienopyridines, ticlopidine and clopidogrel, are platelet adenosine diphosphate (ADP)-receptor antagonists that inhibit platelet function by disrupting interactions with ADP and fibrinogen. Similar to aspirin, these drugs produce a persistent antiplatelet effect that lasts for up to a week after the drug is discontinued.<sup>42</sup> Therefore, these drugs usually should be discontinued 5 to 7 days before invasive procedures.

Abciximab is the prototype of a class of antiplatelet drugs that directly block the binding of fibrinogen to its platelet receptor, glycoprotein (GP) IIb/IIIa (integrin  $\alpha$ IIb $\beta$ 3). Other drugs in this class include eptifibatide and tirofiban. These agents are indicated for use in acute coronary syndromes and to prevent thrombosis of intravascular stents. They are often given in conjunction with other antithrombotic agents such as heparin.<sup>44</sup> Abciximab has an extended biological half-life because of its high affinity for GPIIb/IIIa; its antiplatelet effects can therefore persist for several days. In contrast, the antiplatelet effects of eptifibatide and tirofiban are transient, and usually resolve within a few hours of discontinuation in patients with normal renal function.<sup>45</sup> Management of bleeding in patients receiving GPIIb/IIIa antagonists may be complicated by the development of acute thrombocytopenia (platelet count less than 50,000/ $\mu$ L), which occurs in up to 5% of patients.<sup>46</sup> In cases of severe bleeding, platelet transfusions are an effective approach to control hemorrhage, either in the presence or absence of thrombocytopenia.

Many other drugs can impair platelet function (Table 24-3). The antiplatelet effects of  $\beta$ -lactam antibiotics are generally apparent only in patients receiving large parenteral doses of penicillins or cephalosporins. The frequency of clinically important bleeding in patients taking  $\beta$ -lactam antibiotics appears to be low, and is not predicted by the bleeding time or other laboratory tests of platelet function. Prostacyclin and dipyridamole inhibit platelet aggregation by elevating the intracellular concentration of cyclic adenosine monophosphate. Infusion of dextran inhibits platelet aggregation and enhances fibrinolysis through multiple mechanisms. Nitrovasodilators (nitroglycerin, isosorbide dinitrate, and nitroprusside) inhibit platelet function through nitric-oxide-dependent mechanisms. Both tricyclic antidepressants and selective serotonin reuptake inhibitors can alter platelet function, but the risk of serious clinical bleeding appears to be low.<sup>47</sup> Phenothiazines such as chlorpromazine, promethazine, or trifluoroperazine also have been reported to have mild antiplatelet effects. Consumption of ethanol can produce platelet

dysfunction as well as thrombocytopenia, and may contribute to clinical bleeding in patients with alcoholic liver disease.

## Uremia

Chronic renal insufficiency is associated with both hemorrhagic and thrombotic manifestations. Bleeding often manifests as ecchymoses, epistaxis, or gastrointestinal or genitourinary bleeding. The primary hemostatic abnormality in uremia is thought to be a defect in platelet function, but the pathophysiology of the platelet function defect remains poorly understood. Both dialyzable and nondialyzable substances contribute to the defect. As in many other acquired disorders of platelet function, the clinical importance of platelet dysfunction in uremia is uncertain. The bleeding time and PFA-100 closure time are prolonged, and platelet aggregation studies reveal defects in aggregation with ADP and epinephrine. In general, abnormalities of the bleeding time or platelet aggregation responses do not correlate with the severity of renal insufficiency or the degree of bleeding.

Management of bleeding in uremia is directed by the clinical circumstances rather than the results of laboratory tests of platelet function. Many patients with chronic renal failure do not have significant problems with bleeding despite a prolonged bleeding time and abnormal platelet aggregation responses. If bleeding is encountered in a patient with uremia, assessment of hemoglobin and hematocrit, platelet count, PT, and aPTT is necessary to evaluate for other potential causes of defective hemostasis. Coexisting anemia contributes to a bleeding propensity, and patients with bleeding may benefit from transfusion of red cells, or treatment with erythropoietin or darbopoietin, to maintain the hematocrit above 30%. Treatment with DDAVP or estrogens improves the bleeding time and prevents clinical bleeding in some patients with uremia.<sup>48</sup> Transfusion of cryoprecipitate may partially correct the hemorrhagic diathesis of uremia. Transfusion of platelets is usually not recommended in the absence of thrombocytopenia (platelet count less than 50,000/ $\mu$ L), because uremic plasma can induce dysfunction in transfused platelets. Patients with uremia may be unusually sensitive to anticoagulants or antiplatelet medications such as aspirin, which should be discontinued if possible. The benefit of intensive dialysis in correcting abnormal platelet function and diminishing bleeding is uncertain.<sup>48</sup>

## Cardiopulmonary Bypass

Abnormal platelet function, often in conjunction with thrombocytopenia, is a frequent cause of bleeding in patients undergoing cardiopulmonary bypass. The risk of perioperative bleeding varies depending on the type of surgical procedure, the age of the patient, preoperative renal function, and the duration of bypass. Prior exposure to antiplatelet agents and other antithrombotic medications increases the risk of bleeding.

The platelet defect caused by cardiopulmonary bypass is thought to result from activation of platelets within the extracorporeal circulation. Platelet activation is stimulated by multiple mediators, including thrombin generated from activation of the intrinsic and extrinsic coagulation pathways, mechanical stress,

complement activation, hypothermia, and exposure of platelets to the blood/air interface.<sup>49</sup> Partial activation and degranulation leads to desensitization and decreased adhesiveness of residual circulating platelets. The severity of platelet dysfunction correlates with the duration of bypass. Platelet function abnormalities usually resolve within 5 hours, but can persist for 24 hours or longer following complicated surgery.<sup>50</sup> Bleeding from platelet dysfunction is often exacerbated by thrombocytopenia caused by hemodilution and consumption of platelets. Consumption of coagulation factors, increased fibrinolytic activity, and inadequate neutralization of heparin with protamine sulfate also contribute to bleeding.

Management of bleeding associated with cardiopulmonary bypass is generally based on clinical considerations rather than laboratory testing. Bleeding times and PFA-100 closure times are frequently prolonged but are not predictive of perioperative blood loss.<sup>50</sup> Routine prophylactic administration of plasma or platelets is discouraged.<sup>51</sup> In the setting of excessive perioperative or early (within 24 hours) postoperative bleeding, however, platelet transfusions may be indicated even in the absence of severe thrombocytopenia.

Several drugs have been used to decrease the risk of perioperative bleeding during cardiopulmonary bypass. These include DDAVP, antifibrinolytic agents such as  $\epsilon$ -aminocaproic acid or tranexemic acid, and the protease inhibitor aprotinin. Some recent clinical trials have raised concern that the use of aprotinin might be associated with an increased risk of long-term morbidity and mortality.<sup>52</sup>

## Antithrombotic Therapy

Use of antithrombotic drugs has increased in recent years because of growing recognition of the efficacy of these medications for the prevention and treatment of venous thromboembolism, embolic stroke, and other thrombotic disorders. Although warfarin, heparin, and aspirin continue to be the most commonly prescribed antithrombotic medications, several new antithrombotic drugs are making their way into routine clinical use. These new drugs include LMW heparins, direct thrombin inhibitors, fibrinolytic agents, pentasaccharides, clopidogrel, and platelet GPIIb/IIIa antagonists.<sup>53</sup> The major complication of all these medications is bleeding. In this section, the management of bleeding associated with warfarin, heparin, LMW heparins, pentasaccharides, direct thrombin inhibitors, and fibrinolytic therapy is considered. Management of bleeding associated with antiplatelet medications is discussed above in the section on Drug-Induced Platelet Dysfunction.

### Warfarin

Warfarin and other vitamin K antagonists produce their antithrombotic effects by inhibiting the hepatic synthesis of vitamin-K-dependent coagulation factors. Vitamin K becomes oxidized to vitamin K epoxide during the  $\gamma$ -carboxylation of coagulation

Factors II, VII, IX, and X. Warfarin inhibits the cyclic regeneration of active vitamin K by blocking the action of vitamin K epoxide reductase and vitamin K reductase.<sup>54</sup> In the absence of adequate concentrations of active vitamin K, hepatic production of normally carboxylated factors is limited, and the liver instead produces hypocarboxylated factors with reduced coagulant activity.

Warfarin has a narrow therapeutic range with wide inter-individual dosing requirements. Its metabolism is influenced by diet, patient compliance, genetic factors, liver dysfunction, and interactions with other medications. Numerous drugs influence the pharmacokinetics of warfarin by altering its absorption or metabolic clearance, or by altering the production of vitamin K by intestinal flora. As a general rule, any change in medication regimen, including nonprescription medications and dietary supplements that contain vitamin K, should be presumed to have a potential effect on the anticoagulant response to warfarin. The risk of bleeding is highest during the initial phase of anticoagulation, within the first few weeks after initiation of therapy. Dosing algorithms that consider multiple parameters, such as gender, age, weight, height, race, and use of other medications, offer promise for decreasing the risk of early bleeding. Newer dosing algorithms incorporate pharmacogenomic information derived from genotyping two polymorphic genes (*CYP2C9* and *VKORC1*) that are involved in warfarin metabolism.<sup>55</sup> The clinical utility of these pharmacogenomic approaches is being tested in several clinical trials.<sup>56</sup>

The most common laboratory method for monitoring the anticoagulant effect of warfarin is the PT, often reported as the INR. Because the response of the PT to depletion of vitamin-K-dependent coagulation factors is highly variable when measured in different laboratories, the INR has been widely adopted as a method to standardize monitoring of oral anticoagulant therapy. The INR compares the ratio of the patient's PT to the mean PT of a group of normal individuals. The ratio is adjusted for the sensitivity of the PT reagent used in each laboratory. The target therapeutic INR for most indications is 2.0 to 3.0, although different therapeutic ranges are recommended for some indications.<sup>54</sup>

The risk of major bleeding in patients on chronic warfarin therapy has been estimated to be 1% to 5% per year.<sup>57</sup> Intensity of anticoagulation is probably the most important risk factor for hemorrhage, particularly when the INR is greater than 5.0. Clinical conditions that increase risk of hemorrhage include advanced age, hypertension, cerebrovascular disease, heart disease, renal insufficiency, a history of gastrointestinal bleeding, and concomitant use of antiplatelet agents. The risk of hemorrhagic complications resulting from warfarin therapy is decreased when patients are enrolled in coordinated programs for management of anticoagulation.<sup>58</sup>

Reversal of the anticoagulant effects of warfarin can be achieved through discontinuation of warfarin, administration of vitamin K<sub>1</sub>, transfusion of plasma or prothrombin complex concentrates, or treatment with rFVIIa. Management should be

guided by the degree of elevation of the INR and the presence or absence of clinical bleeding (Table 24-4). Minor or moderate elevation of the INR (above the therapeutic target but less than 9.0) in the absence of bleeding can often be managed safely by decreasing or omitting several doses of warfarin until the INR approaches the therapeutic range. Major elevation of the INR (greater than 9.0), even in the absence of clinically evident bleeding, should be treated by temporary discontinuation of warfarin and administration of vitamin K<sub>1</sub> (5 to 10 mg orally). Vitamin K<sub>1</sub> also can be administered intravenously, but intravenous administration is rarely associated with anaphylaxis. A recent meta-analysis found that oral and intravenous vitamin K<sub>1</sub> were equally effective in achieving a therapeutic INR at 24 hours in patients with excessive oral anticoagulation.<sup>59</sup> Subcutaneous administration of vitamin K<sub>1</sub> is associated with an unpredictable response and is therefore not recommended.<sup>59,60</sup> In patients with active major bleeding, administration of plasma (15 mL/kg) or prothrombin complex concentrates<sup>10</sup> may be lifesaving. Different preparations of prothrombin complex concentrates contain varying amounts of vitamin-K-dependent clotting factors and, therefore, differ in their clinical effectiveness for warfarin reversal.<sup>10</sup> Recombinant Factor VIIa is also used in such patients, especially

if there is life-threatening hemorrhage.<sup>9,54</sup> A dose of rFVIIa as low as 1.2 mg in an adult patient may be effective in normalizing the INR.<sup>9,61</sup> The clinical effectiveness of rFVIIa or prothrombin complex concentrates in the setting of warfarin-associated hemorrhage has not been subjected to randomized, controlled trials, however, and both preparations may be associated with an elevated risk of thromboembolic complications.<sup>62</sup>

Several approaches can be used to manage warfarin anticoagulation in patients who require elective surgery.<sup>54</sup> For many patients, a reasonable approach is to discontinue warfarin 4 to 5 days before surgery and begin heparin or a LMW heparin along with warfarin in the postoperative period. Heparin or LMW heparin can then be discontinued when the INR returns to the target therapeutic range. Patients who require major surgery urgently (within 24 hours) should receive plasma (15 mL/kg) and vitamin K<sub>1</sub> (2.5 to 5 mg orally or parenterally).

### Heparin

The antithrombotic effect of heparin is mediated by its ability to potentiate the inhibition of activated coagulation factors by antithrombin. In the presence of heparin, antithrombin irreversibly inactivates thrombin, Factor Xa, and to a lesser extent, other coagulation factors. Heparin is often administered intravenously, although it also may be given subcutaneously. When administered by intravenous infusion, the onset of its anticoagulant action is rapid.

Weight-based dosing of heparin appears to improve clinical outcomes in patients with venous thromboembolism.<sup>63</sup> A common dosing schedule utilizes an intravenous bolus dose of 80 U/kg followed by 18 U/kg/hour by continuous infusion. The dosage is then adjusted to maintain a therapeutic aPTT. The therapeutic range may vary between different laboratories that utilize different reagents for measuring the aPTT. In many laboratories, prolongation of the aPTT to a value that is 1.5- to 3.0-fold higher than the control value corresponds to a therapeutic heparin level. For certain indications, such as cardiopulmonary bypass surgery, higher doses of heparin are required and monitoring is performed using the activated clotting time rather than the aPTT.

The major side effect of heparin therapy is hemorrhage. In clinical studies of heparin administered for short-term treatment of venous thromboembolism, rates of major bleeding have ranged from 0% to 7%.<sup>57</sup> In some patients, bleeding is exacerbated by thrombocytopenia or platelet dysfunction. Because heparin has a short biological half-life of about 1 hour, the primary approach to management of bleeding is to discontinue the drug. In patients with therapeutic levels of heparin, recovery from its anticoagulant effects can be expected within 2 hours after discontinuation of heparin infusion. In cases of major hemorrhage, or when very large doses of heparin have been given (eg, for cardiopulmonary bypass or through a medication error), protamine sulfate should be administered.

Protamine sulfate is a strongly basic protein that neutralizes the anticoagulant effects of heparin within minutes. It is given by slow intravenous injection. The recommended dose of protamine

**Table 24-4.** Guidelines for Reversal of Warfarin Anticoagulation

| INR     | Bleeding | Recommendation                                                                                                                                                                                |

\*Intravenous administration of vitamin K<sub>1</sub> may produce (but rarely) an anaphylactic reaction.

INR = International Normalized Ratio

sulfate is 1.0 mg for every 100 units of heparin remaining in the patient, which can be calculated based on the 60-minute half-life of heparin. For example, a patient receiving 1000 units of heparin per hour by continuous intravenous infusion should be given enough protamine to neutralize all of the heparin administered within the last hour (1000 units), plus half of the heparin administered in the preceding hour (500 units), plus a quarter of the heparin administered in the hour prior to that (250 units). Therefore, the total dose of protamine sulfate would be 17.5 mg. Protamine sulfate itself has a weak anticoagulant effect, and over-dosage may exacerbate bleeding.

### Low-Molecular-Weight Heparins

LMW heparins are derived from heparin by chemical or enzymatic fragmentation.<sup>63</sup> Several LMW heparins, including dalteparin, enoxaparin, and tinzaparin, are available for prevention or treatment of venous thromboembolism, unstable angina, and other indications. Danaparoid sodium is not derived from heparin, but it is a mixture of LMW heparin-like glycosaminoglycans. Although danaparoid sodium is considered to be a “heparinoid,” its effects are very similar to those of the LMW heparins.

Compared with heparin, LMW heparins have less inhibitory activity against thrombin and greater relative inhibitory activity against Factor Xa. The LMW heparins produce a more predictable anticoagulant response than heparin, reflecting their better bioavailability, longer half-life, and dose-independent clearance. These properties allow LMW heparins to be given subcutaneously once or twice daily, usually without laboratory monitoring. Because LMW heparins are cleared through a renal route, dosages need to be adjusted in patients with renal insufficiency.

A large number of randomized clinical trials have demonstrated that LMW heparins are at least as safe and effective as heparin for most indications.<sup>63</sup> The incidence of heparin-induced thrombocytopenia is lower with LMW heparins than with heparin (see Chapter 23).

Despite the apparently favorable safety profile of LMW heparins, bleeding remains a major side effect. In clinical trials evaluating LMW heparins for treatment of venous thromboembolism, the rates of major bleeding have ranged from 0 to 3%.<sup>57</sup> Epidural bleeding and spinal hematoma have been reported in patients receiving LMW heparins concurrently with spinal or epidural anesthesia.<sup>64</sup> Management of bleeding is complicated by the long half-life of these medications. Unlike heparin, the anticoagulant effects of LMW heparins cannot be reversed completely by administration of protamine sulfate. Protamine sulfate can be administered in an attempt to control active bleeding in patients who have received LMW heparin within 8 hours, but large doses (20 to 50 mg) may be required.<sup>63</sup>

### Pentasaccharides

The pentasaccharides, fondaparinux and idraparinux, are synthetic analogs of the antithrombin-binding region of heparin.<sup>65</sup> These drugs selectively inhibit Factor Xa without having any appreciable

inhibitory effect on thrombin. Fondaparinux has a half-life of 18 to 22 hours and is usually administered subcutaneously once daily. It is used for the prevention and treatment of venous thromboembolism and in acute coronary syndromes. Idraparinux is an investigational pentasaccharide that has a substantially longer half-life of 130 hours and can be administered in a fixed dose once weekly.<sup>65</sup> The pentasaccharides have no specific antidotes, and their anticoagulant effects are not reversed by administration of plasma, prothrombin complex concentrates, or protamine sulfate.

### Direct Thrombin Inhibitors

The direct thrombin inhibitors include desirudin, lepirudin, bivalirudin, and argatroban. Because the direct thrombin inhibitors are structurally unrelated to heparin, one major indication for their use is in the treatment of heparin-induced thrombocytopenia. They also are being evaluated for use in prophylaxis of deep venous thrombosis, cardiopulmonary bypass surgery, and acute coronary syndromes.<sup>65</sup>

Most of the direct thrombin inhibitors are administered parenterally, and are monitored using the aPTT. They have short half-lives (less than 2 hours) when given by intravenous infusion. Because lepirudin, desirudin, and bivalirudin are cleared renally, their half-lives may be prolonged dramatically in renal failure. Clearance of argatroban is not influenced by renal impairment, but may be decreased in the presence of hepatic dysfunction. The risk of bleeding in patients receiving direct thrombin inhibitors appears to be dose-dependent.<sup>66</sup> Management of bleeding relies on prompt discontinuation of the drug.

### Fibrinolytic Agents

Pharmacologic lysis of fibrin thrombi is a commonly used strategy for treatment of acute myocardial infarction and stroke, and also is used in selected cases of peripheral arterial occlusion, and venous thromboembolism. Most fibrinolytic agents in clinical use are plasminogen activators, which include streptokinase, urokinase, and recombinant forms of tissue plasminogen activator such as alteplase and reteplase. Plasminogen activators produce thrombolysis by converting plasminogen to plasmin, which then degrades fibrin into soluble FDPs. Fibrinolytic agents can be administered systemically by intravenous infusion, or delivered in proximity to sites of thrombi via catheter-directed approaches. Contraindications to the use of fibrinolytic therapy include recent hemorrhagic stroke or major surgery, prolonged cardiopulmonary resuscitation, uncontrolled hypertension, and active gastrointestinal bleeding.<sup>67</sup>

In addition to producing therapeutic lysis of pathologic thrombi, fibrinolytic agents generate plasmin in the systemic circulation, resulting in bleeding from lysis of hemostatic plugs at surgical sites and other locations.<sup>67</sup> Bleeding, therefore, is a major complication of fibrinolytic therapy. Because circulating plasmin degrades fibrinogen, hypofibrinogenemia can contribute to bleeding. The extent of systemic fibrinogenolysis varies with different fibrinolytic agents and different routes of administration.<sup>68</sup> Laboratory abnormalities associated with the use of

fibrinolytic agents include decreased fibrinogen, decreased plasminogen, prolonged thrombin time, and decreased euglobulin clot lysis time. These laboratory parameters are poorly predictive of bleeding risk, however.<sup>67</sup>

The risk of major hemorrhage associated with fibrinolytic therapy is influenced by the age of the patient and concomitant use of additional antithrombotic agents such as heparin, direct thrombin inhibitors, or antiplatelet agents. In the absence of invasive procedures or simultaneous heparin therapy, treatment of acute myocardial infarction with fibrinolytic agents generally is associated with a low incidence of major bleeding (less than 5%). Intracranial hemorrhage is a rare, but potentially devastating, complication of fibrinolytic therapy. In large clinical trials of streptokinase, or alteplase for treatment of acute coronary ischemia, the incidence of intracranial hemorrhage has ranged from 0.2% to 0.8%.<sup>67</sup>

Bleeding that occurs in association with fibrinolytic therapy can often be managed by discontinuing infusion of the plasminogen activator and replacing fibrinogen by transfusion of cryoprecipitate (0.2 unit/kg) or (in Europe) by infusion of fibrinogen concentrates. The goal of transfusion therapy with cryoprecipitate is to maintain a plasma fibrinogen level of greater than 100 mg/dL. Adjunctive treatment with antifibrinolytic agents such as  $\epsilon$ -aminocaproic acid or aprotinin may be beneficial when rapid reversal of bleeding is desired.

## Fetal and Neonatal Hematopoiesis

**Robert D. Christensen<sup>1</sup> & Martha C. Sola-Visner<sup>2</sup>**<sup>1</sup> Director of Research, Department of Neonatology, Intermountain Health Care, Ogden, Utah, USA<sup>2</sup> Assistant Professor of Pediatrics, Harvard Medical School, and Physician in Medicine, Childrens Hospital, Boston, Massachusetts, USA

The purpose of hematopoiesis in the fetus differs from that in the adult. The primary function of hematopoiesis in adults is to produce sufficient hemic cells to balance hemic cellular losses. In contrast, in the fetus, constant growth and dramatic physiologic changes necessitate a system with other functions. For example, the remarkable rate of somatic growth in the fetus and neonate and the resultant need to constantly increase blood volume necessitate an extraordinary hematopoietic effort, assessed as daily cell production per kilogram of body weight. In addition, the relatively low oxygen tensions but high metabolic rates of fetal tissues require a system of oxygen delivery fundamentally different from that in adults. Moreover, the sterile intraamniotic environment and consequently the low demand for the antimicrobial actions of neutrophils change markedly at birth. The extrauterine environment demands a constant and lifelong need for the antimicrobial actions of neutrophils. These issues are summarized in Table 25-1.

The hematopoietic system of a fetus and neonate must be sufficiently plastic to accommodate many marked changes and dichotomies. It has been speculated that improved familiarity with developmental hematopoietic regulation improves interpretation of postnatal hematologic data and enhances appreciation of the granulocytopenic, erythropoietic, and thrombopoietic capacities and limitations of prematurely delivered neonates. Cytopenia certainly is common in neonatal intensive care units (NICUs). Neutropenia occurs in 5% to 8% of patients in NICUs,<sup>1</sup> thrombocytopenia in 25% to 30%,<sup>2</sup> and anemia in perhaps as many as 50%<sup>3</sup> at some time before discharge. The prevalence of cytopenia among patients in NICUs is related to gestational age. The prevalence is higher among those delivered at the earliest gestational ages. Transfusion is the only means of managing severe cytopenia among neonates, but alternatives to

**Table 25-1.** Inherent Differences in Hematopoietic Systems of the Fetus, Neonate, and Adult

**Fetus**

- Because the fetus exists in a sterile environment, it does not generally need an antibacterial defense system until near term.
- In preparation for extrauterine life, the fetus must produce a neutrophil reserve.
- Fetal hematocrit and blood platelet concentration increase only slightly from 20 weeks to term, whereas blood volume increases approximately 10-fold. Erythrocyte and platelet production must be extremely rapid during this period to keep pace with the rapid expansion of blood volume.

**Neonate**

- At birth, the fetus moves from a sterile into a nonsterile environment and must have a neutrophil reserve already developed to survive in this environment.
- At birth, oxygen delivery to tissues markedly increases, as PaO<sub>2</sub> increases from 27 to >90 mm Hg. This effectively shuts off erythropoietin production. Consequently, erythropoiesis temporarily ceases, resulting in the physiologic anemia of infancy.
- Rapid growth and blood volume expansion continue. However, platelet concentration does not change, and platelet production is very rapid during this period.

**Adult**

- The rapid somatic growth and blood volume expansion of infancy and childhood cease. The previous need to accelerate hematopoiesis to keep pace with somatic growth ends.
- The neutrophil system must continue to be responsive to rapid increases in demand for cells.
- Blood platelet concentration and hematocrit remain relatively constant throughout healthy life.

repeated transfusions should emerge as more is learned about developmental hematopoiesis.

Developmental hematopoiesis can be viewed as occurring in three anatomic stages—mesoblastic, hepatic, and myeloid. Mesoblastic hematopoiesis occurs in extraembryonic structures, principally the yolk sac, and begins between the 16th and 19th days of gestation. By about 6 weeks of gestation, the extraembryonic sites of hematopoiesis begin to ablate and hepatic hematopoiesis is initiated. By the 10th to 12th week,

mesoblastic hematopoiesis ceases, and a small amount of hematopoiesis is evident in the marrow. In humans, it seems that the clavicle is the first bone to develop a marrow cavity.<sup>4</sup> The first cells present in the developing marrow space have macrophage surface markers and phenotypes. These are followed by myeloperoxidase-positive cells with the characteristics of neutrophils. However, the liver remains the predominant hematopoietic organ until the last trimester of pregnancy.

The anatomic site of hematopoiesis does not simply transfer from yolk sac to liver to marrow.<sup>5</sup> Rather, each organ subsequently houses distinct hematopoietic populations. For example, at 18 to 20 weeks of gestation, more than 85% of the cells in the fetal liver are erythroid, and few neutrophils are present. At the same time, fewer than 40% of the cells within the marrow are erythroid, and most are neutrophils. The mechanisms responsible for the changing anatomic sites of hematopoiesis and for the differences in hemic cells produced in the mesoblastic, hepatic, and myeloid sites have not been determined. Regardless of gestational age or anatomic location, production of all hematopoietic tissues begins with pluripotent cells capable of both self-renewal and clonal maturation into all blood cell lineages. Progenitor cells differentiate under the influence of hematopoietic growth factors, which include those listed in Table 25-2.

Granulocytopoiesis

Sites of Neutrophil Production in the Fetus

A traditional view is that neutrophil production, similar to hematopoiesis in general, begins in the yolk sac and moves to the liver and spleen and finally to the marrow. However, recent results of studies of human fetuses do not support this concept. Specifically, the human yolk sac contains no neutrophils—its hematopoietic activity is limited to erythropoiesis and production of a small number of macrophages.<sup>5</sup> Similarly, the human fetal liver produces few, if any, neutrophils. The few neutrophils found in photomicrographic sections of human fetal liver are not arranged in clusters of hematopoietic nests but are widely separated and found surrounding the blood vessels, as if they were carried in by the circulation, not produced in the organ. Moreover, the spleen is not a granulocytopoietic organ in human fetuses, as it is in rodents.<sup>6</sup> No granulocytopoietic nests are found in human fetal spleen, and the neutrophils within it are mostly mature and evenly dispersed. This finding suggests they were carried there in the blood, not produced locally.

Where, then, do neutrophils originate in the human fetus? The first neutrophils are present approximately 5 weeks after

Table 25-2. Hematopoietic Growth Factors

| Growth Factors             | Molecular Mass (kD) | Chromosomal Location | Principal Target Cell                 |
|----------------------------|---------------------|----------------------|---------------------------------------|
| Erythropoietin             | 30.4                | 7q11-22              | CFU-E, fetal BFU-E                    |
| Colony-stimulating factors |                     |                      |                                       |
| G-CSF                      | 18.8                | 17q11.2-21           | CFU-G                                 |
| GM-CSF                     | 14.4                | 5q23-31              | All CFC                               |
| M-CSF                      | 26 (dimer)          | 1p13-21              | CFU-M                                 |
| SCF                        | 15–20 (dimer)       | 12q2-24              | Primitive CFC                         |
| Interleukins               |                     |                      |                                       |
| IL-1 $\alpha$              | 17                  | 2q13                 | Primitive CFC, hepatocyte, macrophage |
| IL-1 $\beta$               | 17                  | 2q13                 | Primitive CFC, hepatocyte, macrophage |
| IL-2                       | 15-20               | 4q26-27              | T cell                                |
| IL-3                       | 14-15               | 5q23-31              | All CFCs                              |
| IL-4                       | 16-20               | 5q23-31              | T cell, B cell                        |
| IL-5                       | 13.2 (dimer)        | 5q23-31              | CFU-EOS                               |
| IL-6                       | 20.8                | 7p21-24              | Primitive CFC                         |
| IL-7                       | 25                  | 8q12-13              | B cell                                |
| IL-8                       | 8–10                | 4                    | Neutrophil, endothelial cell          |
| IL-9                       | 16                  | 5q31-32              | BFU-E, primitive CFC                  |
| IL-10                      | 23                  | 1                    | Macrophage, lymphocyte                |
| IL-11                      | 22                  | 19q13                | Primitive CFC, BFU-MK, CFU-MK         |
| IL-12                      | 70-75               |                      | T cell, NK cell, macrophage           |
| Thrombopoietin             | 35                  | 3q26-28              | BFU-MK, CFU-MK                        |

BFU-E = primitive erythroid progenitor; G-CSF = granulocyte colony-stimulating factor; CFU-G = colony-forming unit–granulocyte; GM-CSF = granulocyte-macrophage colony-stimulating factor; CFC = colony-forming cells; M-CSF = macrophage colony-stimulating factor; CFU-M = colony-forming unit–macrophage; SCF = stem cell factor; IL = interleukin; CFU-E = colony-forming unit–erythroid; CFU-EOS = colony-forming unit–eosinophil; BFU-MK = primitive megakaryocyte progenitor; CFU-MK = mature megakaryocyte progenitor; NK = natural killer.

conception and are clustered in the periaortic tissue. These first fetal neutrophils contain myeloperoxidase, and they mature into cells with segmented and band nuclei. But beyond these features, any differences or similarities between them and the neutrophils of adults have not been reported.<sup>7</sup> The function of these cells in the fetus and the explanation for this location of origin are unclear. The fetal marrow space begins to develop approximately 8 weeks after conception (Figs 25-1 and 25-2). The space is lined by osteoclast-like cells with cell-surface characteristics of macrophages. These cells appear to core out the space from the primitive cartilage. Eight to 10 weeks after conception, the marrow space progressively enlarges, but no neutrophils are present within the space until 10.5 to 11 weeks<sup>4</sup> (Fig 25-3). The first neutrophils in the marrow do not have segmented or band nuclei, but they contain myeloperoxidase and express the cell surface characteristics of myeloblasts and promyelocytes. From 14 weeks to term, the most common cell type in the fetal marrow space is the neutrophil, although the marrow space is not nearly so densely packed with cells as it becomes in older children and adults.<sup>4,7</sup>

Macrophages are crucial to fetal morphogenesis, because they aid in shaping of organs and scavenging debris and apoptotic cells. Although neutrophils and macrophages have a

**Figure 25-1.** Clavicle approximately 7 weeks after conception, before any marrow space is present. In the human fetus, the first bone to contain a developing marrow space is the clavicle, followed closely by the other long bones. (Hematoxylin and eosin stain; original magnification,  $\times 100$ ).

common progenitor cell, the discordant temporal appearance of neutrophils and macrophages in the fetus and the divergence of their anatomic locations are striking.<sup>8</sup> Recent observations have cast doubt on long-held theories about the origins of macrophages in the human fetus. For example, it was believed that macrophages form from precursor cells in the marrow and mature through a progression of cell types from monoblasts to promonocytes to monocytes, which then migrate to various tissues and differentiate into macrophages. Observations of human fetuses do not support this origin of macrophages. First, macrophages appear in the yolk sac, liver, lung, and brain long before the marrow cavity has been formed. Second, promonocytes and monocytes are absent in the yolk sac and liver, but macrophages are present there nevertheless. Thus, the macrophages in the yolk sac may develop directly from stem cells without passing through a monocyte stage. It is not clear whether these primitive macrophages migrate from the yolk sac to populate the lungs, liver, brain, and other organs.<sup>9</sup>

### Regulation of Neutrophil Production

The mechanisms that regulate neutrophil production during human fetal development are not clear. Granulocyte colony-stimulating factor (G-CSF) and macrophage colony-stimulating factor (M-CSF) are present in developing fetal bone as early as 6 weeks after conception and in the fetal liver as early as 8 weeks.<sup>10</sup> Granulocyte-macrophage colony-stimulating factor (GM-CSF) is widely distributed in fetal tissues, including pulmonary epithelium, and is involved in pulmonary homeostasis. Stem cell factor (SCF) messenger RNA (mRNA) is present in the yolk sac, liver, and marrow at the earliest stages of their respective development.<sup>5</sup> No changes in mRNA concentrations of these factors or of their specific receptors or in the concentrations of proteins, judged by immunohistochemical staining, appear to constitute the signal for production of neutrophils. The precise signals that initiate the production of macrophages and neutrophils in the embryo and fetus are not known. It is curious that the actions of G-CSF, M-CSF, GM-CSF, and SCF are not limited to hematopoiesis in the fetus and neonate. Receptors for all of these factors are located in distinct areas of the fetal central nervous system and gastrointestinal tract, where their patterns of expression change with development. Important undefined developmental roles clearly exist for these factors that are beyond those known for hematopoiesis. Although not fully characterized, these roles appear to be predominantly antiapoptotic, perhaps providing some degree of protection during adverse conditions such as hypoxemia or acidosis.

Although neutrophil production in the marrow space clearly is present by 14 weeks of gestation, the blood of the fetus, even through 20 weeks, contains few neutrophils. Forestier et al.<sup>11</sup> reported that fetuses at 20 weeks of gestation had a mean absolute blood neutrophil concentration of only  $190/\mu\text{L}$ , a range of 0 to  $490/\mu\text{L}$ , and a mode concentration of zero.<sup>11</sup> Despite the near absence of circulating neutrophils in the first trimester, and the relative scarcity (by adult standards) of neutrophils in the second

**Figure 25-2.** Photomicrographs of clavicles 6 to 14 weeks after conception (Hematoxylin and eosin stain; original magnification,  $\times 100$ ). (A) Six weeks after conception. Clavicles at this stage consist of primitive cartilage and contain no marrow cavity and no myeloperoxidase positive cells. (B) Nine weeks after conception. Clavicles at this stage have the beginning of a marrow cavity (*arrowhead*) but

no myeloperoxidase positive cells. (C) Eleven weeks after conception. Clavicles at this stage have an elongated marrow cavity and small hematopoietic islands of myeloperoxidase positive cell in the marrow space. (D) Fourteen weeks after conception. Spiculation has begun, and the volume of hematopoietic marrow has begun to increase. (Modified with permission from Slayton et al.<sup>4</sup>)

**Figure 25-3.** Appearance and subsequent expansion of neutrophils within the clavicular marrow cavity 12 to 15 weeks after conception. (A) At 12 weeks of gestation a small number of myeloperoxidase-positive cells are present in the developing marrow cavity. Many of these cells have the morphologic appearance of neutrophils with

segmented or band nuclei and they appear in discrete clusters within the marrow cavity. (Myeloperoxidase stain; original magnification,  $\times 400$ .) (B) At 15 weeks, clavicles have a marrow cavity that contains numerous myeloperoxidase-positive cells. (Original magnification,  $\times 200$ .) (Modified with permission from Slayton et al.<sup>4</sup>)

trimester progenitor cells with the capacity to generate neutrophils in vitro [colony-forming units-granulocyte-macrophage (CFU-GM)] are abundant in the early human fetal liver, marrow, and blood.<sup>12-17</sup> In rodents, the number of CFU-GMs per gram of body weight is far fewer in animals delivered prematurely than

in those delivered at term and is lower in term animals than in adults. The quantity of neutrophilic progenitor cells per gram of body weight in the developing human fetus has not been reported.<sup>18</sup> It is not clear whether, as in experimental animals, preterm human infants have a relatively small supply of granulocytic progenitors.

The concentration of CFU-GMs in the venous blood of adults is approximately 20 to 300/mL. In contrast, the concentration in term infants is approximately 2000/mL. Even higher concentrations are present in the blood of infants delivered prematurely. The high concentrations of CFU-GMs in fetal blood, however, do not necessarily indicate a large total body quantity of CFU-GMs. It is likely that a significant percentage of fetal CFU-GMs are in the circulation.<sup>16</sup>

When fetal CFU-GMs are cultured *in vitro* in the presence of recombinant G-CSF, they undergo maturation into colonies of neutrophils. Fetal CFU-GMs often mature clonally into larger colonies and contain more cells than do CFU-GMs obtained from the marrow of adults.<sup>19</sup> The physiologic role of G-CSF includes upregulation of neutrophil production. This appears to be the case for the fetus and neonate as well as for the adult. The low quantities of circulating and storage neutrophils in the midtrimester human fetus may be caused, in part, by low production of G-CSF. Supporting this hypothesis are observations of poor production of G-CSF by cells of human fetal origin.<sup>19,20</sup> Monocytes isolated from the blood of adults produce G-CSF when stimulated with a variety of inflammatory mediators, such as bacterial lipopolysaccharide or interleukin-1. In contrast, monocytes isolated from the umbilical cord blood of preterm infants and from the liver and marrow of aborted fetuses up to 24 weeks of gestation generate only small quantities (10 to 100 times less per cell) of G-CSF protein and mRNA after lipopolysaccharide or interleukin-1 stimulation.<sup>19,20</sup> Despite the poor capacity to generate G-CSF, it appears that G-CSF receptors on the surface of neutrophils of newborn infants are equal in number and affinity to those on adult neutrophils.

### Neonatal Neutropenia

Relatively few neutrophils are present in the human embryo and early fetus, and neutrophil production is a relatively minor component of hematopoiesis in the midtrimester fetus. On this basis, one might anticipate that neonates who are delivered extremely prematurely would be at high risk of serious bacterial infection. Indeed, of all the risk factors for neonatal infection analyzed in a national collaborative study<sup>21</sup> on neonatal infections, premature birth had the strongest correlation. One might also anticipate that premature neonates, delivered at the limits of viability (22 to 25 weeks of gestation) would have a high likelihood of developing neutropenia. This propensity is indeed seen. For instance, if neutropenia is defined as a blood neutrophil concentration  $<1000/\mu\text{L}$ , 40% of neonates weighing  $<1000\text{ g}$  at birth develop neutropenia at some time during their hospital stay.<sup>21</sup> Most such cases are detected on the first day after birth. Most are associated with maternal hypertension, or with a birthweight less than the 10th percentile for gestation, and most are relatively transient, with counts exceeding  $1000/\mu\text{L}$  within a few days (Fig 25-4). When neutropenia first appears after the third day of life, the underlying cause is usually obscure.<sup>21</sup> Neutropenia among extremely low birthweight neonates, although common, is viewed as problematic in only two situations—1) neutropenia

during an infectious illness among these patients is a very poor prognostic sign (see Chapter 30 for more information) and 2) neutropenia that is severe and prolonged is important to recognize, because it might indicate one of the syndromes or genetic abnormalities involving severe chronic neutropenia (see Chapter 14 for more information).

## Erythropoiesis

### Erythropoietin in the Fetus and Neonate

Production of erythrocytes requires a constant supply of amino acids, lipids, iron, specific vitamins, and trace nutrients.<sup>23</sup> Limitations in any of these can thwart production. However, the rate of erythrocyte production is regulated not by any of these substances, but rather by the concentration of erythropoietin. Erythropoietin is an 18.4-kD glycoprotein that binds to specific receptors on the surface of erythroid precursors and various other cells and supports their clonal maturation.<sup>23,24</sup> In the human fetus, erythropoietin is produced by a surprising variety of cells, including cells of monocyte-macrophage origin in the liver.<sup>25,26</sup> The absence of erythropoietin or its receptor, as has been produced in murine knock-out models, leads to profound anemia and fetal death on approximately embryonic day 13.<sup>27,28</sup> Postnatally, erythropoietin is produced almost exclusively by peritubular cells of the kidney, with a small amount produced by liver cells and neuronal and glial cells in the central nervous system. Although some erythropoietin production occurs in the fetal kidney, it is minimal. Anephric fetuses have normal serum erythropoietin concentrations and hematocrits.<sup>29</sup> The factors that regulate the switch of erythropoietin production from the liver to the kidney are not known. However, some investigators have suggested that among preterm neonates this switch does not occur until term gestation or close to it; this physiologic delay is responsible for the relatively low concentrations of circulating erythropoietin in the common hyporegenerative anemia known as anemia of prematurity.<sup>30</sup>

It has become clear that the actions of erythropoietin in the human fetus are widespread. Erythropoietin receptors have been documented on the surface of cells within a surprising variety of nonhematopoietic fetal tissues, including intestinal villi, endothelium, mesangium, smooth muscle, placenta, and neurons.<sup>25,26,31,32</sup> Erythropoietin has an antiapoptotic effect on several of these cell types *in vitro*. Erythropoietin also occurs in relatively high concentration in human amniotic fluid, colostrum, and milk—fluids that are swallowed in large amounts by the fetus and neonate.<sup>33</sup> A healthy midtrimester human fetus may swallow 200 to 300 mL of amniotic fluid per kilogram of body weight per day. With an amniotic fluid erythropoietin concentration of 200 mU/mL, the fetus would swallow approximately 60,000 mU/kg a day—an amount that if given systemically to a neonate would have a marked erythropoietic effect. Erythropoietin receptors are present along the villous border of the fetal and neonatal intestine.<sup>25,33</sup> It appears that

**Figure 25-4.** Day of life neutropenia (blood neutrophils  $<1000/\mu\text{L}$ ) was first detected among 338 neutropenia neonates with birthweights  $<1000$  g. (Used with permission from Christensen et al.<sup>21</sup>)

erythropoietin in amniotic fluid, colostrum, and human milk is not absorbed into the circulation and has no systemic effect. Rather, it acts locally in the intestine as a trophic and antiapoptotic factor. Erythropoietin in amniotic fluid, colostrum, and milk tends to resist digestive conditions present in the fetal and neonatal gastrointestinal tract.<sup>33,34</sup>

Erythropoietin is present, in concentrations of 20 to 50 mU/mL, in the spinal fluid of neonates. Markedly greater spinal fluid concentrations of erythropoietin are seen after perinatal asphyxia, and this erythropoietin appears to be derived within the brain as opposed to crossing the blood-brain barrier.<sup>35,36</sup> Further evidence that erythropoietin does not cross the blood-brain barrier in neonatal humans includes the observation that neonates treated with recombinant erythropoietin do not have elevated erythropoietin concentrations in their spinal fluid.<sup>36</sup> The spinal fluid of adults generally has an erythropoietin concentration lower than the lower limit of detectability.<sup>35,36</sup>

The biologic roles of erythropoietin and erythropoietin receptors in the fetal and neonatal intestinal tract and central nervous system are not known. One potential function for erythropoietin in the fetal brain is as a neuroprotectant.<sup>37</sup> This

postulate is supported by the observations that erythropoietin production increases in the brain during fetal hypoxia, and that recombinant erythropoietin protects neurons in tissue culture from hypoxemic damage and does so by diminishing apoptosis, which is analogous to the function it has in erythropoiesis.

### Fetal Erythroid Progenitors

Culture of marrow cells in tissue culture has added to the understanding of erythropoietic regulation. When marrow cells are placed in semisolid media culture systems for 5 to 7 days, the erythropoietin-sensitive precursors [colony-forming units–erythroid (CFU-E)] mature clonally into clusters containing 30 to 100 normoblasts.<sup>38</sup> Erythroid-specific progenitors that are less well differentiated than CFU-E, and hence more primitive cells, are called burst-forming units–erythroid (BFU-E). Twelve to 14 days after marrow cells are placed in semisolid culture systems, BFU-E have developed into large clusters of normoblasts, each containing 200 to more than 10,000 normoblasts. BFU-E from human fetuses respond in a slightly different manner than do BFU-E isolated from adults. Specifically, BFU-E of fetal origin generally develop into erythroid clones more rapidly and generally

develop substantially more normoblasts than do BFU-E of adult origin.<sup>39,40</sup> Also, BFU-E from adult marrow require a combination of erythropoietin plus another factor, such as interleukin-3 or GM-CSF, to mature clonally, whereas many fetal BFU-E mature in the presence of erythropoietin alone.<sup>39,40</sup>

### Embryonic, Fetal, and Adult Hemoglobins

Tissues must receive a constant supply of oxygen. The development of oxygen-carrying proteins increases the ability of blood to transport oxygen. The binding of oxygen and its dissociation from hemoglobin are accomplished without expenditure of metabolic energy.<sup>41</sup> Hemoglobin consists of iron-containing heme groups and globin, a protein moiety. An interaction between heme, globin, and 2,3-diphosphoglycerate (also called 2,3-bisphosphoglycerate) gives hemoglobin its unique properties in the reversible transport of oxygen. Hemoglobin is a tetrameric molecule composed of two pairs of polypeptide chains, each encoded by a different family of genes; the  $\alpha$ -like globin genes on chromosome 16 and the  $\beta$ -like globin genes on chromosome 11. The main hemoglobin of normal adults (HbA) is made up of one pair each of  $\alpha$  and  $\beta$  chains ( $\alpha_2\beta_2$ ). Six distinct hemoglobins can be detected within the erythrocytes of the human embryo, fetus, child, and adult—Gower-1, Gower-2, Portland, fetal hemoglobin (HbF), and the adult hemoglobins HbA and HbA<sub>2</sub>. The time of appearance and quantitative relations among the hemoglobins are determined by complex developmental processes that are not well defined.

Human embryos have the slowly migrating hemoglobins Gower-1, Gower-2, and Portland. The  $\zeta$  chains of Portland and Gower-1 hemoglobins are structurally similar to  $\alpha$  chains. Both Gower hemoglobins contain a unique polypeptide chain, the  $\epsilon$  chain. Gower-1 hemoglobin has the structure  $\zeta_2\epsilon_2$  and Gower-2,  $\alpha_2\epsilon_2$ . Portland hemoglobin has the structure  $\zeta_2\eta_2$ . Four to 8 weeks after conception, the Gower hemoglobins predominate, but by 12 to 14 weeks, they are no longer detected.

Fetal hemoglobin contains  $\gamma$  chains in place of the  $\beta$  chains of HbA and are represented as  $\alpha_2\gamma_2$ . The resistance of HbF to denaturation by strong alkali usually is used in its quantitation. After the eighth postconceptional week, HbF is the predominant hemoglobin. At 24 weeks of gestation, it constitutes 90% of total hemoglobin. Thereafter, a gradual decline in HbF occurs, so that at birth the average is 70% of the total. Synthesis of HbF decreases rapidly postnatally, and by 6 to 12 months of age only a trace is present. Fetal hemoglobin is heterogeneous because of two types of  $\gamma$  chains, synthesis of which is directed by two sets of genes. The chains differ at position 136 in the presence of either a glycine (G $\gamma$ ) or an alanine (A $\gamma$ ) residue. In the neonate, the relative proportion of G $\gamma$  to A $\gamma$  chain is 3:1.

Trace quantities of HbA can be detected in embryos. Thus, it is possible to make an early prenatal diagnosis of major  $\beta$ -chain hemoglobinopathy. Prenatal diagnosis is based on techniques used to examine the rates of synthesis of  $\beta$  chains or the structure of newly synthesized  $\beta$  chains or on molecular techniques from sampling the chorionic villus tissue or amniotic fluid. Gene

deletion disorders, such as  $\alpha$ -thalassemia, can be detected with the same methods.

At 24 weeks of gestation, approximately 5% to 10% of hemoglobin in a fetus is HbA. A steady increase follows, so that at term, the proportion of HbA averages 30%. By 1 year of age, the normal adult hemoglobin pattern appears. The minor adult hemoglobin component (HbA<sub>2</sub>) contains  $\delta$  chains and has the structure  $\alpha_2\delta_2$ . It is seen only when significant amounts of HbA are present. At birth, less than 1% of HbA<sub>2</sub> is present, but by 12 months, the normal level of 2% to 4% is attained. Throughout life the normal ratio of HbA to HbA<sub>2</sub> is approximately 30:1.

In the fetus and neonate, the rates of synthesis of  $\gamma$  and  $\beta$  chains and the amounts of HbA and HbF are inversely related. This has been attributed to a switch mechanism, but the developmental processes that direct the switch from predominantly  $\gamma$ -chain synthesis in utero to predominantly  $\beta$ -chain synthesis after birth are unclear. Primitive erythrocyte progenitors undergoing clonal maturation in culture (BFU-E) predominantly generate HbF. This may be the basis for the increased levels of HbF that occur in anemia with severe erythropoietic stress. Alternative explanations involve more basic genetic regulators in the DNA sequences that flank the hemoglobin gene complexes.

Because hemoglobins containing  $\epsilon$  chains are normally present only very early in intrauterine life, they are largely of theoretic interest. Small amounts of the Gower hemoglobins have been detectable in a few neonates with trisomy 13. Increased levels of Portland hemoglobin have been found in cord blood of stillborn infants with homozygous  $\alpha$ -thalassemia.

The normal adult level of HbA<sub>2</sub> (2.4% to 3.4%) is seldom altered. Levels of HbA<sub>2</sub> exceeding 3.4% are found in most persons with the  $\beta$ -thalassemia trait and in those with megaloblastic anemia secondary to vitamin B12 and folic acid deficiency. Decreased HbA<sub>2</sub> levels are found in those with iron deficiency anemia and thalassemia major.<sup>42</sup>

Erythrocytes of the midtrimester fetus and preterm infant are extremely large and laden with hemoglobin (Fig 25-5). At 22 to 23 weeks of gestation, the mean corpuscular volume (MCV) can be 135 fL or more, compared with a value of  $88 \pm 8$  fL in adults. Similarly, at 22 to 23 weeks of gestation, the mean corpuscular hemoglobin (MCH) can be over 45 pg, compared with  $29 \pm 2$  pg in adults.<sup>43</sup> Even at term, the MCV and MCH are strikingly higher than the upper limit of normal among healthy adults. However, throughout gestation the mean cell hemoglobin concentration is essentially the same as in adults.<sup>43</sup> Presumably, these very large and hemoglobin-laden erythrocytes are advantageous to the early fetus, although it is not clear what those advantages are. Perhaps the very high content of hemoglobin carried by these large cells somehow constitutes a fetal advantage. Whether large erythrocytes are also advantageous for prematurely delivered neonates ex utero is not known. Many preterm neonates have large phlebotomy losses in the first week of NICU care and are transfused with much smaller erythrocytes from adult donors. The consequences of this change in erythrocyte size are not known.

Thrombopoiesis

Platelets were described in the early part of the 19th century, but it was not until 1882 that their role in hemostasis was recognized. The origin of platelets from megakaryocytes was reported in 1906,<sup>44</sup> and since then the study of mechanisms responsible for platelet production has focused on megakaryocytes. The megakaryocyte compartment in the marrow consists of two pools of cells.<sup>45</sup> One is composed of cells that are morphologically unrecognizable but are committed to the megakaryocyte lineage. These cells, the megakaryocyte progenitors, retain a high proliferative capacity and ultimately determine the number of megakaryocytes in the marrow. The other pool consists of nondividing cells that are morphologically recognizable as megakaryocytes and undergo endoreduplication or

endomitosis, a process in which the ploidy of the cell increases without cellular division.

Fetal and Neonatal Megakaryocyte Progenitors

Progenitor cells committed to the megakaryocyte lineage can be identified by two methods: a culture system, in which they are identified by their ability to form megakaryocyte colonies, and immunologic staining, which allows characterization according to the specific antigens expressed on their membranes. With these methods, two different megakaryocyte progenitor cells have been identified; the burst-forming unit–megakaryocyte (BFU-MK), which is a more primitive megakaryocyte progenitor,<sup>46,47</sup> and a later progenitor known as the colony-forming unit–megakaryocyte (CFU-MK).<sup>45,48</sup> In culture, CFU-MK-derived colonies are smaller (3 to 50 cells per colony) and primarily unifocal

**Figure 25-5.** The expected range of values for (A) mean corpuscular volume (MCV) and for (B) mean corpuscular hemoglobin (MCH) for neonates of 22 weeks through 42 weeks of gestation, as measured on the first day after birth. The upper and lower boundaries incorporate 95% of the measured values. (Used with permission from Christensen et al.<sup>43</sup>)

(Fig 25-6), whereas BFU-MK-derived colonies are larger (>50 cells per colony) and have multiple foci of development. When immunologically phenotyped, CFU-MKs express CD34 and HLA-DR, whereas BFU-MKs express CD34 but not HLA-DR.

There are no differences between fetal and adult megakaryocyte progenitors in regard to the expression profile of CD34 and HLA-DR.<sup>49</sup> However, fetal BFU-MK-derived colonies are significantly larger than adult BFU-MK-derived colonies and are usually composed of only one or two foci of development. Adult BFU-MK-derived colonies are typically multifocal.<sup>49</sup> In addition, a unique megakaryocyte progenitor present in fetal marrow has an unusually high proliferative potential and gives

**Figure 25-6.** Photomicrograph showing a megakaryocyte colony derived from a megakaryocyte progenitor (CFU-MK) from the marrow of a thrombocytopenic preterm neonate. (Original magnification,  $\times 400$ ). Light-density mononuclear cells isolated from the marrow were cultured in collagen-based serum-free media with 50 ng/mL of recombinant human thrombopoietin. After fixation, the colonies were stained with a monoclonal antibody against glycoprotein IIb/IIIa to allow accurate identification of megakaryocytes.

rise to very large unifocal colonies (>300 cells).<sup>50</sup> This cell, not found in adult marrow cultures, may represent a more primitive megakaryocyte progenitor. The development of miniaturized assay systems to study megakaryocyte progenitors has made it possible to study these cells in the peripheral blood of neonates. Using these techniques, it has been shown that preterm neonates (24 to 36 weeks) have higher circulating concentrations of all megakaryocyte progenitors than do term neonates.<sup>51,52</sup>

**Fetal and Neonatal Megakaryocytes**

Unlike their progenitors, megakaryocytes have no proliferative abilities but undergo a complex maturational process. Through this process, they evolve from small, mononuclear cells to very large, polyploid cells easily recognized in the marrow as mature megakaryocytes.<sup>53,54</sup> The modal ploidy is 16N in normal adult marrow.<sup>55</sup>

In the human fetus, megakaryocytes are first detected in the circulatory system at 8 weeks of gestation, and the first platelets appear at 5 weeks.<sup>56</sup> Compared with the megakaryocytes of adults, fetal megakaryocytes are significantly smaller at all stages of maturation. Their ploidy distribution is also shifted to the left, with a higher proportion of immature megakaryocytes.<sup>57–59</sup> The modal ploidy in the marrow of near-term fetuses is 8N.<sup>60</sup>

Umbilical cord blood has higher concentrations of circulating megakaryocytes than adult blood. As in the fetus, cord blood megakaryocytes from term infants are considerably smaller than adult circulating megakaryocytes,<sup>61</sup> although they are otherwise phenotypically mature megakaryocytes. “Adult-size” megakaryocytes appear by 2 years of age, but the evolution of the process of megakaryocytopoiesis in the first year of life is poorly understood because of the lack of normal marrow specimens. Because cord-blood-derived megakaryocytes have been shown to generate fewer platelets than adult-derived megakaryocytes,<sup>62</sup> it has been postulated that the normal platelet counts of fetuses and neonates are maintained by the increased proliferative potential of the fetal/neonatal megakaryocyte progenitors (Table 25-3).<sup>63</sup>

The process of platelet production and release is one of the less well understood steps of thrombopoiesis. However, recent work has substantially enhanced our understanding of this process, and has painted a graphic picture of how megakaryocytes—in their

final hours—convert their cytoplasm into branched proplatelet extensions that elongate based on a process of microtubule sliding and polymerization.<sup>64</sup> Organelles and platelet-specific granules are delivered to the nascent platelets (at the tips of each proplatelet extension) by a mechanism involving both traveling of the organelles along the microtubules and movement of the linked microtubules relative to each other.<sup>65</sup> The role of blood-flow-induced shear stress on platelet release has also been evidenced in a recent study using intravital microscopy to observe in-vivo platelet release in intact murine marrow.<sup>66</sup> In this study, marrow megakaryocytes were observed to extend dynamic proplatelet-like protrusions into microvessels. These intravascular extensions were then sheared from their transendothelial stems by flowing blood, resulting in the appearance of proplatelets in peripheral blood.

### Thrombopoietin and Thrombopoietin Mimetics

Thrombopoietin (TPO), the main physiologic regulator of platelet production, was first isolated in 1994.<sup>67</sup> The gene that encodes thrombopoietin has been localized to the long arm of human chromosome 3.<sup>68</sup> Thrombopoietin mRNA is expressed primarily in the liver, and to a lesser extent in other tissues, including kidney and marrow stromal cells.<sup>69</sup> In vitro, TPO acts as a potent stimulator of all stages of megakaryocyte growth and development, except platelet release.<sup>70</sup> It also plays roles in platelet activation, mostly by priming the platelets to the effects of other agonists, and in release of platelets from megakaryocytes.<sup>71</sup> Thrombopoietin and TPO receptor knock-out mice models have been generated.<sup>72,73</sup> These mice have megakaryocyte and blood platelet concentrations of only 10% to 15% those of control mice. These studies confirmed that TPO is the primary regulator of platelet production, but also proved that alternative pathways exist for megakaryocytopoiesis.

Much attention has also been directed to the effects of TPO on other hematologic cell types. In vitro, TPO alone stimulates the proliferation and survival of erythroid, myeloid, and multipotential progenitors.<sup>74</sup> Thrombopoietin also enhances erythropoietin-induced erythroid burst formation, an effect mediated by its ability to inhibit apoptosis of erythroid progenitors.<sup>75</sup> Further studies have shown that TPO acts on early hematopoietic progenitors (including hematopoietic stem cells), thus disclosing an important role for this cytokine in hematopoiesis in general, in addition to its megakaryopoietic functions.<sup>76,77</sup> These findings have significant clinical implications for patients with mutations in the TPO receptor that render it unresponsive to TPO. These patients, such as those with congenital amegakaryocytic thrombocytopenia, frequently progress to aplastic anemia.

Results of several animal studies have confirmed the role of TPO as a potent stimulator of platelet production. The recombinant human full-length TPO molecule (rTPO) and a recombinant human polypeptide that contains the receptor-binding N-terminal domain of TPO (rHuMGDF) were the subjects of several studies. When injected into normal animals, rTPO and rHuMGDF induced marked thrombocytosis.<sup>78,79</sup>

Administered to animals exposed to myelosuppressive chemotherapy, rHuMGDF not only ameliorated the associated thrombocytopenia but also accelerated red cell and neutrophil recovery.<sup>80,81</sup>

Several Phase I and II trials in human subjects also demonstrated the efficacy of rTPO and rHuMGDF as stimulators of platelet production in adults without thrombocytopenia<sup>82</sup> and in patients with chemotherapy-induced thrombocytopenia.<sup>83,84</sup> However, the appearance of thrombocytopenia and ultimately aplastic anemia secondary to the generation of cross-reactive anti-TPO in a small number of patients receiving rHuMGDF<sup>85</sup> led to the discontinuation of all clinical trials involving any of the forms of rTPO. As an alternative, much interest has been directed recently to the development of TPO-mimetic molecules. These are small molecules that have no sequence homology to TPO, but bind to the TPO receptor and have biologically comparable effects. The lack of homology represents a significant advantage over recombinant forms of TPO, because it should preclude the development of cross-reactive neutralizing antibodies against endogenous TPO. At least five different TPO receptor agonists have been described, and at least two of them have been studied in human subjects: AMG 531, an engineered peptibody composed of a recombinant protein carrier FC domain linked to multiple c-mpl-binding domains,<sup>86,87</sup> and Eltrombopag (SB-497115), an oral, nonpeptide TPO receptor agonist.<sup>88</sup> Both compounds showed very promising results in patients with refractory immune thrombocytopenic purpura, and had a favorable safety profile.

### Thrombopoietin in the Fetus and Neonate

Little is known about the role of TPO or the theoretical benefits of administration of rTPO or TPO-mimetic compounds to neonates. Recombinant TPO certainly supports the growth of megakaryocyte colonies from the blood or marrow of neonates (Fig 25-6). In fact, marrow progenitors from neonates are more sensitive to rTPO than progenitors from adults in vitro (Fig 25-7).<sup>89</sup> Similarly, newborn rhesus monkeys are highly sensitive to rTPO in vivo (Fig 25-8) and respond to lower doses (per kilogram body weight) than those required in adult rhesus monkeys to achieve a similar effect.<sup>90</sup> Megakaryocyte progenitors from preterm neonates with or without thrombocytopenia also seem to be more sensitive to rTPO than progenitors from term neonates.<sup>91</sup> However, there are substantial qualitative differences in the response of neonatal and adult megakaryocytes to TPO, as demonstrated by a recent study evaluating the maturation of megakaryocytes cultured in either in TPO alone or in adult marrow stromal conditioned media.<sup>92</sup> In that study, adult megakaryocytes reached the highest ploidy levels when cultured in serum-free medium with maximal concentrations of rTPO, while neonatal megakaryocytes reached their highest ploidy when cultured in marrow stromal cell conditioned media *in the absence* of rTPO. In fact, the addition of supraphysiologic concentrations of this cytokine ( $\geq 0.1$  ng/mL) inhibited the maturation of neonatal megakaryocytes (Fig 25-9). Whether rTPO or

**Figure 25-7.** (A) Dose response to recombinant thrombopoietin of megakaryocyte progenitors obtained from the marrow of neonates with thrombocytopenia (T), neonates without thrombocytopenia (NT), and healthy adults. The marrow obtained from neonates generated approximately three times more colonies (per  $10^5$  low-density cells) than the marrow obtained from adults. (B) In a percentage of maximal colony count vs recombinant thrombopoietin concentration curve, the curves for the neonates with thrombocytopenia and those without thrombocytopenia reached a plateau at 10 ng/mL, compared with 50 ng/mL for the adults. This indicates that megakaryocyte progenitors from neonates are more sensitive to recombinant thrombopoietin in vitro than are their adult counterparts. (Used with permission from Sola et al.<sup>89</sup>)

**Figure 25-8.** Dose-response to polyethylene glycol (PEG)-rHuMGDF (a truncated form of recombinant thrombopoietin) of the blood platelet concentration in newborn rhesus monkeys, demonstrating the sensitivity of megakaryocyte progenitors of neonates to recombinant thrombopoietin in vivo. The monkeys received daily subcutaneous injections of placebo or PEG-rHuMGDF at doses of 0.25, 1.00, or 2.50  $\mu$ g/kg/day for 7 days. Each line represents the average platelet counts of the two monkeys in each treatment group sampled on study Days 2, 4, and 6 and then twice weekly until Day 28. The peripheral platelet count increased on Day 6 of treatment, peaked on Day 11, and returned to baseline by Day 23. The two higher doses generated similar increases in platelet count. (Used with permission from Sola et al.<sup>90</sup>)

**Figure 25-9.** The percentage of megakaryocytes with ploidy levels  $\geq 8N$  in peripheral blood (PB)- and cord blood (CB)-derived megakaryocyte cultures differed depending on media source and recombinant thrombopoietin (rTPO) concentration. PB- and CB-CD34+ cells were cultured for 14 days in serum-free unconditioned media (A) and in adult marrow stromal conditioned media (B), with varying rTPO concentrations. PB-derived megakaryocytes (solid lines) cultured in unconditioned

media (A) exhibited a rTPO dose-dependent increase in ploidy levels, an effect inhibited by the presence of conditioned media (B). CB-derived megakaryocytes (dashed lines) reached highest ploidy levels when cultured in conditioned media with no rTPO, and effect that was reversed by rTPO concentrations  $\geq 1$  ng/mL (B). Data shown represent the means and standard error of the mean (SEM) of four separate experiments. (Used with permission from Pastos et al.<sup>92</sup>)

**Figure 25-10.** Cumulative distribution plots of megakaryocyte diameters in the marrow of thrombocytopenic neonates (dark circles), nonthrombocytopenic neonates (clear circles), thrombocytopenic adults (dark diamonds), and nonthrombocytopenic adults (clear diamonds). The megakaryocyte diameters are displayed on the X-axis, and their cumulative distribution on the Y-axis. Both adult curves are shifted to the right compared to the neonatal curves, indicating the predominance of larger megakaryocytes in these samples. Furthermore, the curve for the thrombocytopenic adults is also shifted to the right compared to that for the nonthrombocytopenic adults, indicating a higher percentage of large megakaryocytes. In contrast, the curves of thrombocytopenic and nonthrombocytopenic neonates are overlapping, indicating no change in the megakaryocyte size distribution in this cohort of thrombocytopenic neonates compared to controls. (Used with permission from Sola-Visner et al.<sup>96</sup>)

any of the TPO-mimetic peptides will be clinically useful as an alternative to platelet transfusions in the care of neonates with thrombocytopenia remains to be determined. However, it is clear that there are substantial developmental differences in megakaryocyte regulation, which will have to be taken into account when considering both the possible efficacy and the potential toxicity of thrombopoietic growth factors in this population.

### Neonatal Thrombocytopenia

When a fetus is delivered prematurely, the thrombopoietic system can be taxed by new demands. For instance, endothelial damage from infection or from the presence of intravascular catheters can accelerate platelet usage well beyond that normally experienced by the fetus. Moreover, disorders that tend to shorten gestation, such as pregnancy-induced hypertension and placental insufficiency, appear to have suppressive effects on fetal platelet production.<sup>93</sup> Because of these and other issues, thrombocytopenia is a very common problem in the neonatal intensive care unit, manifested in 20% to 30% of all NICU patients, and in 75% or more of the extremely low birthweight population.<sup>94</sup> Recent work has suggested that when fetuses or preterm neonates require an increase in platelet production, as a compensation for accelerated platelet usage or destruction, they might face developmental limitations in their ability to upregulate thrombopoiesis. Specifically, TPO concentrations in small-for-gestational-age neonates with hyporegenerative thrombocytopenia are less elevated than those reported in adults

with hyporegenerative thrombocytopenia, suggesting that—at least in this group of neonates—lower than expected TPO concentrations might contribute to the thrombocytopenia.<sup>91,95</sup> Furthermore, thrombocytopenic neonates in general do not seem to increase the size of their megakaryocytes as compared to their nonthrombocytopenic counterparts, thus blunting one of the mechanisms by which adults increase platelet production in response to platelet demand<sup>96</sup> (Fig 25-10). The mechanisms underlying the small size of neonatal megakaryocytes are not clearly understood, but recent studies suggest that they involve a combination of cell-intrinsic factors and factors in the fetal/neonatal microenvironment. Indeed, as demonstrated by stem cell transplant experiments, the adult environment is more conducive to megakaryocyte maturation than the fetal environment, but cell-intrinsic factors (such as the response to TPO) nevertheless limit the ultimate size and ploidy that neonatal megakaryocytes can achieve.<sup>97,98</sup>

### Summary

Neutropenia, anemia, and thrombocytopenia are relatively common problems in the NICU. These forms of cytopenia stem from multiple etiologic factors, and they involve many different kinetic mechanisms. However, all types of cytopenia in the NICU are more prevalent among those of shortest gestation and smallest birthweight. It is proposed that this relationship is

the result of gestational age-linked developmental differences in hematopoietic regulation. Transfusion is currently the main therapy available for NICU patients who have severe and prolonged cytopenia (see Chapter 30 for more information). As more is learned about human fetal hematopoiesis, perhaps alternatives to transfusion will emerge. To a certain extent, this process has already begun, because treatments such as recombinant erythropoietin and administration of recombinant G-CSF have been used in neonatology. However, much remains to be accomplished, such as more precise definitions of which neonates with cytopenias will benefit from treatment with recombinant hematopoietic growth factors, better methods for dosing and monitoring such treatments, and more precise means of identifying their risks and benefits.

**Humphrey H.H. Kanhai,<sup>1</sup> Jos J.M. van Roosmalen,<sup>2</sup> & Anneke Brand<sup>3</sup>**<sup>1</sup> Professor, Department of Obstetrics, Leiden University Medical Center, Leiden, The Netherlands<sup>2</sup> Professor, Department of Obstetrics, Leiden University Medical Center, Leiden, and Section of Health Care and Culture, VU University Medical Center, Amsterdam, The Netherlands<sup>3</sup> Professor, Sanquin Division Southwest and Department of Immunohematology and Blood Transfusion, Leiden University Medical Center, Leiden, The Netherlands

Because of physiologic hypervolemia in a healthy pregnant woman, a certain amount of blood loss after the birth of a child is considered normal. Postpartum hemorrhage (PPH) up to 1000 mL in a healthy mother, therefore, does not lead to disturbances in hemodynamics. PPH of more than 1000 mL in 24 hours occurs in 5% of deliveries. In women with anemia or poor increase in blood volume during pregnancy (eg, in preeclampsia), PPH less than 1000 mL can be hazardous to the mother. Blood loss in pregnancy, with consequences in oxygen-carrying capacity, does lead to additional danger for the fetus.

A worldwide survey shows huge variation in the lifetime risk of maternal mortality—from one in six in developing countries with a low human development index (HDI) to one in 30,000 in Northern European countries.<sup>1</sup> Obstetric hemorrhage and preeclampsia together account for 50% of maternal deaths in low HDI as well as high HDI countries.<sup>1,2</sup> Pregnancy complications and management differ in various parts of the world because of differences in blood groups, genetic and environmentally acquired diseases, socioeconomic status, and logistic and cultural factors.

## Blood Loss in Pregnancy

### Obstetric Causes

Delivery poses the highest risk for blood loss during pregnancy. If administration of at least 4 Red Blood Cell (RBC) units is used as a surrogate definition for major obstetric hemorrhage, then a national survey on severe maternal morbidity in the Netherlands has identified major obstetric hemorrhage in 4.5 per 1000 births.<sup>3</sup> Of a total of 358,874 births during the study period from August 2004 until August 2006, overall severe maternal morbidity occurred in 2552 women (7.1 per 1000 births). Of these

women, 1606 needed 4 or more RBC units, indicating that 70% of severe pregnancy complications are associated with severe hemorrhage. Data on the cause of bleeding were available for 1590 of the 1606 women. Table 26-1 shows the most frequent etiologies of the obstetric hemorrhages. In 1480 women (93%), blood loss occurred during the postpartum period. Antepartum hemorrhage occurred in 135 women (8.5%) and major bleeding in early pregnancy occurred in 51 women (3.2%). These

**Table 26-1.** Primary Diagnosis in Major Obstetric Hemorrhage Defined as the Need for at Least 4 Units of Blood<sup>3</sup>

| Timing                      | Diagnosis*                            | No. of Patients |
|-----------------------------|---------------------------------------|-----------------|
| Early pregnancy<br>(n = 51) | Ectopic pregnancy                     | 29 (56.9%)      |
|                             | Spontaneous abortion                  | 10 (19.6%)      |
|                             | Termination of pregnancy              | 10 (19.6%)      |
|                             | Miscellaneous†                        | 2 (3.9%)        |
| Antepartum<br>(n = 135)‡    | Abruptio placentae                    | 61 (45.5%)      |

|                             | Unknown diagnosis                     | 12 (9.0%)       |
| Postpartum<br>(n = 1480)*   | Retained placenta or placental rests  | 703 (47.8%)     |
|                             | Uterine atonia                        | 567 (38.5%)     |
|                             | Hemorrhage following cesarean section | 183 (12.4%)     |
|                             | Perineal tears/episiotomy             | 148 (10.1%)     |
|                             | Clotting disorders                    | 116 (7.9%)      |
|                             | Placenta accreta/increta/percreta     | 109 (7.4%)      |
|                             | Rupture of cervix                     | 58 (3.9%)       |
|                             | Uterine rupture                       | 44 (3.0%)       |
|                             | Uterine inversion                     | 13 (0.9%)       |
|                             | Miscellaneous                         | 65 (4.4%)       |
|                             | Unknown diagnosis                     | 10 (0.7%)       |

\*Up to three postpartum diagnoses could be coded.

†Molar pregnancy and placenta percreta.

‡In 76 cases both antepartum and postpartum diagnoses were coded.

§Rupture of uterine/ovarian artery, rupture of ovarian cyst, placenta percreta, vasa previa, retroplacental hematoma, rupture of uterine vein.

percentages total more than 100, because 76 women experienced both antepartum and postpartum bleeding. Because only those women in need of at least 4 RBC units were included in the survey, the most frequent causes of obstetric blood loss before birth (such as miscarriage and unexplained minor antepartum hemorrhage) are relatively underrepresented in these figures.

Assuming that the 239 women who received 10 or more units of blood would have died if they had not received those transfusions, the maternal mortality ratio (MMR) in the Netherlands would stand at 70 instead of the actual 12 per 100,000 live births. This underscores the impact of a functioning blood transfusion service on the reduction of maternal mortality. Lack of access to sufficient blood leads to a higher frequency of hysterectomy to stop the bleeding. Although hysterectomy may be a lifesaving procedure for some women, it adds to the risk of dying for others.

The MMR for Jehovah's Witnesses in the Netherlands was recently estimated to be 68 per 100,000 live births (van Roosmalen JJM, personal communication). This is strikingly similar to the likely MMR if blood had not been available for those women who received 10 or more RBC units.

Hematologic Diseases

Maternal diseases such as diabetes, renal failure, hemoglobinopathies, systemic lupus erythematosus, and antiphospholipid antibody syndrome (APAS) are not associated with primary bleeding. Rather, they are associated with increased maternal and fetal mortality resulting from thrombotic and vascular complications leading to preeclampsia, thromboembolism, and placental insufficiency. A few maternal diseases, such as maternal thrombocytopenia and (iatrogenic) coagulopathies, can pose primary bleeding problems during pregnancy and delivery; however, in the absence of obstetric complications, these problems rarely lead to maternal mortality.

Maternal Thrombocytopenia

A platelet count below 150,000/ $\mu$ L is a rather frequent finding in pregnancy. The possible causes are listed in Table 26-2.

Spurious thrombocytopenia caused by laboratory errors or EDTA agglutination is excluded by examination of a blood film or platelet counting in citrated blood.

Table 26-2. Causes of Thrombocytopenia in Pregnancy

|                                                                  |
|------------------------------------------------------------------|
| • Spurious thrombocytopenia                                      |
| • Gestational thrombocytopenia                                   |
| • Preeclampsia and HELLP                                         |
| • Thrombotic microangiopathies (HELLP, TTP, HUS)                 |
| • Disseminated intravascular coagulation                         |
| • Idiopathic/immune thrombocytopenic purpura                     |
| • Antiphospholipid antibody syndrome                             |
| • Congenital thrombocytopenia and/or platelet function disorders |

HELLP = hemolysis, elevated liver enzymes, and low platelet count; TTP = thrombotic thrombocytopenic purpura; HUS = hemolytic uremic syndrome.

Thrombocytopenia (platelet count between 80,000 and 150,000/ $\mu$ L) of unknown origin, often referred to as gestational thrombocytopenia (GT), occurs in approximately 6% of third trimesters.<sup>4</sup> Its cause and significance is often unknown. GT has been considered as subclinical immune thrombocytopenic purpura (ITP) or as a precursor of HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome.<sup>5,6</sup> GT is a diagnosis of exclusion. If, in uncomplicated pregnancy, the blood film is normal in an otherwise healthy female without a history of ITP or antiphospholipid antibodies, no diagnostic tests are needed. However, such women should be monitored carefully for aggravation of thrombocytopenia and symptoms of HELLP after delivery, because they may be at higher risk for postpartum HELLP syndrome.

HELLP syndrome belongs to the microangiopathic hemolytic anemias, also referred to as thrombotic microangiopathic anemias (TMAs), which can complicate pregnancy and puerperium.<sup>7,8</sup> The peak incidence has a relationship with the weeks of gestation (Fig 26-1), but there is considerable overlap with other syndromes (see below).

HELLP complicates 4% to 15% of cases of preeclampsia (hypertension and proteinuria). Its peak incidence is at 36 weeks, although in one-third of cases HELLP presents up to 7 days after a normal delivery not complicated by preeclampsia and in 10% it presents before the 27th week of gestation.<sup>9</sup> Typical symptoms include right-upper-quadrant abdominal pain, nausea, and vomiting. HELLP is not associated with overt disseminated intravascular coagulation (DIC), although in 70% the antithrombin level is decreased in contrast to thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS).<sup>10</sup> Because of vasoconstriction in preeclampsia, severe bleeding rarely occurs. Severe neglected HELLP, often resulting from delayed delivery, leads to DIC. Other complications are pulmonary edema, acute renal failure, abruptio placentae, and liver hematoma. Maternal mortality is as high as 20% and neonatal death ranges from 10% to 60% depending on intervention with elective preterm deliveries, which reduce the risk of death to both mother and fetus. Mild thrombocytopenia and schistocytes are found in 50% of the neonates and resolve without treatment or transfusions. Because termination of pregnancy is the definitive treatment, elective birth should be considered. Severe preeclampsia and HELLP will subsequently resolve 1 to 10 days after termination of pregnancy. If recovery is delayed beyond 3 days or HELLP after delivery progresses to (multi)-organ failure, plasma exchange may support recovery.<sup>11</sup> The ranges of laboratory values that can be found in HELLP are shown in Table 26-3.

HUS typically presents from 2 days after delivery onwards (mean 26 days), although in 5% to 10% of cases antepartum HUS has been described. At presentation 50% of females have thrombocytopenia (platelet counts less than 100,000/ $\mu$ L).<sup>8</sup> Despite plasma exchange, approximately 25% of the patients experience persistent renal failure.

TTP results from an antibody-mediated reduction in the level of von Willebrand factor (vWF)-cleaving protease (ADAMTS13).

**Figure 26-1.** Pregnancy-associated microangiopathic thrombocytopenias. HELLP = hemolysis, elevated liver enzymes, and low platelet count; HUS = hemolytic uremic syndrome; TTP = thrombotic thrombocytopenic purpura.

**Table 26-3.** Laboratory Values in 442 Cases of HELLP<sup>7</sup>

| Test                              | Median | Range      |
|-----------------------------------|--------|------------|
| Platelets<br>(×1000/μL)           | 57.00  | 7-99       |
| Alanine aminotransferase<br>(U/L) | 249.00 | 70-6193    |
| Lactate dehydrogenase<br>(U/L)    | 853.00 | 564-23.584 |
| Bilirubin<br>(μmol/L)             | 26.00  | 8.6-436    |
| (mg/dL)                           | 1.53   | 0.51-25.65 |
| Creatinine<br>(μmol/L)            | 97.00  | 53-1414    |
| (mg/dL)                           | 1.10   | 0.6-16.1   |
| Urine acid<br>(μmol/L)            | 462.00 | 174-900    |
| (mg/dL)                           | 7.70   | 2.9-15     |

TTP is most often seen in the second and third trimesters and requires plasma exchange similar to treatment of TTP in non-obstetric situations. TTP has no relationship with preeclampsia and there is no need to terminate pregnancy. Patients with a history of TTP can have a relapse in pregnancy, but after remission pregnancy is not contraindicated, although close monitoring of the ADAMTS13 level is recommended.<sup>12</sup>

DIC is seen in far-advanced TMA syndromes, predominantly caused by primary obstetric or septic pathology, such as abruptio placentae and severe intrauterine infection. Between 20% and 40% of obstetric patients with critical illness have symptoms of DIC. In pregnancy and puerperium the use of a DIC score (based on decreased platelet count, increased D-dimers, decreased fibrinogen, and prolonged prothrombin time) is less reliable because D-dimers start to increase in the first trimester

and are always increased after the 35th week. Fibrin deposition in DIC not only contributes to multiple organ failure, but also (because of consumption coagulopathy with massive and ongoing activation of coagulation) results in depletion of platelets and coagulation factors with severe bleeding.

With an incidence of 6/100,000 new cases per year, ITP mostly affects young women.<sup>13,14</sup> Consequently, a history or current evidence of ITP is frequently encountered in pregnancy (estimated to be 1-5 cases per 10,000 pregnancies).<sup>15</sup> Often the mother has a history of ITP with or without a low platelet count, although first presentation of ITP or accidentally discovered ITP in pregnancy also occurs. During pregnancy platelets decrease with a nadir in the third trimester.<sup>16,17</sup> Antenatal treatment is given exclusively on maternal indication and aims to maintain the platelet count above 20,000 to 30,000/μL or higher in case of bleeding symptoms, using corticosteroids as first-line treatment.<sup>13,17</sup> Intravenous immunoglobulin (IVIG) is reserved as second-line treatment. IVIG is used to prepare for delivery, if necessary, combined with platelet transfusions. There is no demonstrated effect of maternal treatment with corticosteroids or IVIG on the fetal platelet count.<sup>18,19</sup> Perinatal mortality in ITP is 0.6%.<sup>20</sup> The risk for neonatal thrombocytopenia below 50,000/μL ranges from 8.9% to 14.7%.<sup>19-22</sup> Intracranial hemorrhage (ICH) or other severe bleeding is not increased in the fetus of a mother with ITP. The nadir of the neonatal platelet count and the highest risk for bleeding is 4 (range, 1-7) days after delivery.<sup>15-17</sup> In large series, ICH in the neonate is reported to be 0% to 1.5%.<sup>13,17,23</sup>

Most studies have reported only weak correlations between the fetal platelet count at birth and the maternal platelet counts, the presence of antibodies in the maternal serum, or a history of splenectomy.<sup>13,17</sup> In individual cases, the risk for fetal thrombocytopenia below 50,000/μL cannot be predicted from the maternal platelet count. However, in women who are refractory to corticosteroids and splenectomy and who cannot maintain a platelet count above 30,000/μL despite immunosuppressive treatment, the risk for bleeding and neonatal thrombocytopenia

is higher.<sup>16,17,24</sup> In asymptomatic women, severe fetal thrombocytopenia is rare and approaches the background rate of approximately 1% in term newborns. In approximately 70% of multigravidae, the absence of thrombocytopenia in a previous child predicts a similar good outcome in the next child.<sup>25</sup>

Antiphospholipid antibody syndrome is an acquired condition of hypercoagulability, often associated with systemic lupus erythematosus (SLE). APAS is characterized by arterial and venous thrombosis and gestational vascular complications leading to recurrent fetal loss, growth retardation, and prematurity. In patients with suspected clinical symptoms, antibodies against  $\beta$ 2-glycoprotein I, anticardiolipin autoantibodies, and/or prolongation of plasma clotting time (lupus anticoagulant) are present.<sup>26</sup> On the basis of randomized studies, women with recurrent abortion are treated with a combination of low dosages of aspirin and low-molecular-weight heparin.<sup>23,26</sup> There is no risk for fetal bleeding but the mother has a slight increased risk for bleeding during delivery.

Treatment of inherited disorders of hemostasis and platelet function disorders (such as von Willebrand disease, hemophilia, or Glanzmann's thrombasthenia) aims to avoid blood components when possible, at least during pregnancy, because of the risk of alloimmunization. Before and after delivery, blood transfusion may be unavoidable; this can be problematic if the patient is extensively immunized. Planned delivery and an individualized treatment plan are needed for these rare diseases.

### Chronic Maternal Anemia

Physiologic anemia is caused by plasma volume expansion and is maximal around the 25th week of pregnancy. The World Health Organization defines anemia in pregnancy as a hemoglobin level  $<6.8$  mmol/L (11 g/dL), which is most often caused by nutritional deficiencies. Below a hemoglobin level of 5.5 to 6.2 mmol/L (9–10 g/dL) growth retardation and prematurity are reported, although it is not known whether these are related to the underlying disease or the lower hemoglobin level itself.<sup>27–29</sup>

For chronic hemolytic diseases, such as thalassemia and paroxysmal nocturnal hemoglobinuria, hypertransfusion is applied to maintain hemoglobin levels above 10 g/dL in order to depress hemolysis of autologous red cells.<sup>30</sup> Randomized studies have involved only pregnant patients with sickle cell disease and have showed that maintenance of a hematocrit above 33% with less than 35% sickled cells resulted in no better pregnancy outcome, although painful crises were significantly reduced.<sup>31</sup>

### Assessment of Amount of Blood Loss

Visual estimation is frequently used in routine practice to assess the amount of blood loss. However, this technique is inaccurate and leads to significant underestimates of blood loss.

In a nicely researched experiment using pictorial guidelines to facilitate visual estimation (Fig 26-2), all professionals involved in obstetric care underestimated blood loss.<sup>32</sup> In fact, obstetricians tended to underestimate blood loss to a higher degree than anesthetists, surgical nurses, and midwives. The guidelines used in this study (available at <http://www.bmfms.org.uk>) can be used

as an effective tool to train health-care professionals to improve their abilities to estimate blood loss.

Other methods of estimating blood loss include measuring actual blood loss with a weighing scale or measuring the peripartum hemoglobin change. Measurement with a scale, however, must be corrected for the amount of amniotic fluid and is cumbersome. Peripartum hemoglobin change has been shown to be unrelated to visually estimated blood loss.<sup>33</sup>

In other studies the need for additional therapeutic uterotonic drugs or blood transfusion is taken as an indication of the amount of blood loss.<sup>34</sup> This is not relevant for clinical practice, but is important for audit purposes.

## Maternal Transfusions

### Indications

The indications for maternal transfusion can be categorized in two groups—those occurring after delivery and those occurring during pregnancy or delivery.

### Transfusion Indications for Postpartum Bleeding

Forty percent of women lose more than 500 mL of blood after vaginal delivery and 30% lose more than 1000 mL after cesarean section. As discussed above, the blood loss is difficult to estimate.<sup>33</sup>

Although guidelines suggest a transfusion threshold at a hemoglobin concentration of 7.0 to 8.0 g/dL, concentrations of 5.0 g/dL or more are usually well tolerated if isovolemia is maintained. In a study of healthy individuals, Weiskopf et al<sup>35</sup> found that acute isovolumetric reduction of hemoglobin concentration to 5.0 g/dL does not appear to cause inadequate tissue oxygenation. In healthy women with a median hemoglobin level of 10.5 g/dL (range, 7–15 g/dL) 3 to 6 weeks after delivery, no relationship between hemoglobin level and the quality of life was observed.<sup>36</sup> Studies of the effects of blood transfusion after PPH on quality of life are not available thus far.

Transfusion is required only for symptomatic anemia and should not be given solely on the basis of the hemoglobin level. Limited data exist on outcomes at concentrations below 5.0 g/dL. Two retrospective studies involving patients who declined blood transfusion, mostly Jehovah's Witnesses, found that morbidity and mortality rates were extremely high below this hemoglobin level.<sup>37,38</sup> However, survival has been reported at hemoglobin levels below 2.0 g/dL—even as low as 1.4 g/dL.<sup>39,40</sup>

Life-threatening hemorrhages after delivery are often associated with complex coagulopathies. Therefore, a management protocol must be in place.<sup>41–43</sup> Recent protocols advocate that when massive bleeding in complex trauma is anticipated, the patient should be transfused earlier without waiting for consumption and dilutional coagulopathies. This has been shown to reduce total blood use and mortality.<sup>44,45</sup> This seems to hold for obstetric bleeding as well. Control of bleeding, early transfusion, and correction of coagulopathy must be carried out during the window of opportunity, which may be less than 2 hours, before

**Figure 26-2.** Pictorial guidelines to facilitate visual estimation of blood loss from obstetric hemorrhage.<sup>32</sup>

the vicious circle initiated by hypothermia, acidosis, and irreversible coagulopathy leads to death.

**Platelet Transfusions during Pregnancy and for Delivery**

During pregnancy, thrombocytopenias result from enhanced platelet phagocytosis in ITP or consumption in TMA, both disorders in which platelet transfusions are reserved for therapeutic indications. Reduced marrow platelet production

is rare unless a hematologic or oncologic condition is present. Whatever the cause of thrombocytopenia, most guidelines recommend a platelet count above 50,000/ $\mu$ L for delivery and 80,000/ $\mu$ L for cesarean section, allowing all forms of anesthesia.<sup>13</sup> Because of different pathophysiology, an individual treatment plan for every pregnant patient with thrombocytopenia is required. Except in cases of TTP, platelet transfusions are not contraindicated in TMA, ITP, or DIC. However, because platelet survival is

shortened, other supportive treatment intended to improve the cause of thrombocytopenia is required. (See Chapter 23.)

## Blood Products Used and Special Precautions Industrialized Countries with a High HDI

### Red Cell Transfusions

Pregnancy and transfusions both stimulate red cell antibody formation. A survey of the transfused population in developed countries shows that women have three or four times more alloantibodies than men and children.<sup>46,47</sup> Females with a history of transfusion and pregnancy must be screened early in a new pregnancy to identify alloantibodies as a potential cause for hemolytic disease of the fetus and newborn (HDFN) or availability of blood in case an indication for maternal transfusion should arise. In particular, antibodies against c and K1 antigens can cause HDFN as severe as Rh(D) HDFN.<sup>48</sup> In cases of HDFN caused by c or K1 antigens, more than 40% of the women had received prior transfusions.<sup>49</sup> Transfusions of Rh- and K-compatible components to females of childbearing potential can reduce non-D HDFN. Most national guidelines recommend the use of K-negative donors for women  $\leq 45$  years of age.

### Platelet Transfusions

Platelet transfusions can contain minimal numbers of erythrocytes, sufficient to immunize against the D antigen. If D-positive platelets are given to D-negative females of childbearing potential, prophylaxis with 375 IU intravenous Rh Immune Globulin (RhIG) is indicated.<sup>50</sup>

With increasing numbers of pregnancies, females produce leukocyte antibodies against paternal antigens, which may impair platelet recovery after transfusions from randomly selected donors.<sup>51,52</sup> HLA antibodies must be excluded if a need for platelet transfusion during delivery is anticipated. Because pregnancy stimulates immune anti-A and B, major ABO-incompatible platelet transfusions also show reduced recovery.<sup>53</sup>

### Immunoglobulin

Immunoglobulin preparations are used during pregnancy for immunomodulatory purposes to prevent formation of anti-D, increase the maternal platelet count in ITP, and reduce severe fetal bleeding in fetal and neonatal thrombocytopenia (FNAIT). To prevent Rh HDFN, D-negative women are given RhIG between the 28th and 34th weeks of gestation and also within 72 hours after delivery of a D-positive infant.<sup>54</sup> This reduces Rh HDFN to pregnancies of less than 1% of D-negative women. Nevertheless, Rh HDFN is still the most frequent and severe type of HDFN. The residual immunization results from medical, laboratory, and clerical errors, or an inadequate dose of RhIG after larger fetomaternal hemorrhages during delivery, after trauma, and after obstetric interventions.<sup>55,56</sup>

### General Aspects of Transfusion Products

Blood components can transmit cytomegalovirus (CMV) and parvovirus B19—infections that may harm the fetus. Blood

**Table 26-4.** Risk Factors for Postpartum Hemorrhage

- 
- Overdistended uterus (multiple pregnancy, large fetus, and polyhydramnios)
  - Prolonged labor
  - Induction of augmentation of labor
  - Postpartum hemorrhage in previous pregnancy
  - Chorioamnionitis
  - High parity
  - Coagulation disorders (placental abruption, syndrome of hemolysis, elevated liver enzymes, and low platelet count)
- 

components selected to reduce CMV and parvovirus B19 risk should be administered. Filtration of cellular blood components virtually abolishes CMV transmission. Pooled plasma products (eg, IVIG) must contain less than  $10^4$  copies of parvovirus B19, a load that is neutralized by antibodies present in the product. However, this does not protect against parvovirus B19 in individual cellular products.

### Indications and Practice

Prevention of PPH can be achieved by active management of the third stage of labor.<sup>34</sup> Although active management combines the use of oxytocic drugs, early cord clamping, and active efforts to deliver the placenta, actual practice differs, sometimes including selective radiologic embolization of uterine vessels, and sometimes consisting only of oxytocic drugs.<sup>57</sup>

Postpartum hemorrhage may occur in any woman in labor. Risk factors, however, will help the clinician anticipate the problem (Table 26-4).

The indications for transfusion are guided in the Netherlands by the 4-5-6 Flexinorm.<sup>58</sup> In the United States, guidelines are promulgated by the American Society of Anesthesiologists (ASA). When the hemoglobin levels is  $<4$  mmol/L (hematocrit 20%) in ASA category I patients (healthy persons) with acute blood loss, transfusion is indicated. In ASA category II patients (mild systemic disease without disability) and category III patients (systemic disease and serious disability), the threshold for transfusion lies at a hemoglobin level  $<5$  mmol/L (hematocrit 25%). In ASA category IV patients (constant life-threatening condition) the transfusion threshold is a hemoglobin level  $<6$  mmol/L (hematocrit 30%). In massive hemorrhage, Fresh Frozen Plasma is used to counteract clotting disorders. Preeclampsia, placental abruption, and amniotic fluid embolism are the most important obstetric disorders that may be accompanied by clotting problems. A woman with preeclampsia is already in a hypovolemic condition before hemorrhage starts and this needs special attention. Urinary output is the best indicator of renal perfusion in a bleeding or preclampsic woman and should be at least 30 mL/hour.

### Countries with a Low HDI

In developing countries, blood transfusion services are generally not able to deliver the number of units needed to save the lives of

women with obstetric blood loss. In many places blood donation “on the spot” by relatives after the adverse event has taken place is the only available option. Transmission of hepatitis and human immunodeficiency virus (HIV) is a serious risk. In Tanzania, for instance, a National Blood Transfusion Service was developed in response to the HIV epidemic and a serious train crash in 2002. In 2006, 67,000 units of blood had been donated by volunteer donors. These nonremunerated donors have proven to be safer donors than relatives. However, there are not enough safe donors, and patients remain dependent on relatives as important sources for blood. It is tragic that these relatives have high rates of hepatitis and HIV infections.

Because anemia resulting from malaria, dietary deficiencies (iron and folic acid), sickle cell disease, and infectious disease is rampant in low HDI countries, a relatively small amount of blood loss is often disastrous. Thus, the World Health Organization defines PPH as a blood loss of >500 mL, while in many high HDI countries the threshold is >1000 mL.

Anemia should be treated rigorously during pregnancy in order to reduce the consequences of PPH.<sup>59</sup> The use of bednets, nutritional supplements, and antihelmintics; presumptive treatment of malaria; folic acid and ferrous medication during antenatal care; and active management of the third stage of labor all help women to overcome the problems created by hemorrhage during childbirth. These strategies may reduce the need for blood transfusion. Physicians should remember that unnecessary blood transfusion in a setting of limited resources is not only a waste but also likely to increase exposure to transfusion-related risks and infections.<sup>60</sup>

Transfusion or injection of unsafe blood is responsible for 8 to 16 million hepatitis B virus infections, 2.3 to 4.7 million hepatitis C virus infections, and 80,000 to 160,000 HIV infections annually. At present, 80% of the world’s population has access to only 20% of the world’s safe blood supply.<sup>60</sup> A recent paper from Nigeria reports a blood transfusion rate of 25.2% during cesarean section, a high rate that demonstrates the risk of surgery when resources are not available.<sup>61</sup> A strategy that safely reduces the number of cesarean sections also reduces the need for blood transfusion.

## Fetal Transfusions

This section discusses aspects of fetal transfusion focusing on transfusion for red cell immunization and the management of FNAIT.

### Alloimmune Hemolytic Disease

The first fetal transfusion was performed in 1963 by Liley.<sup>62</sup> After amniography and fetography, red cells were transfused under X-ray guidance in the intraperitoneal cavity of the fetus. This method of treatment of fetal anemia is based on the fact that red cells are absorbed from the peritoneal cavity and enter the circulation. Limitations of this technique include less uptake of the red cells in cases of severe fetal hydrops. Reported survival rates at the time were approximately 50%.<sup>63</sup>

The advent of real-time ultrasound ushered in a new era of fetal management. Since the 1980s fetal transfusions have been performed with the use of ultrasound guidance—specifically, ultrasound-guided puncture of the umbilical vein.<sup>64</sup>

Intravascular transfusions have been performed in thousands of pregnancies worldwide. Although randomized trials comparing intraperitoneal and intravascular transfusions have not been performed, results of the latter technique, which is feasible from 16 weeks of gestation onwards, are widely considered as superior.

Fetal blood sampling (FBS) by cordocentesis or puncture of the intrahepatic umbilical vein is indicated when fetal anemia is suspected (by use of Doppler measurements of the fetal vessels<sup>65</sup>) or in cases of hydrops. Intrauterine transfusion is performed directly after the diagnosis of anemia is established by FBS. The most frequent indication for fetal blood transfusion is anemia caused by red cell alloimmunization of the mother (see Chapter 27). Other indications for fetal blood transfusion include: human parvovirus B19 infection,<sup>66,67</sup> severe fetomaternal hemorrhage,<sup>68</sup> placental chorioangiomas,<sup>69</sup> and homozygous  $\alpha$ -thalassemia.<sup>70</sup> Placental chorioangioma and thalassemia are very rare indications and are not discussed further.

Fetal blood sampling is also applied for the management of other conditions such as thrombocytopenia or severe tachyarrhythmia of the unborn.

### The Technique

The principle of fetal transfusion is to access the fetal circulation with a needle under real-time ultrasound guidance, aspirate blood for diagnosis, and deliver red cells, platelets, or drugs to the fetal circulation. The most frequently used site for transfusion is the umbilical vein when the placenta is inserted anteriorly. When the umbilical vein at the placental insertion cannot be reached safely, the fetus is punctured in the intrahepatic vein. The umbilical vein is preferred for several reasons. First, the vein has a larger diameter than the arteries. Second, because of the eccentric location of the vein in the cord, an overshoot or slip of the needle does not in general lead to a hematoma in the Wharton’s jelly, but to a leakage in the amniotic cavity. A puncture in the artery may lead to leakage in the Wharton’s jelly, inducing spasm of the artery and subsequent fetal bradycardia. Third, fetal transfusion in the vein allows the operating team to monitor the flow of the transfused blood sonographically during the procedure. In some centers intravascular transfusion is combined with an intraperitoneal approach.

The procedure is performed with a 20- or 22-gauge spinal needle. Premedication to the mother is used for relief of maternal anxiety and sedation of the fetus. Routine intravenous or intramuscular administration of muscle relaxants such as atracurium or pancuronium is advocated to achieve fetal paralysis and thus prevent needle displacement caused by fetal movements.<sup>71</sup>

### Donor Blood, Volume, and Rate of Transfusion

The blood selected for fetal transfusion is group O, RhD-negative and compatible with any maternal antibodies that are present.

Because intrauterine transfusions easily stimulate new maternal antibodies against fetal or donor red cell antigens, a freshly derived maternal blood sample should be crossmatched before every subsequent transfusion.<sup>72</sup>

The selected blood component should not carry the risk of transmitting CMV and parvovirus B19 or causing graft-vs-host disease (GVHD). To promote optimal survival, the red cells are stored as briefly as possible. Before transfusion, supernatant solutions containing potassium, ABO antibodies, and red cell preservation solutions are often removed and replaced by saline. A leukocyte-reduced red cell concentrate in 0.9% saline with a hematocrit of 80% irradiated with 25 Gy just before transfusion can correct extremely low hemoglobin values without causing or transmitting disease.

After access to the fetal circulation, 1 to 2 mL blood is aspirated and promptly examined for hemoglobin, hematocrit, and mean corpuscular volume. Some facilities prefer to determine these values immediately, using a cell counter in the operating room. The volume of blood transfused is calculated by using a formula in which pretransfusion fetal hematocrit, the estimated fetal placental blood volume, and the hematocrit of the donor blood are included.<sup>73</sup> The blood is transfused at a rate of 5 to 10 mL per minute.<sup>73</sup> During transfusion, the blood flow and the fetal heart rate are monitored by ultrasound and Doppler. The second transfusion is given 1 to 2 weeks after the first. Following subsequent transfusions, fetal erythropoiesis is depressed and the fetus is completely dependent on transfusions every 3 to 4 weeks. At the end of treatment, more than 70% of women with HDFN requiring intrauterine transfusions have antibodies to multiple red cell antigens.<sup>72</sup> Selection of donors compatible with the mother for clinically relevant antigens could reduce this alloimmunization. In approximately half of the cases, additional antibody formation cannot be circumvented because the antibodies are evoked by fetal red cells.<sup>72</sup>

### Outcome of Treatment

At Leiden University Medical Center, 593 ultrasound-guided intravascular transfusions have been performed in 210 fetuses between 1988 and 1999. The transfusions were given between 17 and 35 weeks of gestation and resulted in an overall survival rate of 86%.<sup>48</sup> In the period from 1999 to 2006 the survival rate improved to 95% (unpublished data). The improvement in the survival rate results from fewer cases presenting with severe irreversible hydrops, after the 1997 implementation of routine screening for red cell antibodies early in pregnancy.<sup>50</sup> There has also been a reduction of procedure-related complications. Follow-up of the infants thus far has revealed no adverse effects of the treatment.

### Fetal and Neonatal Alloimmune Thrombocytopenia

In 0.3% of newborns, thrombocytopenia with an immunologic origin is encountered. Fetal and neonatal alloimmune thrombocytopenia (also known as neonatal alloimmune thrombocytopenia) and autoimmune thrombocytopenia (also known as ITP or Morbus Werlhof disease) are immune-mediated thrombocytopenias. In cases with severe red cell alloimmunization,

thrombocytopenia (platelet count  $<50,000/\mu\text{L}$ ) in the fetus is found before the first intrauterine transfusion in 3% of the cases. In severely hydropic fetuses this percentage is 10% to 30%.<sup>74</sup>

In these cases the mechanism causing thrombocytopenia is not known. Because severe in-utero bleeding is not documented in ITP<sup>19</sup> and the risk of ICH in the neonate is estimated at 0% to 1.5%,<sup>13,17,23</sup> intrauterine platelet transfusions are not indicated; the risk of complications exceed the risk of bleeding.

Approximately 2% of pregnant women of European ancestry are negative for HPA-1a. Anti-HPA-1a is responsible for the majority (75-95%) of cases of FNAIT.<sup>75</sup> About 5% to 25% of FNAIT is caused by other HPA antibodies, most frequently anti-HPA-5b, anti-HPA-3a, and anti-HPA-1b. In 15% to 20% of FNAIT cases no antibodies can be detected. Antibodies against private antigens and new antigens causing FNAIT are still being discovered.<sup>76</sup> In platelet-alloimmunized pregnant women carrying a fetus that is positive for the offending antigen, the risk for thrombocytopenia can be as high as 85%. The incidence of ICH varies from 7% (in alloimmunized pregnancies and a sibling without ICH) to 85% (in alloimmunized pregnancies and a sibling with ICH).<sup>77</sup> It is assumed that most ICH occurs antenatally between 30 to 35 weeks of gestation.

For antenatal management, it is important to know whether the father is homozygous or heterozygous for the offending antigen. In case of heterozygosity of the father, genotyping of the fetus is indicated. Although genotyping is possible by using polymerase chain reaction on either chorionic villi or amniocytes, amniocentesis in the second trimester is preferable because of its lower risk of boosting antibodies. Currently, methods are being developed to assess the fetal HPA type from fetal DNA in maternal plasma. When the fetus is positive for the offending antigen, the pregnancy should be managed in, or in collaboration with, a specialized fetal care center.

Because HPA screening is not routine, FNAIT is recognized most often only after an affected sibling is identified. The antenatal management protocols in FNAIT are intended to prevent ICH. Unfortunately, monitoring HPA antibodies by titration and quantification has not accurately predicted the severity of fetal thrombocytopenia. However, recent studies indicate that it is helpful in predicting the severity of fetal thrombocytopenia.<sup>78-80</sup> In order to diagnose fetal thrombocytopenia as early as possible, various centers have designed protocols for routine FBS beginning as early as 20 weeks.<sup>81,82</sup> In cases of fetal thrombocytopenia and platelet transfusion, the procedure must be repeated frequently, given the fact that the half-life of transfused platelets is only 5 days. Although FBS is a reliable tool for direct monitoring of the fetal thrombocytopenia, the cumulative procedure-related risk for fetal loss is high and approximates 6% per pregnancy.<sup>83,84</sup> The cumulative risk for emergency delivery due to FBS is 13% to 17%.<sup>85,86</sup> Currently, most centers have adopted the use of weekly high-dose maternal IVIG. A few centers use corticosteroids as first-line treatment. Although corticosteroids do not enhance the effect of IVIG,<sup>85,86</sup> combinations of these options are also in use. Bussel et al<sup>87</sup> were the first who reported in 1988 that

weekly maternal IVIG (1.0 g/kg maternal weight) was effective at elevating the fetal platelet count. Later studies showed that not all fetuses showed a substantial increase in platelet count with this treatment. The reported response rate in the literature varies between 30% and 85%. In addition, observational studies have suggested that IVIG reduces the risk of ICH even in nonresponders to IVIG,<sup>86,88,89</sup> possibly by downregulation of endothelial activation by platelet antibodies that cross-react with endothelial epithelial cells.<sup>90</sup>

In the past decade there has been a gradual change in antenatal treatment of platelet alloimmunized pregnancies, from an invasive approach with repetitive FBS to a less invasive approach (treatment with IVIG and less FBS or platelet transfusion) to a completely noninvasive approach (IVIG only). At Leiden University Medical Center, treatment of 52 pregnancies (53 neonates) at risk for fetal ICH (5 with and 48 without a sibling with ICH) resulted in term live births without ICH in all neonates.<sup>89</sup> Long-term follow-up of the infants, treated antenatally with IVIG, showed no adverse effects.<sup>91</sup>

The mechanism of action of IVIG in FNAIT is still unclear. There are several possible explanations. First, in the maternal circulation the IVIG will dilute the HPA antibodies, resulting in a lower proportion of HPA antibodies among the IgG transferred via the Fc $\gamma$  receptors (Fc $\gamma$ Rs) in the placenta. Second, in the placenta, IVIG may block the placenta receptor and decrease the placental transmission of maternal antibodies including anti-HPA. Third, in the fetus, IVIG may block the Fc $\gamma$ Rs on the macrophages and prohibit the destruction of antibody-covered platelets. Recently, Ni et al<sup>92</sup> presented a murine model of FNAIT, measuring response to IVIG therapy. This model demonstrates that maternal IVIG administration has multiple effects on the amelioration of FNAIT, including decreased maternal platelet antibody, decreased fetal platelet clearance, reduced bleeding disorders, and increased fetal survival.<sup>92</sup>

In a cost-effectiveness analysis, Thung et al<sup>94</sup> compared the use of noninvasive empiric IVIG with FBS treatment. They concluded that noninvasive IVIG is a cost-effective strategy.<sup>93</sup>

In the antenatal management of FNAIT, it is important to realize that the majority of at-risk patients are those who have a sibling with a history of severe thrombocytopenia but without internal bleeding. The risk of ICH in this category of patients is low and approximates the risk of fetal loss with invasive management; therefore, a noninvasive approach is preferred. Considering the high cost of IVIG, and that most of the ICH in these patients occurs later in pregnancy, treatment of FNAIT pregnancies without a history of ICH may be started between 28 and 32 weeks. In pregnancies with a previous sibling with an ICH, IVIG should be started at 12 to 18 weeks. To evaluate the response, FBS can be performed at 24 to 28 weeks. When the anticipated risk of the procedure is high (eg, less experienced center or a posteriorly located cord insertion), IVIG should be continued until delivery without FBS. A recent study examined this less invasive approach in seven pregnancies with a prior sibling with ICH.<sup>88</sup> IVIG (1 g/kg/week) was administered from a median of 16 weeks (range, 16–29 weeks)

without initial or follow-up FBS. Although all neonates had a birth platelet count of less than 50,000/ $\mu$ L, none of them showed signs of internal or external bleeding. The neonates needed only one platelet transfusion and did well. The results demonstrate that the primary goal in the management of pregnancies at risk for FNAIT is the prevention of severe bleeding complications and not thrombocytopenia per se. The very rare case of a patient with a history of ICH very early in pregnancy might benefit from a more aggressive approach (eg, high-dose IVIG, followed by repeated FBS and, when necessary, rescue high-dose corticosteroids).

In FNAIT patients, safety precautions may lower the risk of hemorrhage during FBS. The Leiden University Medical Center protocol for FBS includes the following:

1. FBS in FNAIT pregnancies is performed by the most experienced members of the fetal medicine unit.
2. The use of a cell counter in the operating room enables platelet count and histogram to be obtained within 2 minutes.
3. Before each FBS, compatible platelets are made available, and infused during the procedure, if necessary, to achieve a platelet count of  $>300,000/\mu$ L.

Platelet transfusions for fetal indications are generally blood group O RhD-negative (HPA compatible in case of FNAIT) units that have a reduced risk of CMV and parvovirus B19 transmission. The intent is to increase the platelet count to normal levels, preferentially higher than 300,000/ $\mu$ L to achieve a fetal platelet count  $>20,000/\mu$ L for 7 to 10 days. The recovery in the fetal circulation is approximately 25%, because 50% of the platelets remain in the placental bed and 50% of the platelets in the child are pooled in the spleen. This implies that approximately 100,000 to 200,000/ $\mu$ L platelets (depending on gestational age-related fetoplacental volume) are concentrated in 20 to 50 mL for intrauterine transfusion after irradiation with 25 Gy to prevent GVHD.

### Fetal Transfusions for Other Indications

Parvovirus B19 infection during pregnancy may lead to an arrest in maturation of hematopoietic stem cells and thus anemia and thrombocytopenia. Parvovirus B19 is a frequent cause of nonimmune hydrops fetalis and 46% of hydropic fetuses have thrombocytopenia below 50,000/ $\mu$ L. The platelet count will further decrease after transfusion of red cells alone.<sup>94</sup> After serologic and DNA diagnosis of infection in the mother and elevated middle cerebral artery peak velocity at Doppler investigation, intrauterine transfusion is indicated. Usually one intrauterine blood transfusion is sufficient.<sup>67</sup> Because a low platelet count ( $<50,000/\mu$ L) may lead to bleeding complications from the FBS, platelets should be available for transfusion.

Massive fetomaternal (transplacental) hemorrhage is a rare, unexpected, and serious complication in pregnancy resulting in severe fetal anemia, hydrops, and death. Reduced fetal movement is the only cognizant sign for the pregnant woman. The diagnosis can be confirmed when a sinusoidal pattern is observed at cardiotocogram registration and/or when an increased flow in the middle cerebral artery is measured.<sup>95</sup> Fetal red cells in the

maternal circulation can be confirmed with the Kleihauer-Betke test.<sup>93</sup> In the preterm period, fetal red cell transfusion is a realistic option.

After the introduction of laser coagulation of placental anastomosis as treatment for severe twin-to-twin transfusion syndrome (TTTS), TAPS (twin anemia-polycythemia sequence) has been described as a new syndrome.<sup>96</sup> After laser coagulation, very small residual anastomosis may lead to chronic anemia and polycythemia in one of the twins.<sup>97</sup> Robyr et al<sup>98</sup> described 13 cases of TAPS (13% of their group of TTTS cases). In 12 of the 13 cases, between one and five fetal red cell transfusions were performed. Because expectant management can lead to a favorable outcome, further research in this field is needed.

## Conclusion

Postpartum hemorrhage is a serious risk factor in obstetrics. Protocols for both prevention and management should be available in all labor and delivery wards. In high HDI countries, most maternal mortality can be prevented using oxytocics, embolization of uterine vessels, and blood transfusion. Unfortunately, both control of bleeding and early transfusion are difficult to achieve in most low HDI countries. In these countries, blood transfusion services are generally unable to help women who need red cells. Blood donation “on the spot” is often the only available option, and bears a serious risk for transmission of infections such as hepatitis and HIV. The option of fetal transfusion, a widely used treatment of the unborn in developed countries, is not available in many other countries.

**Bjarte G. Solheim<sup>1</sup> & Morten Grønn<sup>2</sup>**<sup>1</sup> Professor Emeritus, Institute of Immunology, Rikshospitalet University Hospital and University of Oslo, Oslo, Norway<sup>2</sup> Head Physician, Division of Paediatrics, Rikshospitalet University Hospital, Oslo, Norway

Hemolytic disease of the fetus and newborn (HDFN) is caused by increased destruction of red cells in the fetus and newborn. The disease is associated with immune-mediated destruction (allo- or autoantibodies), intrinsic red cell abnormalities (hemoglobinopathies, enzyme defects, and membrane defects), and acquired red cell defects (related to infections, see Chapter 26). This chapter focuses on fetomaternal alloimmune-mediated HDFN, and only briefly mentions important intrinsic abnormalities.

**The Changing Spectrum of HDFN****Status in Developed Countries**

During the past 30 to 40 years, the spectrum of HDFN has changed profoundly. In the late 1960s and early 1970s, HDFN was a common neonatal problem dominated by Rh(D) alloimmunization. Overt fetal or neonatal hemolysis, with marked anemia and hyperbilirubinemia in the neonate, were commonly observed symptoms. The neonates were often severely affected and unstable at birth, and required multiple exchange transfusions. HDFN was associated with considerable neonatal morbidity and mortality.

Introduction in the 1970s of routine postpartum prophylactic Rh Immune Globulin (RhIG or anti-D) to D-negative women (with D-positive infants) and after pregnancy termination or abortion, has changed the picture dramatically and reduced D alloimmunization by about 90%.<sup>1</sup> After introduction of additional antepartum prophylactic RhIG, the frequency of D alloimmunization is now well below 0.2%.<sup>1</sup> The introduction of prophylactic RhIG ranks as one of the great success stories of modern perinatal care and immunology.

Programs for antibody screening and ABO/Rh typing of pregnant women allows focus on fetuses and neonates at risk, and has paved the way for the vastly improved antepartum surveillance and therapy outlined in Chapter 26.

Finally, postpartum therapy has improved considerably.<sup>2</sup> Forty years ago, exchange transfusion and early versions of phototherapy were the only therapeutic alternatives for serious HDFN. Today modern phototherapy, if necessary combined with high-dose intravenous immunoglobulin (IVIG), has reduced the need for exchange transfusion to single figures even in large centers. This raises serious challenges in order to keep the necessary competence in the practical execution of exchange transfusion.<sup>2</sup> Alloantibody frequencies in populations of mostly European ancestry before and after introduction of postpartum prophylactic RhIG treatment are indicated in Table 27-1.

**Status in Developing Countries**

Programs for antibody screening and ABO/Rh typing of pregnant women and introduction of postpartum routine prophylactic RhIG treatment have posed both organizational and economic challenges in countries with a low human development index (HDI). Improved neonatal surveillance and therapy has been

**Table 27-1.** Red Cell Antibodies in 1967 and 1995<sup>3,4</sup>

| Antibody       | 1967 (Minnesota, 7 years) | 1995 (Sweden, 12 years) |
|----------------|---------------------------|-------------------------|

| I              | 13 (0.4%)                 | —                       |
| Others         | 194 (6.6%)                | 120 (14.4%)             |
| Total          | 2,956                     | 836                     |
| Blood samples  | 43,000                    | 110,765                 |

introduced only to a limited degree, and antepartum treatment is often nonexistent. HDFN is, therefore, still a major cause of morbidity and mortality in these countries.

### Serologic and Clinical Features

Development of immune HDFN requires maternal IgG antibodies directed against paternal antigens on fetal red cells. Immunization can occur when fetal red cells pass through the placenta to the mother's circulation or the antigens were present in previous transfusions of the mother. Only maternal IgG antibodies can cross the placenta. The transport is an active process dependent upon interaction between maternal IgG and syncytiotrophoblast Fc receptors, and is most active in the third trimester.<sup>5</sup> IgG antibodies can be elicited by most blood group antigens (Tables 27-1 and 27-2, and Chapter 5). The immune response to peptide antigens (eg, D) typically requires T-cell help, and is dominated by IgG antibodies. Because the D antigen is extraordinarily immunogenic and induces high affinity anti-D IgG, it has been a major cause for HDFN in White and Black populations where 10% to 15% of people lack the D antigen. This is not the case in East Asia (particularly China), where the population is D-positive (see Chapter 7). In addition, IgG autoantibodies causing maternal hemolytic anemia can result in HDFN. The common occurrence of antibodies reacting with carbohydrate antigens of the ABO, Hh, Ii, Lewis, and P systems without prior exposure to allogeneic red cells is a result of the wide distribution of these antigens in nature. IgM

is generally the dominating antibody, but IgG anti-A, anti-B, and more rarely anti-H are also present. Because the I antigen and antigens of the Lewis and P systems are almost lacking on fetal cells, they are not associated with HDFN.<sup>7</sup> Table 27-2 summarizes antibody frequencies and severity of HDFN caused by relevant blood group antigens in populations of European and African ancestry.

The direct antiglobulin test (DAT) (see Chapter 5) is one of the cornerstones for the diagnosis of HDFN. It detects IgG antibodies on the surface of red cells, and the number of IgG molecules bound to the erythrocyte surface determines the strength of the reaction. Using the spin antiglobulin test, the detection limit is 100 to 150 IgG molecules per red cell; when over 1000 are bound, the DAT is strongly positive (all cells are agglutinated).<sup>8</sup> Transplacental passage of maternal IgG results in antibody coating of the fetal red cells. High alloantibody concentrations lead to a strong DAT, whereas low concentrations or binding affinity result in a weak or, by traditional methods, often negative DAT. A strong positive DAT is observed particularly with anti-D; however, the reaction is more variable with alloantibodies against other Rh antigens and antigens such as Kell, Duffy, Kidd, and MNSs, which are well expressed on fetal red cells.<sup>5</sup> Because ABO antigens are not fully developed on fetal red cells and A and B substances are expressed by most tissues, the DAT in ABO incompatibility is often negative. However, with very sensitive techniques (eg, automated analyzer with low-ionic-strength medium with enhancing agents) IgG can almost always be demonstrated on the red cells in ABO incompatibility.<sup>9</sup> As a basic test, the DAT has poor predictive value in identifying neonates requiring treatment. Only 23% of newborns found to be DAT positive on neonatal screening have been reported to develop hyperbilirubinemia requiring treatment, but when the DAT was strongly positive (generally because of anti-D) all required treatment.<sup>10</sup> It should also be borne in mind that after antepartum treatment of D-negative women with prophylactic RhIG, neonates may demonstrate a positive DAT without signs of hemolysis.<sup>11</sup>

In an affected fetus, HDFN is caused by the hypoxic effects of anemia, while in the newborn, HDFN is caused by toxic effects of bilirubin and anemia. Bilirubin crosses the placenta during pregnancy and is removed by the mother's liver. However, because of insufficient capacity or failure of the neonate's liver, plasma levels of unconjugated bilirubin can quickly become high enough to cause serious central nervous system damage in the newborn. The anemia causes increased fetal erythropoiesis, which in severe cases leads to erythroblastosis with widespread extramedullary hematopoiesis and many nucleated red cells (erythroblasts) in the circulation. The most severe state of erythroblastosis, hydrops fetalis, can lead to stillbirth and is characterized by severe anemia, massive edema, and hypoproteinemia.

In severe erythroblastosis, blood film examination will show massive presence of nucleated red cells, but only a few spherocytes due to the rapid destruction of the red cells (eg, serious Rh HDFN). In less severe HDFN, spherocytes will dominate the blood film, and only a few nucleated red cells are observed (eg, ABO HDFN). This emphasizes the importance of blood film examination in neonates with nonphysiologic jaundice.<sup>2</sup>

**Table 27-2.** Blood Group Antigens and Hemolytic Disease in the Neonate<sup>6</sup> in Populations of European and African Ancestry

| Antigen                           | Antibody Frequency (per 1000 pregnant women) | Severity of HDFN in Infants with the Antigen |          |        |

Persistent or prolonged jaundice in neonates is a common feature of HDFN, and can be observed in virtually all conditions mentioned in this chapter. Achieving the correct diagnosis is important for the neonate and can have implications also for other family members.

## Hemolytic Disease Predicted by Antepartum Maternal Antibody Screening

Although the majority of cases of acute neonatal hyperbilirubinemia/hemolysis currently occur without antepartum warning in high HDI countries, there remain a number of neonates for whom HDFN is predicted by antepartum screening. Almost all blood group antibodies of IgG type can cause HDFN. However, the severity and frequency of HDFN varies, and anti-D still remains the most common cause of severe HDFN.<sup>2</sup> The most frequent alloantibodies are directed against: Rh antigens (anti-D, anti-E, anti-c, anti-C), Kell antigens (anti-K1), Duffy antigens (anti-Fy<sup>a</sup>), Kidd antigens (anti-Jk<sup>a</sup>), and MNSs antigens (Table 27-2). Anti-D, anti-c, anti-E, and anti-K are found in about 1 per 1000 pregnant women. Anti-K is mostly caused by transfusion, and the frequency of HDFN due to anti-K is much lower than that due to anti-D.<sup>5</sup> However, anti-Kell can cause severe fetal anemia because the antibody also inhibits fetal erythropoiesis.<sup>12</sup> The frequency and severity of HDFN caused by the other antibodies mentioned above is low (Table 27-2). Positive antepartum maternal antibody screening results in frequent antepartum monitoring and makes treatment with intrauterine transfusions possible (see Chapter 26).

Antepartum diagnosis and postpartum management of neonates affected by HDFN require close collaboration among obstetric, neonatal, and transfusion medical teams. Delivery is generally induced around 36 weeks of gestation. All neonates at risk should have cord blood taken for measurement of hemoglobin, DAT, and bilirubin (see Chapter 26). Because of the use of intrauterine transfusions, many neonates have normal hemoglobin at birth and develop only modest hyperbilirubinemia. In these neonates, the DAT demonstrates few antibody-covered red cells, and typing barely reveals the neonate's original blood type. However, all potentially affected neonates should remain in the hospital until hyperbilirubinemia and/or anemia is under control and appropriate follow-up is organized. Phototherapy, high-dose IVIG, and exchange transfusions are often not required. Red cell transfusions can be indicated when anemia develops during the first couple of weeks after birth. Severe anemia (hemoglobin <10 g/dL) at birth or rapidly increasing hyperbilirubinemia should be treated as detailed later in this chapter.

## Early-Onset/Rapidly Progressive Hemolytic Disease not Predicted by Maternal Antibody Screening

Today neonatal pediatricians in developed countries are often alerted to HDFN in a relatively full-term infant whose mother's

antepartum screening was negative. Within the first 48 hours of life such a newborn develops early-onset jaundice with a total bilirubin already in excess of 20 mg/dL (342  $\mu$ mol/L).<sup>2</sup> Because the problem in such cases has not been predicted by antepartum screening for maternal antibodies, therapy would not have been started. The most common causes of HDFN presenting in this way are as follows:

- ABO incompatibility.
- Hemoglobinopathies.
- Erythrocyte enzyme defects.
- Disorders of the red cell membrane.

The reader is referred to Chapter 29 for detailed information on hemoglobinopathies, erythrocyte enzyme defects, and disorders of the red cell membrane.

### ABO Incompatibility

ABO incompatibility is now the leading cause of HDFN in high HDI countries.<sup>10</sup> HDFN resulting from ABO incompatibility generally occurs only in offspring of women of blood group O because IgG anti-A and anti-B is far more common in group O than in group A or B mothers, and is confined to the 1% with antepartum high-titer IgG antibodies.<sup>13</sup> Unlike in non-ABO HDFN, the first ABO-incompatible infant is at risk for significant hemolysis, because ABO antibodies are developed before pregnancy. Minor degrees of red cell destruction are common, as shown by the increased incidence of neonatal jaundice and slightly lower hemoglobin values in ABO-incompatible infants compared to ABO-compatible infants.<sup>5</sup> With respect to ethnic groups, the prevalence of maternal-newborn ABO incompatibility ranges from 31% in those of European ancestry to 50% in Asians. Generally, ABO HDFN causes mild postpartum jaundice, which is detected 24 hours after delivery; in very rare cases, however, hemolysis is severe enough to cause hydrops.<sup>14</sup> The frequency of HDFN caused by anti-A is only about 1 in 150 births, and even lower for anti-B.<sup>2</sup> Higher frequencies that have been reported from Africa and Saudi Arabia are probably related to more potent anti-A and anti-B (caused by environmental factors) and a relatively strong expression of A and B antigens.<sup>5</sup>

Antepartum and postpartum serologic tests are poor predictors of ABO hemolytic disease. The results of the DAT in HDFN caused by ABO incompatibility are very different from those observed with HDFN caused by anti-D (not treated antepartum). In the latter, a positive DAT can be observed even in cases showing minor clinical symptoms. However, in ABO incompatibility only 20% to 40% of incompatible pairs demonstrate a positive reaction and significant hemolysis can be observed with a negative or only weakly a positive DAT. In infants with a positive DAT result, the test differentiates poorly between newborns with clinical hemolysis and unaffected newborns. Only about 10% of the DAT-positive, ABO-incompatible maternal-fetal pairs develop clinically significant HDFN. However, in infants with clinically significant hemolysis, >80% have a positive DAT.<sup>10,15</sup> Also, the clinical symptoms differ in that anti-A and anti-B HDFN result mainly in hyperbilirubinemia detected 24 hours after delivery

without the significant fetal or neonatal anemia observed in anti-D HDFN. This is explained by the few and unbranched A and B antigen sites on fetal red cells, allowing antibody-coated cells to remain in the circulation longer than in anti-D HDFN. Another important factor is that ABO antigens are expressed on virtually all cells in the body, whereas D antigen is restricted to red cells. Thus, anti-D is “focused” to red cells, while anti-A and anti-B are absorbed by tissues and neutralized by soluble A and B substances in plasma. As a reflection of this, the blood film in anti-A or anti-B HDFN shows a large number of spherocytes, with little or no increase in nucleated red cells. In anti-D HDFN there are few spherocytes but large numbers of nucleated red cells. In ethnic groups expressing strong (many and branched) A and B antigen sites, severe anemia, nucleated red cells, and significant antepartum morbidity (even with hydrops fetalis) can be observed.<sup>2</sup>

Management of ABO HDFN is usually successful with modern phototherapy alone. Close monitoring of affected neonates is important, as high-dose IVIG adjuvant therapy and occasionally even exchange transfusion can be required. The latter is particularly relevant in individuals from certain ethnic groups who express strong A and B sites.<sup>2</sup>

### Hemoglobinopathies

Except for  $\alpha$ -thalassemia major, hemoglobinopathies generally do not cause antepartum or neonatal problems. Some occasional structural mutations in  $\alpha$  and  $\gamma$  genes that give no symptoms in adults, however, can result in transient hemolytic anemia in neonates. Mutations in the  $\beta$  genes (eg, sickle cell disease or  $\beta$ -thalassemia) give no symptoms at birth because of the predominance of fetal hemoglobin.

$\alpha$ -thalassemia major occurs when all four  $\alpha$ -globin genes on the homologous chromosome 16 are deleted ( $\alpha^0$ ), and is predominantly seen in some Mediterranean island populations and in Southeast Asia. The lack of  $\alpha$ -globin production leads to the dominating production of fetal  $\gamma_4$  hemoglobin (hemoglobin Bart's), which has a very high oxygen affinity and is physiologically useless. Infants are usually stillborn between 28 and 40 weeks, demonstrating the typical picture of hydrops fetalis with pallor, generalized edema, and massive hepatosplenomegaly. The few that are live-born expire within the first hours after birth. Postpartum management has no impact on survival unless combined with carefully planned antepartum therapy, and has to be followed up with lifelong red cell transfusions or hematopoietic stem cell transplantation. Checking blood samples from the parents will show whether they are carriers of the  $\alpha^0$  gene (hypochromic, microcytic red cells). The diagnosis is confirmed by hemoglobin electrophoresis.

$\alpha$ - and  $\gamma$ -globin chain structural abnormalities are generally clinical silent, but can result in occasional neonatal hemolytic anemia due to formation of unstable  $\alpha\gamma$ -hemoglobin. When the fetal  $\gamma$ -globin is replaced by adult  $\beta$ -globin, the hemolytic anemia resolves. Diagnosis is confirmed by hemoglobin high-performance liquid chromatography. For further details and information see Chapter 29.

### Red Cell Enzyme Defects

The important enzyme defects in the neonatal period are glucose-6-phosphate dehydrogenase (G6PD) deficiency and pyruvate kinase deficiency. They usually present with early onset, often severe, hyperbilirubinemia. Blood smear is normal, and anemia rare. Family medical history and measurement of the relevant pretransfusion enzyme activities are of diagnostic importance.

G6PD deficiency is transmitted in an X-linked recessive form, and seen in all ethnic groups; however, its highest prevalence is in central Africa (20%) and the Mediterranean region (10%). It is not clear why only some neonates develop jaundice. However, because these patients can develop severe hyperbilirubinemia, close monitoring is important. Interaction with other risk factors for hyperbilirubinemia in the newborn, as well as some medicines, chemicals, and foods, can severely aggravate the clinical picture.

Pyruvate kinase deficiency is autosomal recessive, and the second most common red cell enzyme defect in neonates. The severity varies from hydrops fetalis to severe early-onset neonatal hyperbilirubinemia, and mild hyperbilirubinemia mimicking physiologic jaundice. For further details and information see Chapter 29.

### Red Cell Membrane Defects

The main clues that a neonate has a red cell membrane disorder are a family history, DAT-negative hemolysis (with a sensitive method), and an abnormal blood film. Red cell membrane electrophoresis from pretransfusion samples is diagnostic.

Hereditary spherocytosis is the most common red cell membrane defect. It occurs in 1 in 5000 live births in couples of North European ethnicity, but is less frequent in other population groups. It is inherited as an autosomal dominant trait.<sup>2</sup> Blood films have a similar appearance to those in ABO HDFN; the DAT is negative. Some neonates require 1 or 2 red cell transfusions during the first months of life.

Hereditary elliptocytosis is a more complex autosomal dominant disorder. In heterozygotes the only findings are elliptocytes in the blood smear. Neonates who have more than one mutation in a red cell membrane protein (homozygotes or compound heterozygotes) have severe, transfusion-dependent, hemolytic anemia. The blood film is characteristic, showing a high proportion of bizarre fragmented red cells and microcytes (mean corpuscular volume <60 fL). Red cell transfusion is often necessary until splenectomy can be carried out. For further details and information see Chapter 29.

---

## Management of Immune-Mediated Hemolytic Disease of the Fetus and Newborn

### Surveillance and Tests

Antepartum surveillance and treatment are detailed in Chapter 26. After adequate intrauterine transfusion treatment, fetal erythropoiesis is suppressed, and the red cell mass maintained by compatible transfused cells. As a result, most of these neonates present neither neonatal jaundice nor anemia of clinical importance.

after birth, and very few require postpartum exchange transfusion. In contrast, late anemia is common in the newborn because of suppression of erythropoiesis caused by intrauterine transfusions and continued presence of hemolyzing maternal antibodies. Therefore, the neonates need follow-up with monitoring of hemoglobin, blood film, reticulocyte count, and bilirubin in order to determine when hemolysis has stopped and endogenous red cell production takes over.<sup>2</sup> In any consideration of red cell transfusions, the neonate's general condition, growth, and development are of major importance for defining the appropriate hemoglobin level for intervention (see Chapter 30). The Apgar score can be useful because it reflects important signs and symptoms associated with postpartum anemia (eg, color, tachypnea, tachycardia, lethargy).

In developing countries, antepartum treatment is mostly unavailable, and even antibody screening and ABO/Rh typing are often not performed in the pregnant mother. In such areas, the clinical picture can be more like that seen in developed countries in the 1960s, with serious anti-D HDFN (erythroblastosis, hyperbilirubinemia with grave anemia on the first postpartum day, and, in serious cases, hydrops fetalis or even stillbirth).

## Phototherapy

Improved delivery and understanding of phototherapy since its introduction in the late 1950s has had major effect on the clinical

treatment of HDFN. The efficacy of phototherapy is dependent upon the following factors<sup>16</sup>:

- Spectral qualities of the delivered light (wavelength range 400-520 nm, with peak emissions of 460 nm).
- Intensity of light (irradiance).
- Surface area receiving phototherapy.
- Skin pigmentation.
- Total serum bilirubin concentration at the start of phototherapy.
- Duration of exposure.

Modern phototherapy devices with high-intensity gallium nitride light-emitting diodes (LEDs) are small, efficient, easy to use, and ensure the correct distance between the neonate and the device.<sup>16</sup> The total radiation applied to a neonate has vastly increased and made "intensive phototherapy" an important alternative to exchange transfusion, even in the treatment of severe HDFN. "Intensive phototherapy" implies radiation in the blue-green spectrum (wavelengths  $\sim$  430-490 nm) of at least  $30 \mu\text{W}/\text{cm}^2/\text{nm}$  (measured at the infant's skin) and delivered to as much as possible of the infant's body surface area.<sup>17</sup> Figure 27-1 shows guidelines for "intense phototherapy" in neonates of 35 weeks or more with hyperbilirubinemia. The levels shown are approximations adapted to the infant's age and risk factors. Infants are designated as "higher risk" because of the potential negative effects of the conditions listed in the figure on albumin binding of bilirubin, the blood-brain barrier, and the susceptibility of brain cells to damage by bilirubin.<sup>17</sup> Low body

- **Use total bilirubin.** Do not subtract direct reacting or conjugated bilirubin.
- **Risk factors** are isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin  $<3.0 \text{ g/dL}$  (if measured).
- For well infants 35-37 weeks and 6/7 days, TSB levels can be adjusted for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 weeks and at higher TSB levels for those closer to 37 weeks and 6/7 days.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2 to  $3 \text{ mg/dL}$  ( $35\text{-}50 \mu\text{mol/L}$ ) below those shown, but home therapy should not be used in any infant with risk factors.

**Figure 27-1.** Guidelines for phototherapy in hospitalized infants of 35 weeks or more of gestation with hyperbilirubinemia, including that caused by HDFN. The guidelines refer to the use of "intensive phototherapy," which should be used if total serum bilirubin (TSB) exceeds the line indicated for each category. Used with permission from American Academy of Pediatrics.<sup>17</sup>

weight, particularly <1000 g, is an additional risk factor to be considered.

Today the “typical” neonate with HDFN presents in countries of high HDI as a well, term neonate with ABO incompatibility and a total serum bilirubin often in excess of 20 mg/dL but without significant anemia. “Intensive phototherapy” during the 4 to 6 hours it generally takes to organize an exchange transfusion most often results in a significant decrease in total serum bilirubin, thus frequently removing the indication for exchange transfusion.<sup>2</sup> When high-dose IVIG is given as adjuvant to phototherapy the indication for exchange transfusion is even further reduced.

## High-Dose IVIG

Since the beginning of the 1990s, several pilot studies have reported the effect of high-dose IVIG as adjuvant to standard therapy for HDFN. Two systematic reviews have performed a meta-analysis of the impact of high-dose IVIG on the use of exchange transfusion, comparing IVIG plus phototherapy with phototherapy alone.<sup>18,19</sup> The conclusion of both reviews was that IVIG significantly reduced the risk of exchange transfusion. However, the authors of the two systematic reviews differ with respect to their recommendation as to the use of high-dose IVIG. The Cochrane review<sup>18</sup> concludes that the number and quality of studies, and the number of infants included is too small to recommend the use of adjuvant IVIG in HDFN, and suggests further well-designed studies. However, the other review<sup>19</sup> supports the use of high-dose IVIG, and also shows that when IVIG is used in addition to phototherapy in HDFN, both duration of phototherapy and hospital stay are reduced to a point that equals the cost of the IVIG in the United Kingdom.

With the decline in the number of exchange transfusions, the opportunity for further large, well designed studies is limited. Although exchange transfusions are associated with a mortality of 2% and serious complications in 12% of the patients (Table 27-3), no serious side effects have been reported in neonates treated with phototherapy and high-dose IVIG. It must, however, be remembered that IVIG is a pooled plasma product, which before the introduction of adequate pathogen inactivation, was involved in several cases of viral transmission. Since 1994 there has been no transmission of blood-borne infections with pathogen-inactivated IVIG prepared from selected donors<sup>20</sup> (see also Chapter 19). Thus, further randomized studies as suggested by the authors of the Cochrane meta-analysis<sup>18</sup> may even be considered unethical.

Recently the IVIG Hematology and Neurology Expert Panels have recommended that high-dose IVIG be offered to neonates with HDFN as treatment for severe hyperbilirubinemia<sup>20</sup> and endorsed the recommendations outlined in the American Academy for Pediatrics guideline on the treatment of hyperbilirubinemia.<sup>17</sup> That guideline states:

“In isoimmune hemolytic disease, administration of IVIG (0.5–1.0 g/kg over 2 hours) is recommended if the total serum

bilirubin (TSB) is rising despite intensive phototherapy or the TSB level is within 2 to 3 mg/dL (34–51 μmol/L) of exchange level.

If necessary, this dose can be repeated in 12 hours.”

The exact action of IVIG in HDFN is still unclear, but following mechanisms are probably involved (see also Chapter 18):

- Prevention of phagocytosis of IgG-coated red cells by blocking of Fc receptors on cells in the reticuloendothelial system.
- Neutralization of maternal antibodies by anti-idiotypic antibodies in IVIG.
- Cytokine modifying actions of IVIG.

## Exchange Transfusions

Criteria used to assess the need for exchange transfusion include total bilirubin level, hemoglobin level, and clinical symptoms. Traditional guidelines suggest exchange transfusion in the following circumstances:

Within 12 hours of birth if

- Cord blood bilirubin concentration exceeds 3 to 5 mg/dL for preterm infants, 5 to 7 mg/dL for term infants, or the rate of increase is >0.5 mg/dL/hour.
- Severe anemia: hemoglobin <10 g/dl combined with hyperbilirubinemia.

After 24 hours of birth if

- Total bilirubin concentration >20 mg/dL or a bilirubin increase of >0.5 mg/dL/hour or hemoglobin <10 g/dL combined with hyperbilirubinemia.

Today, the effect of “intensive phototherapy” and reduction of hemolysis by high-dose IVIG treatment almost always results in a considerable decrease in bilirubin levels during the 4 to 6 hours

**Table 27-3.** Complications of Exchange Transfusion

### Vascular

- Embolization of air or thrombi
- Thrombosis

### Cardiac

- Arrhythmias
- Volume overload
- Cardiac arrest

### Electrolytes

- Hyperkalemia
- Hyponatremia
- Hypocalcemia
- Acidosis

### Coagulation

- Overheparinization
- Thrombocytopenia

### Infectious

- Bacteremia
- Hepatitis
- Cytomegalovirus

- **The dashed lines for the first 24 hours** indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy and high-dose IVIG.
- **Immediate exchange transfusion** is recommended if infant shows signs of **acute bilirubin encephalopathy** (hypertonia, arching, retrocollis, opisthotonos, fever, high pitched cry) or if TSB is  $\geq 5$  mg/dL ( $85 \mu\text{mol/L}$ ) above these lines.
- **Risk factors** are isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin  $< 3.0$  mg/dL (if measured).
- **Use total bilirubin.** Do not subtract direct reacting or conjugated bilirubin.
- If infant is well at 35-37 weeks and 6/7 days (median risk), TSB levels can be individualized for exchange based on actual gestation age.

**Figure 27-2.** Guidelines for exchange transfusion in infants 35 weeks or more of gestation with hyperbilirubinemia, including that caused by HDFN. The guidelines refer to the use of exchange transfusions, which should be used if total serum bilirubin (TSB) exceeds the line indicated for each category. During birth hospitalization, exchange transfusion is recommended if TSB rises to these levels

despite "intensive phototherapy." For readmitted infants, if TSB level is above the exchange level, repeat TSB measurements every 2 to 3 hours and consider exchange transfusion if the TSB remains above the levels indicated after "intensive phototherapy" for 6 hours. Used with permission from American Academy of Pediatrics.<sup>17</sup>

needed to set up an exchange transfusion. Thus, the clinical indication for exchange transfusion may be removed, but the need for simple transfusion increases.<sup>2</sup> Exchange transfusions are considered indicated when "intensive phototherapy," with or without IVIG, fails to adequately reduce bilirubin concentration or when the initial serum bilirubin places the infant at risk for kernicterus. Factors potentiating bilirubin toxicity include immune-mediated hemolysis, acid-base disturbances, asphyxia, free heme groups, and other byproducts of hemolysis or drugs that displace bilirubin from albumin and other plasma binding proteins.<sup>6</sup>

Figure 27-2 shows current guidelines for exchange transfusion in neonates of 35 weeks or more with hyperbilirubinemia.<sup>17</sup> The dashed lines for the first 24 hours on the figure indicate uncertainty due to the range of responses to phototherapy and to differences in clinical circumstances, thus emphasizing the importance of individualized treatment decisions. Treatment decisions after the first 24 hours are dependent upon gestational age, bilirubin concentration, the rate of its increase ( $> 0.5$  mg/mL/hour) and risk factors that have a potential negative effect on albumin binding of bilirubin, the blood brain barrier, and the susceptibility of brain cells to damage by bilirubin (see Fig 27-2). Immediate exchange transfusion is recommended if the

infant shows signs of acute bilirubin encephalopathy as detailed in Fig 27-2, or if total bilirubin is 5 mg/dL above the lines.

Exchange transfusions supply the neonate with compatible red cells and fresh plasma, while incompatible red cells, bilirubin, and maternal antibodies in plasma are removed. A standard exchange transfusion of twice the infant's blood volume reduces incompatible fetal red cells by about 85%; bilirubin and maternal antibody concentrations are reduced by 25% to 45%.<sup>6</sup> The amount of blood needed for an exchange transfusion is 170 mL/kg (200 mL/kg in preterm infants). An exchange transfusion consists of hemoglobin S-negative red cells that are compatible with maternal serum and/or plasma and are reconstituted with fresh frozen group AB plasma to obtain a hematocrit of 45% to 50%. The red cells should be leukocyte-reduced (to prevent transmission of cytomegalovirus), irradiated, and preferably  $< 5$  days old. Platelet addition is to be considered only if an infant's platelet count is seriously compromised or after multiple exchange transfusions.

In view of the declining number of exchange transfusions, and the risks involved with the procedure (Table 27-3) it is important that maternity and neonatal services develop, maintain, and teach appropriate written guidelines for the use of exchange transfusion in HDFN and the performance of the procedure itself.

## Conclusion

In immune-mediated HDFN, maternal IgG antibodies—usually related to the ABO, Rh, or Kell blood groups—cross the placental barrier, causing hemolysis of fetal red cells. HDFN caused by hereditary red cell disorders are less frequent. Although HDFN can be fatal, advances in diagnosis, treatment, and prevention have made immune-mediated HDFN increasingly controllable in developed countries. Diagnostic modalities include maternal assays, antepartum treatment, and routine prophylactic RhIG given to D-negative women at risk. Postpartum management includes treatment of hyperbilirubinemia and anemia. Hyperbilirubinemia is usually treated by means of “intensive phototherapy,” while adjuvant high-dose IVIG is given in order to reduce hemolysis. In addition, anemia is corrected by simple transfusion of red cells. These approaches have reduced the indications for exchange transfusion to very severe HDFN or when “intensive phototherapy” combined with IVIG fails to reduce hyperbilirubinemia to acceptable levels. Further improvement of phototherapy equipment, IVIG treatment, and possible administration of D-penicillamine and/or metalloporphyrins in order to reduce bilirubin formation<sup>21,22</sup> could reduce the need of exchange transfusions and change the spectrum of HDFN treatment even more.

While mortality and morbidity of HDFN have been greatly reduced in developed countries, HDFN still poses a serious challenge in many developing countries. In these countries with low HDI, introduction of maternal assays, routine prophylactic RhIG treatment, and affordable phototherapy should be encouraged. Because high-dose IVIG often will be beyond economic reach, phototherapy combined with drugs to reduce the postpartum formation of bilirubin could be of interest, and further studies with the administration of D-penicillamine<sup>21</sup> or metalloporphyrins<sup>22</sup> are to be encouraged.

# Congenital Disorders of Clotting Proteins and Hypercoagulable States in Pediatrics

**Linda J. Butros<sup>1</sup> & Prasad Mathew<sup>2</sup>**

<sup>1</sup> Assistant Professor of Pediatrics, Pediatric Hematology/Oncology, University of New Mexico, Albuquerque, New Mexico, USA

<sup>2</sup> Professor of Pediatrics, Pediatric Hematology/Oncology, University of New Mexico, Albuquerque, New Mexico, USA

Historically, inherited disorders of coagulation lead to severe, debilitating disability and early demise. Even 20 to 30 years ago, children afflicted with hemophilia and thrombosis suffered much with few safe and effective treatment options. Today, the treatment of pediatric coagulopathies consists of effective modalities that are primarily administered on an outpatient basis. There are life-saving treatment options exist even for some of the most difficult-to-treat hemophilia patients with inhibitor or children with inherited thrombophilia. Multicenter prospective clinical trials involving children with bleeding disorders, as well as those with thrombophilia, are being performed in order to make accurate recommendations of care. Although studies in children with thrombotic conditions are few, evolving treatments contribute to an exciting era of growth in pediatric coagulopathy.

## Hemophilia

The hemophilias form a group of inherited lifelong bleeding disorders caused by deficiency of Factor VIII (hemophilia A) or Factor IX (hemophilia B). Hemophilia A and hemophilia B have many features in common. Both are inherited as X-linked recessive traits and thus affect males almost exclusively. The incidence of hemophilia A is 1 in 5000 male live births, and that of hemophilia B is 1 in 30,000.<sup>1,2</sup> Hemophilia affects at least 20,000 persons in the United States alone. Results of a US epidemiologic survey indicated that 43% of hemophiliacs are classified as severe, with 26% classified as moderate, and 31% as mild.<sup>3</sup> There are, however, some reports of hemophilia A and B in females, which could be caused by inheritance of a gene for hemophilia from both parents or a new mutation. The genes for Factor VIII and Factor IX are on the long arm of the X chromosome in band Xq28 and Xq27, respectively.

Hemophilia A and B are clinically indistinguishable. Bleeding into joints and soft tissues is the hallmark of both conditions. Laboratory screening tests are the same in both disorders as well. Persons with hemophilia A or B characteristically have normal values for prothrombin time, platelet count, and platelet function analyzer testing (which has replaced the template bleeding time in many institutions), but have a greatly prolonged activated partial thromboplastin time (aPTT). The two disorders can be distinguished by performance of assays for Factor VIII and Factor IX coagulant activity. Hemophilia is worldwide in distribution and affects all racial groups.

## Clinical Features

In hemophilia A, Factor VIII coagulant activity is deficient or abnormal, whereas other components of the Factor VIII system—von Willebrand factor (vWF) and vWF antigen (vWF:Ag)—are normal. In general, clinical severity is correlated with the degree of Factor VIII deficiency. Persons with severe hemophilia have <1% (<0.01 IU/mL) Factor VIII activity. Severely affected persons have spontaneous bleeding into joints and soft tissues. Those with 1% to 5% of normal Factor VIII activity are classified as moderate, and have little, if any, spontaneous bleeding. Those with Factor VIII values of >5% to 40% (>0.05 to 0.40 IU/mL) have clinically mild disease, usually bleeding only with surgery or trauma.<sup>1</sup> The degree of Factor VIII deficiency is fairly consistent in individuals, and in affected members in the same kindred. “Normal” is 1 IU/mL of Factor VIII (100%), as defined by the current World Health Organization International Standard for Plasma Factor VIII [as distributed by the National Institute for Biological Standards and Control (NIBSC) in the United Kingdom].<sup>1</sup> Female carriers of the disease have variable factor levels; bleeding does not occur in those with near normal levels, but those with <50% levels may bleed more often than unaffected relatives or matched controls.<sup>4</sup>

Hemophilia B (Christmas disease) is characterized by subnormal Factor IX activity. Depending on the genetic defect, Factor IX deficiency may reflect a quantitative or qualitative abnormality in the Factor IX molecule. Several different subtypes of hemophilia B

have been described. In fact, genotype heterogeneity is quite marked; almost every family with hemophilia B has its own unique mutation.<sup>5</sup> Hemophilia B is far less common than hemophilia A, accounting for approximately 15% to 20% of cases of hemophilia. As in hemophilia A, clinical severity is correlated with the degree of Factor IX deficiency, with those with Factor IX levels of  $\leq 1\%$  generally having spontaneous bleeding into joints and soft tissues. The Leyden phenotype of hemophilia B is characterized by severe hemophilia in childhood that becomes mild after puberty.<sup>6,7</sup>

Joints are the classical bleeding sites in patients with severe hemophilia. Those with severe hemophilia have an annual average of 20 to 30 episodes of spontaneous or excessive bleeding after minor trauma. Some patients with severe disease have a milder clinical course. Coinheritance of the Factor V Leiden mutation (see below) occurs in a small proportion (4.4% in one series) of patients with severe hemophilia A.<sup>8</sup> The presence of this and other prothrombotic conditions partially counteracts the bleeding tendency of hemophilia, resulting in fewer bleeding episodes and a later onset of first bleeding.<sup>8-10</sup>

Clinical presentations may vary depending on the age of the patient. In the perinatal period, approximately 5% of such patients develop significant subgaleal or intracranial hemorrhage (ICH).<sup>11-13</sup> In a multicenter survey, symptomatic ICH occurred in 4% of 744 patients, with 40% occurring within the first week of life due to trauma as the major precipitating factor.<sup>11</sup> These hemorrhages may be complicated by seizures, psychomotor retardation and cerebral palsy.<sup>12</sup> In approximately 50% of undiagnosed hemophiliacs early bleeding occurs in association with circumcision.<sup>14</sup>

Children become symptomatic more often after the newborn period but within the first 2 years of life.<sup>15</sup> In one study, the first symptomatic bleeding leading to the diagnosis of severe hemophilia occurred at a median age of 0.9 year in children not carrying any prothrombotic risk factors, and 1.6 years in those carrying prothrombotic risk factors (eg, Factor V Leiden) ( $p = 0.01$ ).<sup>8-10</sup> The onset of disease occurs later in patients with moderate and mild hemophilia, sometimes as late as 22 months.<sup>16</sup> Mild hemophilia, in the absence of an informative family history, may go undetected for significant periods (age 14 to 62 years in one report).<sup>17,18</sup> With ambulation, bleeding episodes occur more often and in any location.

The factors that initiate hemorrhage are not known, and the onset of hemorrhage often is a random event, occurring either spontaneously or after minimal injury. Bleeding into a joint (hemarthrosis) is the commonest bleeding manifestation; the ankles are most commonly affected in children, and the knees, elbows, and ankles are more affected in adolescents and adults. Spontaneous hemarthroses are so characteristic of severe hemophilia as to be almost diagnostic.<sup>1,19</sup> Hemarthrosis is painful and physically debilitating, and is the initiating event in hemophilic arthropathy. One joint is usually affected at a time, often leading to a target joint, but multiple bleeding sites are common.<sup>20</sup> Repeated hemorrhages into joints initiate the

progressive destruction of a joint, leading to fibrosis of the joint with contractures, pain, and limitation of motion.<sup>21</sup> The number and type of hemarthroses correlate with function and future quality of life. Thus, orthopedic complications remain a serious problem.

Bleeding into muscles is the next most common manifestation, and most often affects the quadriceps, iliopsoas, and forearm muscles, and sometimes are large enough to compromise neurovascular structures and produce a compartment syndrome.<sup>22</sup> Other sites of bleeding include the nose (epistaxis), oral mucosa, gastrointestinal tract, and hematuria. Intracranial hemorrhage occurs in older children as well as neonates. In one study of children, the prevalence of ICH was 12%.<sup>23</sup>

### Genetics in Hemophilia

Hemophilia A and B can be “familial” or can occur as a “sporadic” mutation. Seventy percent of mild to moderate cases of hemophilia, 57% of severe hemophilia B cases, and 45% of severe hemophilia A cases are clearly familial on pedigree analysis. Regardless, in isolated cases of hemophilia the mother of the index case carries the mutation in 85% of the cases; however, the mother’s mother carried the mutation in only 11% of isolated cases. Isolated cases, referring to only one affected individual in a family, account for approximately 25% of severe hemophilia cases and 15% of mild hemophilia cases. These “isolated cases” do not include sporadic cases in which a sibling (second child) is also diagnosed with hemophilia even if there is no family history.<sup>24</sup> One study looked for the genetic origin of sporadic cases of hemophilia A. It found that the majority of these boys inherited their Factor VIII inversion mutations from a *de novo* mutation that originated in the male germ cells of the maternal grandfather.<sup>25</sup>

Neither Factor VIII nor Factor IX crosses the placenta; thus, the diagnosis of hemophilia A or B can be made at birth from a sample of cord blood drawn from a vessel on the fetal side of the placenta, after the infant is born. The blood should be collected in citrate (1:10 dilution) and sent immediately to the laboratory for a Factor VIII or IX assay. The diagnosis can also be made by cordocentesis at 18 to 20 weeks of gestation. Similarly, umbilical cord blood can be collected and tested for Factor VIII or IX activity. However, prenatal diagnosis of hemophilia is now accomplished almost exclusively through molecular biological techniques analyzing various polymorphic markers from DNA obtained from chorionic villus sampling. These modern techniques, including restriction fragment length polymorphism analysis, denaturing gradient gel electrophoresis, single-strand conformation polymorphism, DNA sequencing, and others, are accurate and can be obtained earlier in the pregnancy with less morbidity than cordocentesis.<sup>26</sup>

Although several mutations in the Factor VIII and Factor IX genes have been described,<sup>2,4-6</sup> an inversion in the intron 22 of the Factor VIII gene accounts for roughly 45% of cases of severe (not mild or moderate) hemophilia A.<sup>27</sup> Thus, the search for inversions of Factor VIII should be considered as the

first DNA diagnostic option in a person or a family with severe hemophilia A.<sup>28</sup> The inversion mutation can be detected by polymerase chain reaction amplification and other molecular techniques from a person with hemophilia A or from a possible carrier, or using fetal or chorionic villus cells. These techniques can be used to diagnose virtually 100% of the intron 22 inversions seen in severe hemophilia. In one study, however, genomic analysis techniques failed to detect the defect in approximately 4% of moderately affected hemophilia A persons and approximately 12% of mildly affected persons.<sup>29</sup>

Treatment of Hemostatic Abnormalities in Hemophilia

The optimal management of these patients is very complex, and requires the provision of preventive care, the use of replacement therapy, and treatment of complications of the disease and its therapy. During the first half of the 20th century, life for these patients was at best miserable because they all developed disabling arthropathy (usually before the age of 20), often leading to permanent disability. Hemophilia also had a high mortality rate from ICH. In the 1920s and 1930s, life expectancy in developed countries such as Finland and Sweden was only 8 to 11 years. As recently as 1960, life expectancy was <30 years.<sup>30-33</sup> Improvements in hemophilia care saw its share of setbacks, the most burdensome of which was the transmission of human immunodeficiency virus (HIV) and hepatitis C virus (HCV), both of which had a devastating effect on this community.<sup>34,35</sup> With replacement therapy came two further challenges—the development of inhibitors to Factor VIII or IX, and the rising costs of treatment. Because of the increasing costs of care, developing countries struggle to provide factor concentrates to

their patients. The challenge facing clinicians today is to maintain state-of-the-art care in an environment of rising treatment costs.<sup>36</sup>

Rapid advances within the last 30 years in the evolution of factor replacement products have been made (Table 28-1). The availability of factor concentrates, the emergence of comprehensive hemophilia treatment centers, and the widespread adoption of home-administered replacement therapy led to the early control of hemorrhages and reduced the musculoskeletal damage typical in patients with inadequately treated disease.<sup>19</sup>

Blood Component Therapy

Until the mid-1960s, fresh plasma or Fresh Frozen Plasma (FFP) were the only preparations that could be used to treat Factor VIII or Factor IX deficiency. Then, in 1965, Pool et al<sup>37</sup> described a simple method for concentrating Factor VIII in the form of a cold-insoluble precipitate (cryoprecipitate). By the late 1960s, the availability of Cryoprecipitated AHF had revolutionized the treatment of hemophilia A and made possible elective surgery and outpatient treatment of bleeding episodes.

Cryoprecipitates, prepared from single units of plasma, contain approximately 50% of the Factor VIII activity, vWF, and fibrinogen, as well as Factor XIII, from the starting unit of plasma. Thus, for purposes of calculation, a single bag of cryoprecipitate contains, on average, 100IU of Factor VIII and 0.2g of fibrinogen in a volume of 8 to 10 mL.

In the late 1970s and early 1980s, approximately half of the hemophiliacs in the United States or about 9300 people developed HIV from lyophilized concentrates and cryoprecipitates. In addition, about 80% of HIV-positive hemophiliacs were eventually found to have HCV.<sup>38</sup> As a result, cryoprecipitates

Table 28-1. Evolution of Hemophilia A and B Therapy

| Year | Hemophilia A                                                                     | Hemophilia B                                                                                |

were largely replaced by lyophilized Factor VIII concentrates and recombinant Factor VIII (rFVIII) concentrates. Regardless, cryoprecipitates are still used in many developing countries to treat persons with severe or moderately severe hemophilia A. Disadvantages of cryoprecipitates over commercially prepared concentrates include 1) a slightly increased risk of blood-borne viral disease transmission (particularly HCV), 2) a required storage temperature of  $<20$  to  $<30^{\circ}\text{C}$ , and 3) marked variation in the Factor VIII and vWF content of preparations.

By 1970, methods of fractionation had been developed to produce concentrates of both intermediate-purity Factor VIII and prothrombin complex concentrate (PCC), the latter of which contained the vitamin-K-dependent clotting factors (Factors II, VII, IX, and X) as well as proteins C and S. The availability of these lyophilized concentrates quickly led to home treatment (self-infusion) programs throughout the United States and abroad. For the first time, persons with hemophilia were not totally dependent on family members, hospital personnel, and emergency rooms. Bleeding episodes could be treated more promptly, less time was lost from work or school, and the incidence of progressive chronic musculoskeletal disease was decreased. However, it soon became apparent that many persons with hemophilia had developed hepatitis and had persisting alterations of liver function.<sup>39-41</sup> Some had progressed to cirrhosis. As many as 90% of hemophiliacs became seropositive to hepatitis B surface antigen.<sup>42</sup> Because of this serious complication, in 1980 a Factor VIII concentrate (Hemofil T, Hyland Laboratories, Glendale, CA) was developed that was heated in the dry state for 72 hours at  $60^{\circ}\text{C}$ . Studies in chimpanzees suggested that this method of heating destroyed hepatitis viruses; however, when Hemofil T was infused into previously untreated children with hemophilia, 84% developed non-A, non-B hepatitis (currently referred to as HCV).<sup>42</sup>

In the early 1980s, the first cases of acquired immunodeficiency syndrome (AIDS) in persons with hemophilia were noted. It quickly became apparent that this too was being transmitted by blood and blood components, including clotting factor concentrates.<sup>43</sup> Approximately 90% of persons who received Factor VIII concentrates and 55% of those who received PCCs prepared in the United States between 1979 and 1984 became seropositive for HIV. Fortunately, HIV proved to be heat labile.<sup>44</sup> Although the dry heating method used in production of Hemofil T did not prevent HCV, it did seem to destroy HIV. Thus, by late 1984 almost all hemophiliacs in the United States were receiving dry heat-treated concentrates. Additionally, by the spring of 1985, mandatory screening of all blood and plasmapheresis donors for HIV seropositivity was in place. These measures greatly improved the safety of plasma-derived Factor VIII and Factor IX concentrates in terms of HIV transmission. Since 1987, there has not been a new case of HIV or hepatitis in the North American hemophilia population.<sup>45</sup>

In addition to better virus-attenuated products, Factor VIII concentrates purified by using murine monoclonal antibodies and immunoaffinity chromatography became commercially available in 1987.<sup>46</sup> Several logs of virus were eliminated in the purification process. These monoclonal antibody-purified

products were further virus-attenuated by pasteurization or by solvent/detergent treatment.

Creutzfeldt-Jakob disease (CJD) was another potential threat for the hemophilia community. Although there have been no documented instances of transmission of CJD or variant CJD, the mere possibility of such transmission has been cause for further concern among hemophilic patients and their physicians.<sup>38</sup> Thus, the use of safer alternatives to blood concentrates/derivatives was explored.

### Recombinant Factor VIII

Despite improved methods of donor screening and virus attenuation of plasma-derived clotting factor concentrates, the transmission of certain blood-borne viruses remained a concern. Thus, recombinant clotting factor concentrates have had great appeal. After scientists described the molecular cloning of a complementary DNA (cDNA)-encoding human Factor VIII<sup>47</sup> and the expression of human Factor VIII from recombinant DNA clones,<sup>48</sup> scale-up, purification, and standardization were rapidly accomplished. Preliminary clinical trials in humans began in 1987.

In patients with hemophilia A, the original, “first-generation” full-length rFVIII products have demonstrated the same pharmacokinetics and clinical effectiveness as plasma-derived Factor VIII products.<sup>49,50</sup> Despite the cost of rFVIII, many patients (especially those who are HIV seronegative) now have been switched from plasma-derived to rFVIII, because of the added margin of safety. Still, there were concerns among some that human serum albumin was in these rFVIII products (and was, in fact, the major component in the final products) and *might* transmit a blood-borne disease.

The “second generation” of rFVIII products that were developed included truncated molecules. Because the heavily glycosylated B domain seemed to be dispensable for the hemostatic activity of Factor VIII,<sup>51</sup> a B-domain-deleted (BDD) form of Factor VIII was developed.<sup>31,32</sup> This much smaller molecule is secreted more efficiently by Chinese hamster ovary (CHO) cells, is less prone to proteolytic degradation, and no serum albumin is needed for stabilization of the final product. B-domain-deleted rFVIII has proven to be effective in a wide variety of situations (acute bleeding episodes, prophylaxis, home treatment, surgery, etc), is safe, and is well tolerated.<sup>52</sup>

The only “problem” with BDD rFVIII is that usual, one-stage (aPTT-based) Factor VIII assays give roughly 50% of expected values in the recipient’s plasma.<sup>52-54</sup> There are marked differences in the phospholipid requirement in the assay of BDD rFVIII compared to the other Factor VIII preparations. Thus, if one is monitoring Factor VIII levels in a patient with hemophilia A who is receiving BDD rFVIII, one-stage Factor VIII assays will appear to be lower than expected (calculated). On the other hand, chromogenic substrate assays, although infrequently performed by US clinical laboratories, will give expected recovery values. Also, if one uses a small test vial of BDD rFVIII as the Factor VIII standard in the one-stage assay, results will be as expected. Small

test vials of BDD rFVIII (prepared by the (NIBSC) are available for this purpose.

Another “second-generation” rFVIII product is a full-length preparation formulated with sucrose, rather than human serum albumin.<sup>55</sup> The purification process for this product (Kogenate FS, Bayer Healthcare, West Haven, CT) eliminates the need for the addition of albumin. A solvent/detergent treatment step has also been added during purification. In 2003, a third-generation Factor VIII product (Advate, Baxter, Deerfield, IL) was released. This product has no human or animal proteins either in the initial stages of preparation or in the final formulation.

Dosage and Administration of Factor VIII

Factor VIII concentrates are routinely used for treating acute bleeding episodes in persons with moderate or severe hemophilia A. Factor replacements may be given either “on demand” (ie, after a bleeding episode to treat the hemorrhage) or as “prophylaxis” (ie, scheduled infusions to prevent or decrease the frequency and intensity of hemorrhages). The most common indications for treatment are acute hemarthrosis and intramuscular bleeding. Such events should be treated promptly to prevent or reduce complications (such as chronic joint disease) and to minimize the need for additional infusion of clotting factor (Table 28-2). In addition, Factor VIII concentrates are often used for prophylaxis (to prevent bleeding), for surgical coverage, and for immune tolerance induction (ITI) in persons with Factor VIII inhibitors.

In calculating the dose, it can be assumed that 1 IU of Factor VIII/kg of body weight will raise the patient’s Factor VIII level by 2% (0.02 IU/mL). Thus, if the patient’s baseline Factor VIII level is 0.01 IU/mL, a dosage of 20 IU/kg would be expected to

raise the level to 40% (0.40 IU/mL). The half-life of Factor VIII is 10 to 12 hours but may be shorter if the recipient is febrile, is bleeding extensively, has a Factor VIII inhibitor, or is a small child.

Serious, life-threatening bleeding into the central nervous system or intraoperative and postoperative bleeding may be treated with a continuous infusion of Factor VIII. After an initial bolus of 40 to 50 IU/kg (which will raise the patient’s Factor VIII level to 80% to 100%), a continuous infusion could be started. An initial rate of 3 to 4 IU/kg/hour should be subsequently adjusted as indicated by the recipient’s Factor VIII level. In general, a rate of 2 IU/kg/hour will achieve a Factor VIII level of 25%; 3 IU/kg/hour will yield a 50% level; and 4 IU/kg/hour will result in a 75% level. However, these levels should not be assumed, and daily monitoring should be performed. If continuous infusion becomes a logistical issue, then twice a day bolus infusions may be substituted to keep a trough Factor VIII level >50%.

Prophylaxis

Chronic hemophilic arthropathy, resulting from repeated bleeding into joints, is the major cause of morbidity in persons with severe hemophilia. In those whose Factor VIII or IX levels are less than 0.01 IU/mL, bleeding episodes occur approximately 20 to 30 times per year.<sup>1</sup> Primary prophylaxis, which is aimed at preventing spontaneous hemarthroses, was begun in Malmö, Sweden, over 35 years ago.<sup>57</sup> All boys with severe hemophilia currently seen at the Malmö center start prophylaxis when they are 1 to 2 years old. Most standard prophylaxis regimens aim to keep the factor level >1%.<sup>58</sup> For Factor VIII deficiency, the standard implies infusions three times per week; for Factor IX replacement, the standard implies two infusions per week because of

Table 28-2. Management of Bleeding Episodes in Hemophilia: Suggested Recommendations

| Type of Bleeding | Examples                                                                                               | Factor VIII/IX Levels Desired* | Duration of Therapy                                     |
|------------------|--------------------------------------------------------------------------------------------------------|--------------------------------|---------------------------------------------------------|
| Minor            | Uncomplicated hemarthroses, superficial muscle or soft tissue bleeding                                 | 20-40%                         | 1-3 days                                                |
| Moderate         | Intramuscular or soft tissue bleeding with dissection; mucous membranes; dental extractions; hematuria | 30-60%                         | 2-7 days                                                |
| Major            | Pharynx; retropharynx; retroperitoneum; central nervous system (CNS) surgery                           | 60-100%                        | 5-14 days; CNS bleeding—6 weeks to months to indefinite |
|                  | Postoperative management                                                                               | 60-80%                         | 7-14 days                                               |
|                  | Prophylaxis therapy— administered 3 or 4 times/week†                                                   | Trough factor >1%              | ??                                                      |

\*The required dosage for Factor VIII is determined using the formula:  
Required units = Body weight (kg) × Desired Factor VIII Rise (%) × 0.5 IU/kg.  
The required dosage for Factor IX is determined using the formula:  
Required units = Body weight (kg) × Desired Factor VIII Rise (%)  
†One study<sup>56</sup> showed that once-a-week prophylaxis may be feasible in some patients.

the longer half-life of Factor IX.<sup>59</sup> Although venous access may be a problem in younger children, central venous catheters are often used. With such devices the risk of bleeding or infection is generally low but must be considered. Another historical concern has been the propensity for increased Factor VIII inhibitor formation with the increased number of infusions given in prophylaxis. However, recent reports suggest that there may be a benefit resulting in decreased inhibitor formation with prophylaxis.<sup>58</sup>

Prophylactic treatment with recombinant Factor VIII has been shown to prevent joint damage in young boys with severe hemophilia A. A prospective randomized, multicenter study conducted in the United States enrolled 65 boys <30 months of age with severe hemophilia A between August 1996 and March 2000. The boys were randomly assigned to receive either prophylactic Factor VIII dosing at 25 IU/kg every other day or episodic therapy only at the time of a joint hemorrhage with an initial dose of 40 IU/kg and 20 IU/kg 24 and 72 hours after the first dose. Parents were also encouraged to re-treat up to 4 weeks with 20 IU/kg every other day until the symptoms of joint hemorrhage resolved. Radiography, magnetic resonance imaging (MRI), and a physical examination scoring system were used to assess joint damage. The prophylaxis group had a significant decrease in structural joint damage as assessed by MRI. An 86% relative risk reduction in joint damage as assessed by the scoring systems was noted as compared to on-demand therapy.<sup>60</sup>

### Coagulation Concentrates Available for the Treatment of Hemophilia B

Until late 1990, intermediate-purity PCCs were the mainstay of treatment for persons with hemophilia B. They contain the vitamin-K-dependent clotting Factors II, VII, IX, and X, as well as proteins C<sup>61</sup> and S. In addition to nonactivated factors, PCCs contain some coagulation factors in activated forms as well. This occasionally results in disseminated intravascular coagulation (DIC) or thromboembolic complications in recipients of these products. The risk of DIC and thromboembolism is greatest in recipients who have sustained crush injuries or extensive soft-tissue bleeding, or who have undergone orthopedic surgery and are immobile. In such situations, thromboplastic materials are released into the circulation. The risk is also enhanced in persons with hepatocellular disease, because clotting intermediates are not optimally cleared from the circulation, and antithrombin levels are often low.<sup>62</sup> Because of the potential, albeit rare, thrombotic complications of activated PCCs (aPCCs), most physicians avoid concurrent treatment with aPCCs and antifibrinolytics.<sup>63</sup> Recent studies using PCCs as prophylaxis in the treatment of hemophiliacs with inhibitor (see below) demonstrated no prothrombotic complications at doses of 75 to 100 U/kg every other day to three times per week.<sup>64</sup> The only aPCC (FEIBA-VH, Baxter Healthcare) currently available and licensed for use in the United States is now relegated to treatment as a bypassing agent for patients with inhibitors.<sup>64</sup>

In view of the thrombogenic potential of PCCs, there was an obvious need for high-purity Factor IX concentrates. These

so-called coagulation Factor IX concentrates are considerably more expensive than PCCs; however, they are far less thrombogenic.<sup>65</sup> These high-purity virus-attenuated Factor IX concentrates and recombinant concentrates are recommended for use in neonates and children, in persons with hemophilia B undergoing surgery (particularly orthopedic surgery), in those with crush injuries or large intramuscular hemorrhages, in those with hepatocellular dysfunction, and in anyone with a history of thrombotic problems after receiving PCCs (ie, in any high-risk situation for thrombosis or DIC)—in fact, they are the preferred products for anyone with hemophilia B.

### Recombinant Factor IX

The CHO cell line used in the manufacture of recombinant Factor IX is co-transfected with a human Factor IX cDNA expression plasmid and a cDNA expression plasmid that encodes an engineered form of the paired amino-acid-cleaving enzyme, which improves the processing efficiency of profactor IX expressed in CHO cells.<sup>66,67</sup> No albumin is used, and no human plasma, animal plasma, or animal-derived protein is used in its manufacture or purification.<sup>68</sup> A reformulation (BeneFix, Wyeth, Collegeville, PA) now exists that seems to exhibit equal efficacy to the original preparation with a more concentrated formulation. There were no instances of inhibitor development, allergic reactions, or thrombosis in 34 patients tested.<sup>69</sup>

### Dosage and Administration of Factor IX

Because Factor IX is a smaller molecule than Factor VIII and diffuses from intravascular to extravascular sites, a larger dose must be given to achieve the same concentration in the circulation. Whereas a dose of Factor VIII of 1 IU/kg will raise the serum Factor VIII level by 0.02 IU/mL (2%), the same dose of (plasma-derived) Factor IX will raise the circulating Factor IX level by only 0.01 IU/mL (1%). As in the case of Factor VIII deficiency, in hemophilia B the recommended dosage for treatment of bleeding depends on the nature and severity of the bleeding episode. For most situations, dosages should be calculated to raise the Factor IX level to 0.2 to 0.3 IU/mL (20%-30%). However, larger doses are recommended for treatment of serious, life-threatening bleeding episodes and for surgery.

Recombinant Factor IX does have a decrease in recovery of the product by ~50% to 72% with respect to plasma-derived Factor IX.<sup>70</sup> However, the recombinant preparation has also been shown to exhibit a longer half-life of 13.7 vs 12.9 hours for the plasma-derived product to the extent that in three of the 13 patients in this recovery study, less recombinant product was infused to maintain the same baseline level of 2%.<sup>71</sup> The difference in recovery results from a simple difference in the posttranslational modification, or namely, the differences in sulfation of tyrosine 155 and phosphorylation of serine 158, residues that play a role in the clearance of Factor IX.<sup>70</sup> Thus, it is recommended that one use a somewhat larger dose of BeneFix than one would of a plasma-derived Factor IX product. The product package insert recommends the following calculation of dosage: number of

Factor IX units required = body weight (kg)  $\times$  desired Factor IX increase (%)  $\times$  1.2. However, one should be aware that there are wide variations in recovery among individuals. Infants and children tend to have lower recovery rates than adults.<sup>68</sup>

### **Surgery in Persons with Hemophilia B**

Through the 1980s many hemophilia centers avoided elective surgery (particularly orthopedic surgery) in persons with hemophilia B because of the risk of DIC and thromboembolic complications. As noted earlier, the risk is greatest in persons undergoing extensive orthopedic surgery on the lower extremities, because there is release of thromboplastic materials into the circulation and the patient is likely to be immobile. Now that less thrombogenic plasma-derived Factor IX preparations [Mononine (CSL Behring, King of Prussia, PA) and Alphanine SD (Grifols, Los Angeles, CA)] and recombinant Factor IX (BeneFix) are available, these should be used during and after surgery. Continuous infusion of BeneFix can be used safely and efficaciously to control bleeding in the perioperative period with little to no thrombotic side effects. The stability is maximized (90%) up to 14 days when stored at 4°C with the addition of 4  $\mu$ /mL of unfractionated heparin (UFH). The addition of the UFH also prevents thrombophlebitis, a known complication of continuous infusion.<sup>72,73</sup>

### **Other Ancillary Therapeutic Options**

#### ***Desmopressin***

Desmopressin (DDAVP) is the treatment of choice for persons with mild hemophilia A<sup>74</sup> whenever an approximately three-fold increase in Factor VIII is sufficient to control bleeding. This synthetic agent effects a three- to fivefold (average of threefold) increase in Factor VIII and vWF:Ag 30 to 60 minutes after administration.<sup>75</sup> It shortens the bleeding time and the aPTT. However, only a fraction of mild hemophiliacs and patients with von Willebrand disease (vWD) respond to this agent so a trial of desmopressin is important to confirm a response before a hemostatic challenge. The recommended dosage is 0.3  $\mu$ g/kg given intravenously.<sup>76</sup> The levels of Factor VIII (and vWF) generally remain elevated for 8 to 12 hours and the dose can be repeated at 8- to 12-hour intervals. If repeated doses are given in rapid succession, many (but not all) persons develop tachyphylaxis (a diminishing response). This is thought to reflect a depletion of the storage sites for Factor VIII and vWF. Desmopressin is remarkably free of undesirable side effects. In most persons, side effects are limited to facial flushing and a feeling of facial warmth. The antidiuretic properties of the drug seldom cause a problem. However, if repetitive doses of desmopressin are used along with large amounts of intravenous fluids, fluid and electrolyte balance must be carefully monitored to avoid hyponatremia and water intoxication. This precaution is particularly important in infants, small children, and elderly patients. In fact, when desmopressin is given to small children, fluid intake during the next 18 hours should be limited to avoid the possibility of water intoxication. Several formulations of desmopressin are available. The highly

concentrated intranasal spray is ideally suited for outpatient and home use, but patients must be counseled not to use the spray more than twice daily and not more than for 3 to 4 consecutive days.<sup>77</sup> For patients weighing <50 kg, one spray (in one nostril) is recommended, while for those weighing >50 kg, two sprays (one in each nostril) should be given. The prescription must be specific for the metered dose pump that delivers 0.1 mL (150  $\mu$ g of desmopressin) per actuation.

#### ***Antifibrinolytic Agents***

$\epsilon$ -Aminocaproic acid and tranexamic acid are antifibrinolytic agents that inhibit plasminogen activation. These agents are useful adjuncts in certain situations, to prevent lysis of a clot that has already formed as a result of specific replacement therapy. The oral mucosa has significant fibrinolytic activity, and antifibrinolytic agents are particularly useful in the control of bleeding in the oral cavity (eg, extraction of permanent teeth, lacerations of the tongue and mouth, and oral surgery).<sup>78</sup> The recommended dosage of  $\epsilon$ -aminocaproic acid is 75 mg/kg every 4 to 6 hours orally, after a loading dose of 100 mg/kg; the dose of tranexamic acid is 25 mg/kg every 6 to 8 hours. For invasive dentistry, antifibrinolytic therapy should be started the evening before the procedure and be continued for 7 to 10 days.

Swedish investigators<sup>79</sup> have demonstrated that transfusion requirements and postoperative bleeding after oral surgery in patients with hemophilia can be significantly reduced by the use of a tranexamic acid mouthwash in addition to systemic antifibrinolytic treatment. The mouthwash is prepared from 10% tranexamic acid for injection, diluted with sterile water. Sindet-Pederson et al<sup>79</sup> recommend the use of 10 mL of 4.8% tranexamic acid solution for 2 minutes four times daily.

#### ***Hepatitis B Vaccine***

In view of the risk, albeit very slight, of posttransfusion hepatitis, all persons with hemophilia (and without, according to the American Academy of Pediatrics) should be immunized against hepatitis B. Although all units of blood or plasma collected are tested for hepatitis B surface antigen, such testing may not be 100% effective in screening out all units that might transmit hepatitis B, and the risk is multiplied substantially in the case of plasma-derived clotting factor concentrates in which plasma from 2500 to 20,000 plasma donors is used to produce a single lot of concentrate. Vaccination against hepatitis B (with recombinant hepatitis B vaccine) should be given subcutaneously as soon as the diagnosis of hemophilia has been made.

#### ***Hepatitis A Vaccine***

Hepatitis A vaccine is also available, and is recommended for children (or any seronegative persons) with hemophilia 2 years of age or older.<sup>74</sup> It can be given subcutaneously,<sup>80</sup> which is preferred over intramuscular injections because of the tendency to develop muscle bleeding with intramuscular vaccination.<sup>81</sup> The Centers for Disease Control and Prevention did investigate the seroconversion to hepatitis A or B of people with blood disorders

and found no seroconversions that could be attributed to blood components.<sup>82</sup>

### **Avoidance of Drugs that Can Cause Platelet Dysfunction**

Certain drugs, aspirin in particular, induce platelet dysfunction that can aggravate the bleeding tendency in persons with hemophilia (or another underlying abnormality of hemostasis). Joint or soft-tissue bleeding is often painful. If aspirin or an aspirin-containing compound is taken to relieve that pain, the bleeding tendency may worsen, and a vicious cycle may ensue. This effect of aspirin is caused by an irreversible inhibition of platelet cyclooxygenase, which inhibits prostaglandin synthesis. Thus, aspirin and all aspirin-containing compounds should be avoided by people who have underlying coagulation disorders. Acetaminophen is a good alternative to relieve mild pain in addition to rest, cooling, and elevation. Other drugs that induce platelet dysfunction include antihistamines, phenothiazines, and nonsteroidal antiinflammatory agents such as indomethacin and ibuprofen. Recently, celecoxib and other cyclooxygenase 2 (COX-2) inhibitors known to exhibit antiinflammatory and antiangiogenic properties have been effectively utilized for analgesia in hemophilic arthropathies. COX-2 inhibitors do not interfere with platelet function as do the more traditional nonsteroidal antiinflammatory drugs.<sup>83</sup>

### **Treatment of Hemophilia with Inhibitors**

Approximately 20% to 35% of persons with hemophilia A develop inhibitor antibodies to Factor VIII, measured in Bethesda units (BU). A lesser percentage (between 2% and 5%) of persons with hemophilia B develop Factor IX inhibitors. The development of inhibitors (antibodies, primarily IgG) currently represents one of the most serious complications of hemophilia.<sup>84</sup> These antibodies complicate bleeding episodes because of diminished responsiveness to factor concentrates and increase the risk of uncontrollable bleeding, disability, and premature death. In addition, life-threatening symptoms of anaphylaxis can occur in about 5% of patients with Factor IX inhibitors and in some cases, development of a nephrotic syndrome has been reported.<sup>85</sup> The latter is seen, especially, in those individuals whose severe hemophilia B results from a large deletion, frameshift mutation, or stop codon in the Factor IX gene and occurs whenever a Factor IX-containing product is infused.<sup>86-88</sup> Inhibitors are much less common in patients with mild or moderate disease. Inhibitors typically develop in early childhood, within the first 10 to 20 exposure days to exogenous factor concentrates. Compared with hemophilia patients without inhibitors, patients with inhibitors experience bleeding that is harder to control once it starts. Not surprisingly, progressive joint disease and significant mobility impairments are far more prevalent in patients with inhibitors than in those without. Soucie et al<sup>89</sup> analyzed joint range of motion (ROM) data on 2378 children (ages 2 to 19 years) with severe hemophilia, 186 of whom had an inhibitor titer of  $>0.5$  BU at the time the joint measurements were made. Those with a measurable inhibitor had a twofold greater loss of joint ROM

(expressed as a percentage of normal ROM) when compared with those with inhibitor levels  $<0.5$  BU. In an Italian study of older inhibitor patients (mean age 36 years, range 15 to 65), it was noted on study entry that 80% were physically disabled,  $>60\%$  had measurable flexion contractures, and over 70% had mobility impairments.<sup>90</sup> These studies suggest that predictable and progressive impairment in joint function in inhibitor patients begins in childhood and worsens with the passing of time, with older adults experiencing significant orthopedic disabilities.

Many persons with hemophilia and inhibitors (approximately 50%) have a high response titer with  $>5$  BU/mL upon exposure to Factor VIII. These high-responder patients are particularly difficult to treat.<sup>91</sup> The remainder of hemophiliacs with inhibitors have a low-response inhibitor with  $<5$  BU/mL.<sup>86</sup> Approximately one-third of inhibitors (usually low-titer inhibitors) are transient.<sup>87,88</sup>

### **Inhibitors and Type of Replacement Product Used**

The early studies of the first-generation recombinant Factor VIII products demonstrated inhibitor antibodies in previously untreated patients (PUPs). This raised some concern, but as the trials progressed it became apparent that neither product was any more antigenic than plasma-derived Factor VIII.<sup>92,93</sup> A more recent PUP trial<sup>94</sup> studied various plasma-derived vs first- and second-generation recombinant products over a 23-year period with 72 hemophilia A patients enrolled. Thirty-one percent of the patients developed inhibitors (43% of the severely affected patients and only 8% of the moderately affected). Fifty-one patients were treated with plasma-derived products and 21 were treated with recombinant products. There was no significant difference in high-titer ( $>5$  BU) inhibitor development between the two groups.<sup>94</sup> In another PUP study<sup>95</sup> with BDD rFVIII, 33 of 101 patients (all severely affected) developed inhibitors to Factor VIII after a median of 12 exposure days. Seventeen of the 33 patients who developed an inhibitor had peak values of  $<5$  BU, while 16 had peak values of  $\geq 5$  BU. Eight of the 33 inhibitors were transient, disappearing despite “on demand” treatment with BDD rFVIII. Twelve additional patients (most high-responder inhibitor patients) had a good response to immune tolerance induction (ITI) with BDD rFVIII, with their latest inhibitor titers being negative.<sup>52</sup> These results are very similar to those seen with the two full-length rFVIII preparations.<sup>95</sup> Inhibitor development follows a typical pattern; the highest risk is within the first 20 days of exposure to Factor VIII.

The management of patients with Factor VIII inhibitors has two important aspects. The first is treatment for bleeding, and the second involves attempts to eliminate the inhibitor. The management of patients with Factor IX inhibitors involves a third important consideration: the monitoring for and management of allergic reactions or frank anaphylaxis to Factor IX concentrates and Factor IX-containing agents.<sup>96</sup>

Bleeding in patients with low inhibitor titers ( $\leq 5$  BU) often can be treated with Factor VIII concentrates in usual or somewhat increased dosages, because anamnestic responses are

minimal and hemostatic levels of Factor VIII can be achieved. However, other approaches must be used in high responders. If the inhibitor titer is >5 BU, infusion of large doses of human Factor VIII concentrates often results in a marked increase in the inhibitor titer (anamnestic response) without controlling the bleed.<sup>63</sup> The choice of treatment depends on several variables: the patient's inhibitor concentration, whether he is naive to plasma-derived products, the degree of cross-reactivity of the inhibitor to porcine Factor VIII, the nature and extent of bleeding, product availability, and the experience and preference of the medical personnel involved.<sup>86</sup>

### Prothrombin Complex Concentrates

Prothrombin complex concentrates and aPCCs have been used extensively for the treatment of bleeding in patients with inhibitors since 1972 and until recently have been the mainstay of treatment for joint and soft-tissue bleeding. They can be used in both Factor VIII and Factor IX inhibitor patients. The so-called nonactivated or standard PCCs have been largely replaced by the purposely activated products, particularly FEIBA-VH (Baxter). Although they are not always effective, there is no readily available laboratory test for monitoring the recipient, and no one has demonstrated convincingly how they work,<sup>97,98</sup> many clinicians use aPCCs.<sup>86</sup> The recommended dose of FEIBA is 50 to 75 IU/kg every 12 to 24 hours.<sup>64</sup> If necessary, this dosage can be repeated for a total of 3 to 5 days. However, the use (particularly for traumatic injuries) of frequent repetitive doses should be avoided and total doses should not exceed of 200 U/kg/day, because of the thromboembolic complications referred to earlier. Multiple studies have demonstrated the efficacy of FEIBA in the control of bleeding in patients with inhibitors. FEIBA has been used in treating acute bleeding, in perioperative control of bleeding, and most recently in prophylaxis for patients with inhibitors.<sup>59,64,99</sup>

### Porcine Factor VIII Concentrates

Factor VIII inhibitors exhibit varying degrees of species specificity. Most human Factor VIII inhibitors destroy human Factor VIII to a greater degree than Factor VIII from another species. Polyelectrolyte porcine Factor VIII was a highly purified freeze-dried porcine Factor VIII concentrate that had a much lower incidence of side effects than the older porcine preparations that were largely abandoned in the 1960s. Polyelectrolyte porcine Factor VIII was licensed in the United States in 1986 for life- and limb-threatening emergencies. Porcine Factor VIII may be ineffective for hemophilia patients with inhibitors because of human antibody cross-reactivity or development of porcine Factor VIII antibodies. Allergic reactions are generally mild but can be as serious as anaphylaxis. Either allergic or pyrogenic reactions are seen in as many as 40% of cases. In addition, viral contamination, particularly with parvovirus B19, is limiting the availability of porcine Factor VIII.<sup>63</sup> On the other hand, polyelectrolyte porcine Factor VIII, unlike PCCs and aPCCs, permits the measurement of Factor VIII levels in the recipient, and it has proved lifesaving in many serious situations. It is no longer produced because of

parvovirus infection of the swine colony that was used to manufacture this product. A recombinant version is currently undergoing clinical trials.

### Recombinant Factor VIIa

The development of recombinant Factor VIIa (rFVIIa) has been an important landmark in the management of hemophilia patients with inhibitors. The drug (Novo Seven, Novo Nordisk, Copenhagen, Denmark) has been used with clinical success in hemophilic patients with inhibitors who had life-threatening bleeding episodes,<sup>98</sup> in patients with acute bleeding that was not life- or limb-threatening, as prophylaxis for joint bleeding, and as prophylaxis in elective surgical procedures.<sup>100-102</sup> Monroe et al<sup>103</sup> demonstrated that concentrations of Factor VIIa much higher than those found normally in the circulating blood are able to mediate a tissue-factor-independent conversion of Factor X to Factor Xa on a phospholipid surface. rFVIIa induces hemostasis in the absence of Factor VIII and Factor IX, probably by enhancing thrombin generation on the thrombin-activated platelet surface. The rFVIIa binds to the platelet membrane. Factor VIIa, in concentrations of 50 to 100 nmol/L, then proceeds to activate Factor X on the platelet surface in the absence of Factors IX and VIII. This thrombin activation recruits more platelets and enhances the platelet-to-platelet adhesion. In addition, the thrombin activation leads to a tighter fibrin clot structure by recruiting Factor XIII.<sup>104</sup>

Since the first human patient's successful treatment with rFVIIa, during and following open synovectomy,<sup>105,106</sup> many clinical trials with rFVIIa have been conducted. These included pharmacokinetic studies (which documented the short half-life of the product, 2 to 3 hours),<sup>107</sup> dose-finding studies, home treatment studies,<sup>108</sup> and multiple surgical studies.<sup>100,109</sup> In most of these studies, as well as in a large compassionate-use database, rFVIIa has been given by intravenous (IV) bolus injections. The recommended dose is 90 µg/kg of body weight per dose, with repeat dosing (if necessary) given every 2 to 3 hours for the first 24 hours (or more), with increasing intervals of 3 to 6 hours thereafter. However, the clearance rate varies among individuals, with some children less than 15 years of age having three times the clearance rate achieved in adults.<sup>110</sup>

Adverse effects found with the use of rFVIIa are rare with the exception of lack of efficacy. The Hemophilia and Thrombosis Research Society (HTRS) Registry reported on the use of rFVIIa in treating 719 bleeding episodes in 50 hemophilia patients. There were nine reported adverse events in five of the patients. Eight of the nine events were "decreased therapeutic response." The ninth reported adverse event was a maculopapular rash on both arms after 5 days of rFVIIa infusions.<sup>108</sup> One of the worries of using rFVIIa has been the risk of thromboembolic events. However, studies in hemophilia patients have shown that this risk is extremely low. There is some evidence, as well, that the initial treatment dose of rFVIIa could be increased as a one-time dose without thromboembolic complications. The bleeding episodes from the HTRS Registry

were treated with bolus IV doses ranging from  $<100\mu\text{g/kg}$  to a maximum of  $346\mu\text{g/kg}$ . None of the patients experienced a thromboembolic event. The doses used were divided into four groupings:  $<100\mu\text{g/kg}$ ,  $100$  to  $150\mu\text{g/kg}$ ,  $150$  to  $200\mu\text{g/kg}$ , and  $>200\mu\text{g/kg}$ . Bleeding stopped in 86%, 82%, 92%, and 93% for each of the respective groups of patients including the 23 patients who were under 18 years of age. In the adult groups, bleeding stopped in 100% of the patients treated with  $>200\mu\text{g/kg}$ .<sup>108</sup>

In those persons (usually infants and young children) who have severe hemophilia B and develop an inhibitor, roughly 40% to 50% will have severe allergic reactions (including anaphylactic shock) when infused with any Factor IX-containing product (plasma, plasma-derived Factor IX concentrates, or recombinant Factor IX).<sup>98</sup> Although a few such patients have been desensitized to Factor IX, for the majority of hemophilia B patients who have had severe allergic reactions to Factor-IX-containing products, rFVIIa is regarded as the treatment of choice.<sup>96</sup>

### Prophylaxis Using Recombinant Factor VIIa

Despite its short half-life, two recent studies demonstrated that a daily prophylactic dose of either  $90\mu\text{g/kg}$  or  $270\mu\text{g/kg}$  was effective in patients with inhibitors in decreasing the frequency of joint bleeding.<sup>102,111</sup>

### Staphylococcal Protein A Immunoabsorption of Inhibitor Antibodies

Staphylococcal protein A immunoabsorption columns (to rapidly reduce a very high-titer Factor VIII or Factor IX inhibitor) are widely available but not often used. In view of the availability of “bypassing” agents such as aPCC and rFVIIa, which work as well in patients with high-titer inhibitors, there is not often a need to rapidly reduce an inhibitor titer in a bleeding patient. The columns are, however, used on occasion in order to decrease an inhibitor titer in a patient in preparation for certain immune tolerance regimens, such as the Malmö regimen. The International Workshop on Immune Tolerance Induction consensus recommendations address the potential utility for immunoabsorption in patients with severe hemophilia B before immune tolerance in order to reduce the incidence of nephrotic syndrome.<sup>112</sup>

### Prevention of Inhibitor Development

The CANAL (Concerted Action on Neutralizing Antibodies in Severe Hemophilia A) study group studied children with severe hemophilia A who were started on regular prophylaxis at an early age (median age of 20 months). These children, who received treatment at least twice weekly, had a 60% reduction in the risk of developing inhibitors.<sup>113</sup> Other studies have confirmed these findings.<sup>114,115</sup> These studies infer that the institution of early prophylaxis may be a reasonable means for the prevention of inhibitor development and must be considered, particularly in patients at high risk for inhibitor development (positive family history, at-risk mutations).

### Attempts to Suppress or Eradicate Inhibitors: Immune Tolerance Regimens

In the 1970s, a demanding regimen for ITI, called the “Bonn protocol,” used very large and very frequent doses of both Factor VIII and aPCC (FEIBA) during a period of many months or even years.<sup>116</sup> In the 1980s other investigators began reporting success with modifications of the Bonn regimen that involve smaller doses of Factor VIII given at less frequent intervals.<sup>97</sup> Ewing et al<sup>117</sup> had considerable success with a regimen consisting of a daily infusion of Factor VIII of 50IU/kg, and others have reported<sup>118</sup> suppression of inhibitors in a high percentage of patients given Factor VIII at 25IU/kg on alternate days or two or three times a week. Other groups reported an enhancement of immune tolerance with the addition of intravenous  $\gamma$ -globulin, immunosuppressive agents, or both.<sup>119,120</sup>

Although these modifications of the Bonn regimen are costly and require good venous access and patient compliance (and a guaranteed supply of Factor VIII), it now seems that such approaches suppress many inhibitors completely and convert other high responders to low responders. Observations to date indicate that timing is extremely important in the use of ITI. The optimal time to start a regimen is when the inhibitor titer is  $<10$  BU; this is best accomplished by avoiding exposure to Factor VIII. It is important to watch the titer closely and initiate treatment promptly when the titer falls sufficiently. Of course, ITI may need to be started sooner if a 1- to 2-year period does not yield the desired titer levels or there is a life-threatening hemorrhage. The optimal dose and frequency for ITI varies between investigators and patients. Hemophiliacs with inhibitors can be divided into “good risk” and “poor risk” patients. The “good risk” patient has an inhibitor titer  $<10$  BU before the initiation of immune tolerance, has a maximum inhibitor level that never exceeded 199 BU, and is starting immune tolerance less than 5 years since the diagnosis of an inhibitor. The “poor risk” patient does not fall into those categories. There is some evidence that “good risk” patients may require less Factor VIII, but “poor risk” patients may require as much as 200IU/kg/day to maximize the efficacy of ITI.<sup>112</sup>

Although many physicians treating hemophiliacs now institute ITI in an attempt to suppress or eradicate Factor VIII inhibitors, the success rate has been only about 70%, and is poorer when immune tolerance is attempted in hemophilia B patients with inhibitors. The North American Immune Tolerance Registry data suggested only a 36% success rate in hemophilia B patients; however, patients with allergic reactions were over-represented.<sup>121</sup> The success rate is hindered by the development of nephrotic syndrome, which has been reported in 13 patients internationally. This generally occurs 8 to 9 months after the start of ITI, and its etiology remains unclear. Although the nephrotic syndrome generally resolves with the avoidance of Factor IX products, this complication often mitigates further ITI.<sup>122</sup>

### Gene Therapy

Gene therapy replaces the missing factor or protein with a nucleic acid rather than the protein itself. The goal would be to transfect certain targeted tissues with the nucleic acid to replace

the mutated area of the genome. Hence, the targeted tissue would produce normal protein either fully or partially correcting the factor deficiency. Hemophilia has a favorable combination of features for a positive response to gene replacement therapy. A reduced-intensity stem cell transplant in mice with stem cells transduced with the BDD porcine Factor VIII has been effective in decreasing clot times and increasing Factor VIII levels.<sup>123</sup> A few dog models have been used successfully in transgene expression. The targeted tissues were skeletal muscle and liver/hepatocytes. The problem of immune reaction to the transgene product exists and may necessitate approximately 6 months of immune suppression. Vector safety is another important consideration in transporting the transgene product to the recipient.<sup>124</sup> A few gene therapy trials in humans have now been completed and the preliminary data are moderately encouraging; however, the results are far from satisfactory with regard to safety and efficacy.<sup>125</sup> In terms of efficacy, the plasma levels of Factor VIII or Factor IX reached so far are insufficient to free patients from the need for infusion of exogenous factors. No inhibitor developed in gene replacement trials, but this risk is still of concern especially in previously untreated patients. Additionally, small amounts of the viral genome have been detected in the semen of a few patients, suggesting that the risk of germline integration and passage from the vector to descendants cannot be ruled out.<sup>19,125</sup>

## von Willebrand Disease

von Willebrand disease is characterized by mucous membrane bleeding, excessive bruising, and excessive bleeding during and after surgery or invasive dental procedures. It is the most common of the hereditary coagulation disorders. The incidence of vWD in the United States is estimated to be between 0.82% and 1.6% of the population. Clinical severity varies greatly, and many affected individuals have minimal symptoms unless challenged by surgery. A number of subtypes of vWD have been described; the more common of these are discussed below (Types 1, 2, and 3).

The basic defect is in vWF, a large multimeric plasma glycoprotein (GP) that supports the adhesion of platelets to the vascular subendothelium. It is normally present in plasma in multimers of up to 20 million daltons. The highest-molecular-weight multimers are the most important hemostatically for platelet adhesion and connective tissue binding. vWF circulates as a complex with Factor VIII and protects Factor VIII from rapid proteolytic degradation, as well as transporting it to sites of active hemostasis.

vWF is synthesized in endothelial cells and megakaryocytes and is stored in organelles (in Weibel-Palade bodies of endothelial cells and in the alpha granules of platelets). The gene for vWF is located on the short arm of chromosome 12.<sup>126</sup> vWF levels are influenced by ABO blood group,<sup>127</sup> with the lowest levels being found in persons of blood group O and the highest in those with blood group AB. The A and B alleles code for A and B glycosyltransferase, which converts the H antigen into A and B blood groups. Blood group O individuals lack this enzyme and

continue to express the H antigen. H-antigen-rich blood groups have significantly lower vWF and Factor VIII.<sup>128</sup> Hormonal changes accompanying pregnancy increase the levels of vWF, Factor VIII, and fibrinogen.

von Willebrand factor is a plasma glycoprotein composed of multimeric subunits. It is the high-molecular-weight (HMW) subunits that mediate platelet adhesion during vessel injury. vWF also binds to Factor VIII in the circulation and stabilizes its presence there. In the absence of vWF (Type 3 vWD), Factor VIII levels are also very low. Once released from the Weibel-Palade bodies or alpha granules, the multimers can interact with platelets, connective tissue, or other cells, but the larger subunits may also be cleaved by the ADAMTS13 metalloprotease into smaller multimers. These cleavage products are seen on an agarose gel when a von Willebrand multimer analysis is ordered. A mutation involved in multimer assembly and function results in Type 2 vWD.<sup>126</sup>

von Willebrand disease results from a quantitative or qualitative deficiency of vWF. If vWD is suspected, a battery of tests should be performed. Screening tests such as the aPTT and bleeding time may or may not be abnormal, especially in persons with mild vWD. More specific tests include quantitation of vWF:Ag by an immunoelectrophoretic assay (the Laurell technique) or by an enzyme-linked immunosorbent assay, a ristocetin cofactor (RCoF) assay as a measure of vWF activity, a Factor VIII assay, and multimeric analysis of vWF using sodium dodecyl sulfate agarose gel electrophoresis.

## Classification of von Willebrand Disease

A revised classification from an international subcommittee, intended to reflect the research on the function and fate of vWF and differences in pathophysiologic mechanisms that lead to particular vWD phenotypes, was recently published.<sup>126</sup> Type 1 vWD is by far the most common of the types of vWD, accounting for at least 80% of cases. The Type 2 variants account for 10% to 15%, whereas Type 3 is relatively rare (Table 28-3).

Type 1 vWD is caused by autosomal dominant heterozygous mutations. The diagnosis of vWD Type 1 is difficult because of significant variations in vWF levels as discussed above. Bleeding symptoms also vary widely with vWF:Ag ranges of 30 to 50 IU/dL<sup>-1</sup>. Linkage to a vWF gene mutation has been shown to be only 0.4 to 0.5 in patients with vWF:Ag levels >30 IU/dL<sup>-1</sup>.<sup>126</sup> The diagnosis of Type 1 vWD is characterized by a prolonged closure time on the platelet function analyzer and proportionately low levels of vWF:Ag, vWF activity, and Factor VIII. Therefore, a vWF:RCoF/vWF:Ag ratio should be proportionate (0.7-1.2) for Type 1 vWD.<sup>126,129</sup> Multimeric analysis of the patient's vWF reveals that all sizes of vWF multimers are present. In Type 1 vWD, vWF levels are subnormal, but the vWF produced is structurally and functionally normal.

Type 2 variants are characterized by qualitative defects in vWF.<sup>126</sup> Type 2A results either from decreased production or from accelerated clearance of the hemostatically important

**Table 28-3.** Laboratory Diagnosis of von Willebrand Disease and Suggested Treatment Options\*

| Condition | vWF:RCoF (IU/dL) | vWF:Ag (IU/dL)       | Factor VIII     | vWF:RCoF/vWF:Ag  | Therapeutic Options                 |
|-----------|------------------|----------------------|-----------------|------------------|-------------------------------------|
| Type 1    | <30 <sup>†</sup> | <30 <sup>†</sup>     | ↓ or Normal     | >0.5-0.7         | DDAVP/Stimate <sup>‡</sup>          |
| Type 2A   | <30 <sup>†</sup> | <30-50 <sup>‡§</sup> | ↓ or Normal     | <0.5-0.7         | DDAVP; vWF-Factor VIII concentrates |
| Type 2B   | <30 <sup>†</sup> | <30-50 <sup>‡§</sup> | ↓ or Normal     | Usually <0.5-0.7 | vWF-Factor VIII                     |
| Type 2M   | <30 <sup>†</sup> | <30-50 <sup>‡§</sup> | ↓ or Normal     | <0.5-0.7         | vWF-Factor VIII                     |
| Type 2N   | 30-200           | 30-50                | ↓↓              | >0.5-0.7         | vWF-Factor VIII                     |
| Type 3    | <3               | <3                   | ↓↓↓ (<10 IU/dL) | Not applicable   | vWF-Factor VIII                     |
| "Low vWF" | 30-50            | 30-50                | Normal          | >0.5-0.7         | Case-by-case need                   |
| Normal    | 50-200           | 50-200               | Normal          | >0.5-0.7         |                                     |

\*Adapted with permission from Sadler et al.<sup>126</sup>

<sup>†</sup><30 IU/dL is designated as the level for a definitive diagnosis of vWD; there are some patients with Type 1 or Type 2 vWD who have levels of vWF:RCoF and/or vWF:Ag of 30-50 IU/dL.

<sup>‡</sup>In nonresponsive patients, use a vWF-Factor VIII concentrate.

<sup>§</sup>The vWF:Ag in the majority of individuals with Type 2A, 2B, or 2M vWD is <50 IU/dL.

↓ Refers to a decrease in the test result compared to the laboratory reference range.

vWF:RCoF = von Willebrand factor:ristocetin cofactor; vWF:Ag = von Willebrand factor antigen; DDAVP = desmopressin.

HMW vWF multimers. The loss of HMW multimers causes a decrease in platelet-vWF interactions as expressed in a decreased vWF:RCoF assay result. Loss of HMW multimers can also cause a decrease in connective tissue-vWF interactions as measured in decreased vWF:collagen binding (vWF:CB) assay results. Patients may have normal or only slightly reduced vWF and Factor VIII levels but may have a loss in the intermediate and HMW multimers of vWF in plasma. Affected individuals usually have a mild-to-moderate bleeding tendency and generally have a poor response to DDAVP.<sup>126,129</sup>

In vWD Type 2B, mutations in the A1 domain results in a heightened affinity of vWF binding to platelet glycoprotein 1b (GP1b). Affected individuals often have mild thrombocytopenia caused by in-vivo platelet aggregation, and on ex-vivo testing, their platelets aggregate with very low concentrations of ristocetin (enhanced ristocetin-induced platelet aggregation). Upon secretion, the HMW multimers in vWD Type 2B bind spontaneously to platelets and are then cleaved by ADAMTS13 for excretion. The small multimers do not enhance platelet adhesion or connective tissue binding, resulting in decreases in vWF:RCoF and vWF:CB. Another disorder caused by a mutation on the platelet GP1b causes a similar phenotype with increased binding affinity of the platelet for vWF. This is called pseudo-vWD.

von Willebrand disease Type 2M variants have decreased affinity of vWF for platelets. This results in an increase in HMW multimers on the agarose gel testing. These multimers have a decreased activity in platelet adhesion and decreased cleavage by ADAMTS13. Similar to Type 2B, most patients with Type 2M have a mutation in the vWF A1 domain responsible for binding the GP1b.

von Willebrand disease Type 2N is an uncommon but interesting variant. It is characterized by a mutation in vWF that prevents the binding of Factor VIII but does not interfere with

platelet adhesion. Thus, uncomplexed Factor VIII is rapidly degraded in the circulation, resulting in low levels of Factor VIII, mimicking hemophilia A.<sup>126</sup>

In vWD Type 3, patients have a severe bleeding tendency and very low levels of vWF and Factor VIII. Type 3 is inherited in an autosomal recessive pattern and has levels of vWF:Ag <1 to 5 U/dL. Although the vWF:Ag levels of Type 3 can approach those of severe Type 1, the two types of vWD are almost always clinically distinguishable. In addition to severe mucous membrane bleeding, Type 3 patients may bleed into joints and soft tissues. Type 3 patients are not responsive to desmopressin, whereas type 1 patients generally are responsive (see below). Most cases of vWD Type 3 are caused by deletions, nonsense, missense, and frameshift mutations in the vWF gene.<sup>126,129</sup>

### Treatment of von Willebrand Disease

Treatment is determined by the type of vWD (Table 28-3). The goals of therapy are to increase both vWF and Factor VIII levels, which predict clinical response. Generally, raising the vWF and Factor VIII levels into the normal range (above 50%) is sufficient to alleviate the bleeding manifestations of vWD. However, a qualitative defect (Type 2 vWD) may also require completely replacing the patient's vWF with normal vWF to give a clinical response.

For persons with Type 1 vWD, the treatment of choice is DDAVP.<sup>74,76,129,130</sup> When given intravenously in a dosage of 0.3 µg/kg diluted in 50 mL saline over 30 minutes, the drug will effect a rapid three- to fivefold increase in vWF activity, vWF:Ag, and Factor VIII levels in most patients with Type 1 vWD and some with Type 2A. Generally, the increase in vWF and Factor VIII levels will last for 6 to 8 hours. It is important to give a patient with vWD a test dose of DDAVP to confirm responsiveness and to determine the magnitude of the response.

Although the magnitude of response varies among individuals, the response in a given individual is generally consistent over time (ie, threefold increases in vWF activity and vWF:Ag on one occasion are likely to be duplicated during retreatment at a later date). The dose can generally be repeated every 12 to 24 hours with efficacy. Most patients treated repeatedly over a short period do become less responsive, a phenomenon called tachyphylaxis.<sup>76</sup> Because the effectiveness of DDAVP is attributable to the rapid release of vWF from storage sites, DDAVP is ineffective in patients with Type 3 vWD, who have nothing in storage to be released. Most clinicians consider DDAVP to be contraindicated in Type 2B, because the release of the functionally abnormal vWF causes a worsening of thrombocytopenia and is hemostatically ineffective.<sup>76</sup> Although desmopressin is generally given intravenously to hospitalized patients, the highly concentrated intranasal spray formulation is ideal for home use. It provides excellent bioavailability of the drug and effects an increase of vWF similar to that obtained with an intravenous dose of 0.3 µg/kg DDAVP. The compression metered spray pump delivers 0.1 mL (150 µg) of solution per spray. The dose for children and adolescents is one spray; for adults a spray is given in each nostril. This highly concentrated intranasal spray is particularly useful for prophylaxis before invasive dentistry or other minor surgery.<sup>131</sup>

The side effects of DDAVP are generally well tolerated. Facial flushing, mild tachycardia, and headaches are often transient and mild. DDAVP does have an antidiuretic effect and rarely can cause hyponatremia, leading to seizures. This effect has been seen most often in the use of DDAVP in small children. All patients using the drug at home must be counseled to not give repeat doses within 24 hours without consulting a physician. Thrombosis has been reported in DDAVP treatment of diseases other than vWD, and in one patient with concurrent vWD and thrombophilia.<sup>76</sup>

Replacement therapy with a plasma-derived intermediate-purity Factor VIII concentrate rich in vWF is still needed in certain situations. For patients with vWD Type 1 or Type 2A whose responses to DDAVP are not sufficient (eg, for major surgery), a clotting factor concentrate containing the HMW multimers of vWF should be given.<sup>74,130</sup> For persons with vWD Types 2B and 3, concentrates rich in the hemostatically important HMW multimers of vWF should be given for the treatment of serious bleeding episodes or for surgical prophylaxis.

The optimal replacement therapy for vWD corrects both the vWF defect (quantitatively and qualitatively) and the Factor VIII concentration. Because most commercial Factor VIII concentrates do not contain the hemostatically important HMW multimers of vWF, several investigators have conducted comparative studies of various products in patients with severe vWD. Humate-P (CSL Behring) was found to contain the highest amount of HMW multimers and therefore to be most effective for patients with vWD.<sup>74,130,132</sup> This pasteurized concentrate is thought to be safer than cryoprecipitate, which is not virus-inactivated. For the treatment of severe bleeding or for major surgeries in patients with Type 3 vWD, some studies recommend a bolus dose of 60 to 80 IU vWF:RCoF/kg<sup>-1</sup> followed by 40 to 60

vWF:RCoF/kg<sup>-1</sup> every 8 to 12 hours for a few days then spaced out to daily dosing as needed for control of bleeding. A multicenter, retrospective study<sup>132</sup> showed an average daily use of 80 IU vWF:RCoF/kg<sup>-1</sup> per day for surgery coverage. The efficacy was 97% in these patients. The on-demand treatment of bleeding averaged 72 IU vWF:RCoF/kg<sup>-1</sup>/day of Humate P with an efficacy of 95% in these patients. A prospective, multicenter open-label cohort study<sup>133</sup> was conducted in patients with hereditary vWD (acquired vWD patients excluded) and a history of abnormal bleeding. The median vWF:RCoF dose after individual pharmacokinetic testing was 62.4 IU/kg<sup>-1</sup> with full control (analogous to expected bleeding in a normal patient) of intraoperative bleeding in 96.3% of the patients.<sup>133</sup>

An interesting use of DDAVP and Humate P occurred in a hemophilia treatment center in Germany. Two patients had severe hemophilia A with Type 1 vWD, one patient had severe hemophilia B with Type 1 vWD, and two patients had severe hemophilia B with Type 2 vWD. All five patients experienced more mucosal bleeding than would be expected with a diagnosis of hemophilia alone. The two of these patients with severe hemophilia B and Type 2 vWD had very difficult-to-treat bleeding with recombinant replacement of Factor IX alone. Even with prophylaxis, breakthrough bleeding was a problem. These patients responded to concurrent infusions of BeneFix and Humate P or DDAVP.<sup>134</sup>

Other agents that may be useful include the antifibrinolytic drugs, ε-aminocaproic acid and tranexamic acid. For the treatment of minor mucosal bleeding, particularly in patients with mild vWD, an antifibrinolytic drug may suffice. Antifibrinolytic agents also should be used in conjunction with desmopressin or Humate-P for invasive dental procedures, tonsillectomy, or other bleeding in the oral cavity. As is true for all coagulopathies, persons with vWD should avoid aspirin, all aspirin-containing compounds, and other drugs that interfere with platelet function.

---

## Other Inherited Disorders of Coagulation

Rare hereditary deficiencies of all the other known coagulation factors have been described, and are heterogeneous. Thus, not all affected families with a particular factor deficiency have the same bleeding tendencies. Because these disorders are inherited in an autosomal recessive pattern, patients who are homozygotes or compound heterozygotes tend to bleed more. Because no specific clotting factor concentrates are licensed and available in the United States for use in these relatively rare deficiency states, the treatment of choice for bleeding in most of them is still PCCs, plasma, or cryoprecipitate. In general, the level required to achieve hemostasis is relatively low and thus can be attained by plasma in a dosage of 10 mL/kg. Once hemostasis has been achieved, continued treatment may not be necessary.<sup>135</sup> However, plasma (solvent/detergent-treated FFP or donor-retested FFP) and cryoprecipitates have the disadvantages of potential viral contamination, volume overload, and allergic reactions.

Bleeding in persons with congenital afibrinogenemia or hypofibrinogenemia should be treated with cryoprecipitate in a dosage of four bags/10 kg of body weight. Cryoprecipitate contains approximately 200 mg of fibrinogen per bag, or “unit.” (Because of the long half-life of fibrinogen, replacement therapy is generally given every 3 to 4 days.) Although seldom necessary, additional doses of two bags/10 kg can be given every 3 to 4 days. In Europe a specific fibrinogen concentrate (treated to be virus-free) is available.

In rare hereditary factor deficiencies (ie, Factor II, V, or X deficiencies), plasma or a PCC can be used. For serious, life-threatening bleeding, PCCs should be used to achieve higher levels of the missing factor. Recombinant Factor VIIa is the treatment of choice for congenital Factor VII deficiency, for on-demand treatment and prophylaxis. The current recommended dose for surgical or invasive procedures is 15 to 30 µg/kg every 4 to 6 hours.<sup>100</sup> Deficiencies of the “contact factors,” Factor XII, prekallikrein, and HMW kininogen, are rarely associated with clinical bleeding and thus do not require treatment.

The hemorrhagic tendency in Factor XI deficiency is usually mild and independent of the Factor XI levels. On occasion excessive bruising, epistaxis, and postoperative bleeding have been observed. One study<sup>136</sup> found that bleeding tendency in tissues with fibrinolytic activity (ie, oral mucosa, tonsils, nose) was increased 49% to 67%, while the tendency to bleed in other tissues was reduced to 1.5% to 40% irrespective of Factor XI deficiency genotype. Therefore, in patients with Factor XI undergoing a procedure in areas of fibrinolytic activity, an antifibrinolytic agent with on-demand replacement may be sufficient. Patients undergoing other surgeries or procedures such as circumcision or appendectomy may require on-demand therapy only for intra- or postoperative bleeding.<sup>135</sup> FFP infused at the rate of 10 to 20 mL/kg/day usually provides sufficient Factor XI to maintain hemostasis. The aPTT, the specific assay for Factor XI, or both should be used to monitor treatment.

Congenital deficiency of Factor XIII (fibrin-stabilizing factor) is a rare disorder characterized by delayed umbilical bleeding in neonates, subcutaneous bleeding, muscle hematomas, bleeding after surgery, hemarthroses, and ICH.<sup>136</sup> It is also characterized by a lifelong bleeding tendency and impaired wound healing. Only homozygous individuals with no detectable Factor XIII activity have bleeding manifestations. Factor XIII circulates in the plasma with the A and B subunit in an A<sub>2</sub>B<sub>2</sub> tetramer. The patients with most severe disease have a deficiency in the A subunit. The prothrombin time, aPTT, and thrombin time are normal in Factor XIII deficiency. The diagnosis used to be made exclusively by testing for clot solubility in 5 mol urea, but currently both Factor XIII assays and assays for the A- and B-subunit antigens are available. Unfortunately, the clot solubility testing is useful only for patients with zero Factor XIII activity, but bleeding may still be a problem at higher levels. Additionally, it is difficult to interpret the Factor XIII levels at low levels; the accuracy of this test at levels <10% is questionable. There is no correlation between bleeding and Factor XIII levels.<sup>137</sup> Fibrogammin

P (CSL Behring), although not licensed in the United States, is available on a clinical trial basis for patients with severe Factor XIII deficiency.<sup>74</sup> Because the half-life of Factor XIII is long, prophylactic therapy with Factor XIII concentrates can be given with a monthly dosage of 250 IU in children and 500 IU in adults.<sup>138</sup> If it is not readily available for some reason, a single infusion of plasma of 5 to 10 mL/kg usually will provide effective therapy for bleeding episodes.

## Hypercoagulable States

### Congenital and Acquired Thrombophilia

Thrombophilia refers to a blood condition, whether acquired or inherited, with an increased propensity to develop thrombosis. Acquired thrombophilia is seen in autoimmune and infectious or postinfectious states. Inherited thrombophilia indicates a congenital deficiency of an antifibrinolytic agent or a genetic mutation in one of the clotting factors leading to an increase risk of thrombosis. An example of acquired thrombophilia is antithrombin deficiency. Antithrombin deficiency can be seen in nephrotic syndrome, protein-losing enteropathy, and as a side effect of the commonly used chemotherapeutic agent, L-asparaginase. Additionally, protein C and S deficiencies can be seen as a consumptive process in patients with severe sepsis and DIC.<sup>139</sup> Protein C deficiency, in particular, has been associated with an increased risk for mortality in sepsis and protein C replacement is being investigated in the treatment of meningococcal-induced purpura fulminans.<sup>140</sup> Antiphospholipid antibodies including lupus anticoagulant often occur after infections and are self-limited. Detection of antiphospholipid antibodies in the serum for 6 weeks or more connotes antiphospholipid antibody syndrome (APAS) and is more commonly seen in adolescents. APAS may be a result of lupus or other autoimmune disorders (Table 28-4).<sup>139</sup>

Genetic mutations cause hypercoagulability by decreasing the amount or function of various proteins responsible for the regulation of coagulation. These proteins include antithrombin, protein C, protein S, plasminogen, and fibrinogen. Point mutations in genes encoding prothrombin and Factor V, such as prothrombin 20210 and Factor V Leiden, represent a genetic risk factor for thrombophilia. The prothrombin 20210 mutation

**Table 28-4.** Risk Factors for Thrombosis in Children<sup>141</sup>

#### Temporary Risk Factors

- Indwelling catheters
- Surgery
- Infection

#### Ongoing Risk Factors

- Thrombophilia—genetic or acquired
- Malignancy and chemotherapy
- Inflammatory diseases
- Prosthetic heart valves
- Sickle cell anemia

causes a 15% to 30% increase in the production of the procoagulant, prothrombin. Factor V Leiden is a mutation that causes resistance of Factor V to physiologic downregulation by activated protein C. Other genetic hypercoagulable states include hyperhomocysteinemia and platelet membrane glycoprotein defects. In a recent study<sup>142</sup> involving children with stroke, laboratory testing was performed to look for a prothrombotic condition in 338 of the study participants. Of these 338 children, 64% percent had laboratory results consistent with a prothrombotic condition, 24% had a Factor V Leiden mutation, and another 12% had antiphospholipid antibodies detected.<sup>142</sup>

## Venous Thromboembolism in Infants and Children

### Incidence and Risk Factors

Venous thromboembolism (VTE) is relatively rare in the pediatric population. A multicenter Canadian VTE Registry trial<sup>143</sup> reported an incidence in the general pediatric population of 7 per million children or 5.3 per 10,000 hospital admissions in children. The risk for VTE is greatest in the neonatal and adolescent age groups with indwelling catheters representing the most common risk factor found in 33% of children with VTE. It is for this reason that VTEs in children are more commonly seen in the upper venous system, contrary to the location of VTEs in adults.<sup>144</sup> A study<sup>145</sup> that investigated the incidence of VTE in children with acute lymphoblastic leukemia treated with L-asparaginase, also studied risk factors for VTE in children with indwelling catheters. Left-sided catheters, particularly in the subclavian vein, inserted by percutaneous rather than venous cut-down technique were at greatest risk of catheter-associated VTE.<sup>145</sup> The current recommendations from the American College of Chest Physicians do not support primary anticoagulation prophylaxis in children with indwelling catheters.<sup>146</sup>

Only 3.6% of children on the Canadian Registry with VTE had thrombosis with no predisposing condition.<sup>143</sup> All others had at least one predisposing factor including catheters, cancer, congenital heart disease, infection, trauma, obesity, nephrotic syndrome, surgery, lupus, sickle cell disease, and liver failure. Twelve children had a prothrombotic condition—six had protein C deficiency and six had protein S deficiency. The contribution of a prothrombotic condition is difficult to assess from these data, because only 33% (45 of 137) of the children with VTE underwent testing for a prothrombotic condition.

Umbilical venous catheters can also be a source for clot formation. These clots often go undetected and occur in the inferior vena cava and portal vein. Clots from umbilical venous catheters can cause lobar atrophy or portal hypertension that may be discovered later in life. An incidence of 3.6 per 1000 neonates admitted to the neonatal intensive care unit at Toronto's Hospital for Sick Children has been reported.<sup>147</sup> Anticoagulation did not appear to affect the development of portal hypertension or lobar atrophy.

In a pediatric stroke trial,<sup>142</sup> 36% of the 1065 children studied had cerebral sinovenous thrombosis (CSVT) and 54% had arterial ischemic strokes (AIS). Of the children with CSVT, 39% had identifiable risk factors for VTE. The older infants and children had a statistically higher number of identifiable risk factors than the neonates. Systemic disease was an identifiable risk factor for children with CSVT. Systemic diseases included genetic syndromes, malignancy, chronic infection, hypertension, and chronic prenatal conditions. Of the children with genetic syndromes, 38.5% had Down syndrome. Other genetic syndromes were not specified but were associated with congenital heart disease or other chronic medical conditions. Acute infections were also reported more commonly in children with CSVT than those with AIS.

### Diagnosis and Treatment

The diagnostic evaluation for VTE is dependent upon the location of the suspected clot and the clinical index of suspicion. Clots related to umbilical venous catheters are best diagnosed with ultrasound and/or venography. Clots related to indwelling central venous catheters often develop in the upper venous system. The initial evaluation would include a color Doppler ultrasound, but often venography and an echocardiogram are necessary to identify the suspected clot. Doppler ultrasound carried a sensitivity of only 37% in one study,<sup>145</sup> but it has the advantage of a noninvasive evaluation. The sensitivity of bilateral venography was found to be 79%, but venography is a more invasive method of detection. Venography was the most sensitive for the central upper venous system, whereas Doppler appeared superior in the diagnosis of jugular venous clots. The diagnosis of VTE in the upper venous system should encompass Doppler sonography, echocardiography, and the more invasive alternative, venography, as needed.<sup>148</sup>

Data are limited on the optimal treatment of VTE in children. Evidence-based evaluation and management of pediatric thrombosis and thrombophilia is in its infancy. Most of the information available today is based largely on small case series or extrapolated from adult recommendations.<sup>141</sup> The agents currently available for antithrombotic therapy in children include UFH, low-molecular-weight (LMW) heparin, warfarin, and tissue plasminogen activator (tPA). UFH is an effective drug, but has a short half-life of 25 minutes in neonates (to 1 hour in adults).<sup>149</sup> LMW heparins are being used increasingly for initial therapy for acute thrombosis in children. In one study,<sup>150</sup> 53% of 190 children treated with enoxaparin for thromboembolism had complete resolution of the thrombus. Children with arterial clots and clots that were not occlusive at diagnosis were more likely to have complete resolution of their clots after taking enoxaparin. Forty-eight percent of the children with VTE had complete resolution of the thrombus; this is not appreciably different from the adult data of VTEs treated with LMW heparins. Age at diagnosis, location of the thromboembolus (excluding arterial vs venous), and initial treatment with fractionated vs UFH did not appreciably affect the complete

resolution of the clots. The mean dose of enoxaparin also did not affect the complete resolution of the clot.<sup>150</sup>

LMW heparins have many advantages over UFH and other anticoagulants in children, and they are rapidly becoming the treatment of choice for children with hypercoagulability and clots. The advantages of treatment with LMW heparin include: effectiveness equal to UFH, a lower frequency of bleeding complications, decreased incidence of heparin-induced thrombocytopenia, minimal monitoring required (the pharmacokinetics of LMW heparin are more predictable than those of UFH), decreased amount of drug-to-drug interactions, and possibly a decreased risk of osteoporosis with long-term treatment relative to UFH. The current recommended dose of LMW heparin depends on the anti-Factor Xa level in a sample drawn 4 to 6 hours after a subcutaneous dose of LMW heparin. The targeted therapeutic anti-Factor Xa level is generally 0.5 to 1 U/mL. Neonates and infants less than 2 to 3 months of age or 5 kg of weight generally require a higher dose per kilogram to maintain therapeutic anti-Factor Xa levels. Because of increased clearance in children, LMW heparins (especially enoxaparin) are administered subcutaneously twice a day.<sup>146</sup> Schobess et al<sup>151</sup> recently evaluated 80 children over 3 months of age with DVT in an open-label pilot randomized safety study, using once-a-day enoxaparin administration, with a target 4-hour anti-Factor Xa activity between 0.5 and 0.8 IU/mL. The children were stratified to receive either once daily or twice daily doses. The mean duration of treatment was 5 months, with a median follow-up of 24 months. The authors found no significant differences between the two groups with regard to the study endpoints, postthrombotic syndrome, rethrombosis, bleeding, or therapy-related death.<sup>151</sup>

Systemic or local thrombolysis should be strongly considered in children with “high-risk” clots that present within 2 weeks of symptomatic onset. Low-dose (0.03–0.06 mg/kg/hour) systemic infusions of tPA for 12 to 96 hours have been shown to be effective in children.<sup>152</sup> Warfarin, despite being an oral agent, is difficult to administer in children and requires frequent monitoring with dose adjustments.<sup>153</sup> Children with thrombophilia do not always require lifelong anticoagulation even if a genetic cause for hypercoagulability is isolated. A single thrombophilic gene mutation can certainly cause an increased risk of thrombosis in childhood; however, it is not necessarily implicated in a worse outcome or greater risk of recurrence.<sup>154</sup> For instance, no increase in DVT-related pulmonary embolus was seen in otherwise-healthy children diagnosed with thrombophilia.<sup>155</sup> An elevated D-dimer in the absence of infection or chronic inflammation can be indicative of excessive thrombin generation and suggest a need for prolonged anticoagulation. In addition, a recurrence of thrombus could be a strong indication for prolonged or possibly lifelong anticoagulation with or without an isolated genetic thrombophilia.<sup>139</sup> Because prospective randomized studies in children are lacking, one strategy to select optimal antithrombotic therapy is to tailor treatment based upon assessed risk for an unfavorable clot outcome. Manco-Johnson,

in a review of antithrombotic therapy, suggested using patient-specific and thrombus-specific characteristics to stratify the likelihood of a poor outcome.<sup>141</sup> Thus, children without underlying thrombophilia in whom a transient triggering event has resolved are classified as “low risk” while those with at least three thrombophilic traits, or those with persistence of antiphospholipid antibodies who at the time of presentation have an occlusive DVT, a Factor VIII level >150 U/dL, and a D-dimer level >500 ng/mL are considered “high risk” (Table 28-5).

### Complications

A Canadian study reports a recurrence rate of approximately 8%.<sup>144</sup> The recurrence rate is higher with increasing age of the child at diagnosis. Mortality is uncommon but occurs in 2.2% of children with deep vein thrombosis (DVT)/pulmonary embolus.<sup>156</sup>

Postthrombotic syndrome (PTS), also referred to as postphlebotic syndrome, is an important consequence of DVT. PTS describes limb pain, swelling, development of visible collateral circulation, and chronic venous insufficiency. PTS can often be severe enough to limit the child’s activity. The incidence of PTS following childhood DVT is difficult to assess and estimated between 10% and 63% depending on the study.<sup>157,158</sup> It is felt to be underreported and underdiagnosed in childhood. The wide variation in reporting has been due in part to a lack of standardization among assessment tools used to evaluate this problem in children. A pediatric scale for PTS has recently been validated in children.<sup>159</sup> PTS has been reported to increase in patients with elevated Factor VIII and D-dimer levels. A thrombolytic treatment study in high-risk pediatric DVT was shown to significantly

**Table 28-5.** Risk Assessment for Poor Outcome from a Thrombotic Event in Children<sup>141</sup>

#### Patient Characteristics

- Low-risk features
  - Transient triggering event
  - No thrombophilic trait
- Standard risk features
  - Less than three thrombophilic traits
  - Factor VIII <150 U/dL and D-dimer <500 ng/mL at the time of presentation
- High-risk features
  - At least three thrombophilic traits
  - Persistent antiphospholipid antibody >6 weeks
  - Factor VIII >150 U/dL and D-dimer >500 ng/mL at the time of presentation

#### Thrombus Characteristics

- Low-risk features
  - Thrombus resolved within 6 weeks
  - Nonocclusive thrombus
- High-risk features
  - Occlusive deep venous thrombosis
  - Persistence of thrombus at 6 weeks

decrease the incidence of PTS in children with “high-risk DVT.”<sup>160</sup> High risk was defined as acute lower extremity DVT and measured Factor VIII level  $\geq 150$  U/dL and/or D-dimer  $\geq 500$  ng/mL. The patients were stratified to receive thrombolytic therapy with an initial low-dose infusion of tPA. The tPA was continued until radiographic studies showed complete resolution of the thrombus. All of the patients received anticoagulation with either UFH to maintain a plasma anti-Factor Xa level of 0.3 to 0.7 U/mL or enoxaparin to maintain a level of 0.5 to 1.2 U/mL for at least 7 days. The long-term anticoagulation was accomplished with enoxaparin or warfarin for at least 3 months from diagnosis.

Pulmonary embolus is a well-known complication of DVT in adults, but it is likely that many cases in children go unrecognized. Pulmonary embolus occurred in 16% or 39 children with central venous catheters in the Canadian Pediatric Thrombophilia Registry.<sup>161</sup> Eleven of these children had isolated episodes, and the remaining 28 developed pulmonary embolus after catheter-related DVTs. Thirteen of the DVTs were located in the lower venous system, and 15 DVTs were located in the upper venous system. There is no single “best” imaging technique for pulmonary embolus. A positive helical computed tomography scan confirms the diagnosis, whereas a normal ventilation-perfusion scan rules this out.<sup>141</sup>

## Arterial Thromboembolism in Infants and Children

### Incidence and Risk Factors

Arterial thromboembolism occurs most often in the setting of catheter-related endothelial trauma.<sup>139</sup> In the neonatal period, umbilical artery catheterization with vascular injury precipitates the thrombus. After the neonatal period, peripheral arterial catheterization and cardiac catheterization are the most common precipitating events.<sup>144</sup> Arterial thromboembolism in childhood is rare without a catheter-related event, but some predisposing risk factors have been identified. Familial hyperlipidemia, hyperhomocysteinemia, Takayasu arteritis, Kawasaki disease, congenital arterial malformations, and congenital heart disease all serve as predisposing risk factors for arterial thromboembolism. In addition, children who test positive for lupus anticoagulant are at risk for venous and arterial thrombosis.

Arterial ischemic stroke is rare in neonates, with an estimated annual incidence of 12 per 100,000 in neonates and 0.5 to 6 per 100,000 in children older than 1 year.<sup>144</sup> In the pediatric stroke study,<sup>142</sup> 675 children had AIS; of these children, 46% had identifiable risk factors for arterial thromboembolism, and 60% had vasculopathy. Cardiac disorders were found in 11% and other chronic disease occurred in 24%. Ten of the 115 children with cardiac disease and AIS were older children with a patent foramen ovale. Approximately 65% of the children, equal numbers for CSVT and AIS, tested positive for a prothrombotic disorder.

### Diagnosis and Treatment

The diagnostic workup for arterial thromboembolism depends on the suspected location of the clot or ischemia. Angiography

is helpful for peripheral catheter-related arterial thromboembolism. The diagnosis of AIS generally is confirmed with an MRI (79% of the cases in the stroke study). Magnetic resonance angiography can be helpful for small or recurrent clots that are not well visualized on a standard MRI. Recurrent embolic AIS could occur from a cardiac defect or cardiac vegetations, which should be ruled out with contrast echocardiography.

Children who develop Kawasaki disease should be treated with aspirin therapy and IV gammaglobulin replacement within 10 days of onset. The aspirin doses should begin at 80 to 100 mg/kg/day during the initial or acute phase, up to 14 days from the onset of symptoms. Aspirin should be continued in lower doses, 3 to 5 mg/kg/day for at least 7 weeks more.<sup>146</sup>

As discussed previously, children with arterial thrombosis have been found to be more responsive to treatment with LMW heparin than children with venous thrombosis, particularly in a nonocclusive clot. LMW heparin has also been used acutely to treat children with AIS, particularly in children found to have vasculopathies, thrombophilia, or antiphospholipid antibodies.<sup>142</sup> Neonatal strokes are generally not treated and generally do not recur. Randomized clinical trials are necessary to identify the thromboembolic states that mandate treatment and determine the optimal treatments when treatment is needed.

## Summary

Hemophilia A (Factor VIII deficiency) and hemophilia B (Factor IX deficiency) are clinically indistinguishable, sex-linked coagulopathies that affect approximately 20,000 persons in the United States. Hemophilia A is the more common of the two and accounts for 80% of the cases. In the past, the treatment of hemophilia with plasma-derived products resulted in extremely high rates of hepatitis and HIV seroconversion. However, improved donor screening tests and newer virus attenuation and purification methods have resulted in much safer plasma-derived Factor VIII and Factor IX concentrates. Recombinant Factors VIII and IX concentrates are also available. Although the currently available plasma-derived Factor VIII concentrates seem to be safe in terms of both hepatitis and HIV, one cannot be absolutely sure of the safety of these products because of the risk of emerging infections. The majority of Factor VIII and Factor IX used in the United States is now recombinant (DNA-derived).

Desmopressin is considered the treatment of choice for bleeding in patients with vWD Type 1, with plasma-derived Factor VIII concentrates rich in the HMW multimers of vWF being used in those with Type 2 variants and Type 3 vWD. FFP (either solvent/detergent-treated or donor-retested) and cryoprecipitates are still used to treat many of the rare coagulation factor deficiencies, but aPCCs and rFVIIa are used more and more in rare bleeding disorders with good efficacy and limited side effects.

Venous and arterial thromboembolism in infancy and childhood have been described with increasing frequency over the past decade. The thrombus location, quality, and characteristics

of the patients (including age, genetic thrombophilia, immobility, etc) all affect the type and duration of treatment. LMW heparin or enoxaparin has been used to treat many pediatric patients with thromboembolism with good efficacy and minimal toxicities. The optimal type and duration of treatment for pediatric thromboembolism remains to be determined using prospective, randomized, controlled studies.

# Management of Congenital Hemolytic Anemias

**Bruce I. Sharon**

Associate Professor, Department of Pediatrics, University of Illinois College of Medicine and University of Illinois Hospital, Chicago, Illinois, USA

The congenital hemolytic anemias comprise a heterogeneous group of intrinsic red cell abnormalities that may be conveniently classified as disorders of hemoglobin (hemoglobinopathies and thalassemia syndromes), red cell enzyme-deficiency disorders, and abnormalities of the red cell membrane and cytoskeleton. In patients affected with any of these conditions, Red Blood Cell (RBC) transfusions may be indicated to compensate for the decreased oxygen-carrying capacity associated with the underlying anemia. In addition, pathophysiologic consequences unique to each of these disorders may lead to other indications for transfusion. The hemoglobin-related abnormalities have special significance in clinical transfusion medicine, and particular emphasis is devoted to this group of disorders.

## Hemoglobinopathies and Thalassemias

The hemoglobinopathies are characterized by structural changes affecting the protein globin portion of the hemoglobin molecule, resulting from DNA mutations in the corresponding globin genes. Most forms of thalassemia are characterized by the production of diminished quantities of globin chains that are structurally normal. In certain globin-gene disorders, the molecular defect produces both a quantitative and a qualitative abnormality; examples include hemoglobin (Hb) E (a  $\beta$ -globin abnormality) and Hb Constant Spring (an  $\alpha$ -globin abnormality). This discussion on hemoglobin disorders focuses on sickle cell disease (SCD) and the  $\alpha$ - and  $\beta$ -thalassemias.

### Sickle Cell Disease

#### Epidemiology

The geographic distribution of the sickle globin ( $\beta^S$ ) gene in the Old World is shown in Fig 29-1. The greatest concentration of

individuals carrying this gene is localized in central West Africa, where the gene frequency for sickle hemoglobin (HbS) may be as high as 0.14. Appreciable numbers of affected individuals have also been identified in other parts of equatorial Africa, the Mediterranean, the Saudi Arabian peninsula, and India. This distribution substantially coincides with regions that historically have had endemic *Plasmodium falciparum* malaria. Ample epidemiologic evidence suggests that the  $\beta^S$  gene was subject to positive selection pressure because of the survival advantage that it confers in heterozygous individuals who are infected by the malarial parasite. In the New World, the  $\beta^S$  gene arrived as a result of the importation of slaves from Africa; in North America its gene frequency is approximately 0.04 to 0.05 among those of African ancestry. (Thus, approximately 10% of African Americans are sickle heterozygotes.)

#### Molecular and Cellular Pathophysiology

The fundamental defect in SCD is the substitution of thymine for adenine in the sixth codon of the gene for the  $\beta$ -globin chain, leading to a replacement of glutamic acid by valine at this site. In contrast to normal hemoglobin tetramers, HbS has an altered surface charge that promotes the formation of lengthy polymeric chains (gelation) when in the deoxygenated state. The oxygen affinity of dilute, unpolymerized HbS is similar to that of normal hemoglobin. However, the oxygen affinity of concentrated HbS solutions is decreased,<sup>2</sup> thereby representing a further stimulus for molecular polymerization.

Once a critical nucleation step has been achieved, the polymerization process may quickly progress to form rapidly lengthening fibers, which can further organize into filaments and even thicker strands. At the cellular level, this is reflected by the conversion of normal, deformable, biconcave red cells to rigid, highly viscous cells with the characteristic sickle shape. For the most part, the process of HbS gelation and erythrocyte sickling is a reversible one, but after repeated cycles these cells may become irreversibly sickled cells (ISCs). These ISCs maintain an abnormal sickled shape even in the absence of HbS polymerization and are probably a consequence of cumulative red

**Figure 29-1.** The geographic distribution of (A) hemoglobins S, C, and E and (B)  $\beta$ -thalassemia. The regions where *P. falciparum* malaria was formerly endemic are also indicated.<sup>1(p238)</sup>

cell membrane damage sustained during repeated sickle-unsickle cycles. Irreversibly sickled cells are much more rigid than biconcave red cells and have a much shorter life span, thus appreciably contributing to the hemolytic anemia that is characteristic of this disorder. Curiously, there is no close correlation between the percentage of circulating ISCs in an individual and the clinical severity of the disease.

As the process of sickling progresses and an increasing number of cells assume the sickle shape and become rigid, blood viscosity rises sharply. This change causes a marked delay in the transit of blood through the microvasculature, which in turn leads to increased oxygen extraction at the local tissue level. The resultant decrease in hemoglobin oxygen saturation further increases the propensity toward sickling, thus completing a self-propagating cycle.

A critical determinant for the initiation of the sickling process is the intraerythrocytic concentration of deoxygenated HbS (deoxy-HbS). As the concentration of deoxy-HbS rises, the delay time (ie, the time required to achieve a critical minimum polymer nucleus) diminishes exponentially, approximately on the order of the 15th to 30th magnitude.<sup>3</sup> Several genetic and cellular (erythrocyte) modulators of disease severity have been proposed and are reviewed below.<sup>4,5</sup> Some act by altering the intraerythrocytic concentration of HbS, whereas others exert their effect through unrelated and, in some cases, undetermined mechanisms.

Genetic factors that contribute most importantly to the severity of SCD include the concurrence of  $\alpha$ -thalassemia,  $\beta^0$ - or  $\beta^+$ -thalassemia, or any of several other hemoglobin abnormalities including HbC, HbD, HbO, and syndromes of hereditary persistence of fetal hemoglobin (HPFH) (see Sickle Cell Syndromes).

Other genetic determinants of the clinical expression of SCD appear to be related to the DNA “background” on which the sickle mutation is found. The  $\beta$ -globin gene cluster is located on the short arm of chromosome 11 and contains the  $\beta$ -,  $\delta$ -, and  $\gamma$ -globin genes, whose globin chain products, in combination with  $\alpha$  chains, form hemoglobins A, A<sub>2</sub>, and F, respectively. The DNA “haplotype” of a given region is defined by the local array of restriction endonuclease fragment-length polymorphisms. Three major DNA haplotypes have been described for the African  $\beta^S$ -globin region,<sup>6</sup> and it appears that at least certain measures of SCD severity may correlate with the different DNA haplotypes, probably in large part because of the differences they mediate in fetal hemoglobin (HbF) expression. Despite the influence that these genetic factors may have on the expression of SCD, they clearly are not the sole determinants of disease severity. Individuals with apparently identical globin genotypes can vary markedly in their clinical courses.

Several erythrocyte-related factors have also been implicated as possible modulators of disease severity.<sup>4,5</sup> They include the erythrocyte levels of 2,3-diphosphoglycerate (2,3-DPG; also known as 2,3-bisphosphoglycerate) or adenosine triphosphate, glucose-6-phosphate dehydrogenase (G6PD) deficiency, calcium or zinc deficiency, the ISC count, the degree of intraerythrocytic polymerization of deoxy-HbS, and the degree of cellular dehydration.<sup>4,5</sup>

Increasingly, the role of extraerythrocytic factors in the vasoocclusive process is being appreciated. Sick erythrocytes have been shown to have abnormal interactions with coagulation and other plasma proteins, neutrophils, platelets, and vascular endothelium.<sup>7,8</sup> The consequence is a red cell environment characterized by abnormally adherent sickle erythrocytes, vascular inflammation, oxidant damage, and excessive stimulation of the coagulation system. Chronic intravascular hemolysis further contributes to these pathologic processes.<sup>9</sup> These abnormalities may lead to increased transit time through the microcirculation, or cause altered vascular tone; either consequence has the potential to enhance the likelihood of vasoocclusion. Certain interactions, such as those between neutrophils and the endothelium, result in inflammatory or oxidative injury to the vessel wall. Subsequently, damaged vascular endothelium contributes to increased adhesion of sickle erythrocytes. Thus, the vasoocclusive process is propagated by a cycle of events: sickle cell adhesion damages endothelium and vessel walls, and the damaged microvasculature in turn becomes a more potent nidus for adhesion, and ultimately, vasoocclusion. The interplay between sickle red cells and other factors in their environment that contribute to sickle vasoocclusion is illustrated in Fig 29-2.

Sickle red cells have increased adherence to vascular endothelium,<sup>11</sup> and this property appears to have a strong correlation with the severity of vasoocclusive disease.<sup>12</sup> Red cell adhesion occurs through direct interaction between erythrocyte and endothelial proteins, or through plasma proteins such as thrombospondin and von Willebrand factor, which act as bridges between red cell and endothelial binding sites. Elevated levels of red cell and endothelial binding sites, and plasma proteins contributing to adhesion, have been demonstrated in SCD.

Nitric oxide (NO) is an important vasodilator that is synthesized by the vascular endothelium,<sup>13</sup> and low levels in SCD contribute to the pathophysiology of complications such as acute chest syndrome (ACS) and stroke.<sup>14,15</sup> In addition, levels of the vasoconstrictor endothelin (ET-1) are elevated in SCD, and further contribute to increased vascular tone. Increased plasma homocysteine levels, probably related to folic acid deficiency, appear to be associated with an increased risk of stroke.<sup>16</sup>

### Mechanisms of Anemia

The anemia of sickle cell (HbSS) disease is characterized by increased peripheral destruction of the HbS-containing red cells. Progressive membrane damage to these spiny, brittle, poorly deformable erythrocytes is further intensified by secondary changes, including alterations in membrane lipid composition and oxidant damage. Erythrocyte production is substantially increased, in partial compensation for the rapid peripheral destruction. However, compensation is incomplete because of the rightward shift of the oxygen-hemoglobin binding curve that results from deoxy-HbS polymerization. The red cell life span in patients with SCD is approximately 5 to 20 days. Sickle cell complications, including acute splenic sequestration crisis (ASSC) and aplastic crisis, intensify the anemia (see Clinical Features).

Representative examples in each area are provided. Thick lines indicate binding. Please see the text for additional details.

1. Adhesion. Binding between membrane proteins on erythrocytes and endothelial cells is responsible for increased adhesion between the two. Circulating plasma factors, eg, thrombospondin (TSP) or von Willebrand factor (vWF), serve as bridges between these membrane proteins. Alternatively, direct binding may occur, eg, between  $\alpha 4 \beta 1$  integrin of the erythrocyte and VCAM-1 of the endothelial cell. In addition, erythrocytes may bind to laminin, an endothelial extracellular matrix protein. (VCAM-1 = vascular cell adhesion molecule 1; GPIb = glycoprotein Ib; BCAM/LU = basal cell adhesion molecule/Lutheran blood group; LW = LW blood group protein)
2. Erythrocyte membrane pump dysfunction. Loss of  $K^+$  and water result in intraerythrocytic dehydration, increasing the propensity for sickle polymerization.
3. Vasoconstriction/Vasodilation. The endothelium elaborates endothelin-1 (ET-1) and nitric oxide (NO). ET-1 is a potent vasoconstrictor, and may be produced in excess in sickle cell disease (SCD). NO is a potent vasodilator, and diminished production in SCD can lead to abnormal vasoconstriction. On the other hand, NO is normally inactivated by oxyhemoglobin. In a severe anemic state such as SCD, decreased hemoglobin concentration causes diminished inactivation, or relative excess, of NO. This may produce inappropriate localized vasodilation, and contribute to ventilation/perfusion mismatching seen in acute chest syndrome. NO may also inhibit endothelial adhesion of erythrocytes and platelet aggregation.
4. Leukocytes. Leukocytes in SCD are often increased in number, and demonstrate increased adhesion to both endothelium and erythrocytes. They are a source of cytokines and other mediators of inflammation.
5. Platelets. Increased platelet adhesion and aggregation, and a thrombogenic state of coagulation factors (C) may impede flow.
6. Oxidant damage. Increased generation of oxidants by sickle erythrocytes leads to denaturation of hemoglobin (Hb) and membrane lipid peroxidation.

**Figure 29-2.** Schematic representation of factors potentially influencing the vasoocclusive process.<sup>10</sup>

In addition, other conditions common in sickle cell patients contribute to anemia, including fever or infection or both, immune hemolysis, G6PD deficiency, and folic acid deficiency.

### Sickle Cell Syndromes

Because of the prevalence of other  $\alpha$ - and  $\beta$ -globin mutations within the African sickle cell population, SCD is a heterogeneous

group of disorders. In each individual syndrome, the primary determinants of sickling are the intracellular concentration of HbS and the propensity of other nonsickle globins present within the cell to participate in the polymerization process. Fetal hemoglobin is virtually totally resistant to incorporation into sickle globin polymers, whereas both adult hemoglobin (HbA) and HbC participate to some degree in this process.

**Table 29-1.** Hematologic Values Associated with Common Sickle Cell Syndromes in Adults

| Hemoglobin Genotype        | Hemoglobin Concentration (g/dL) | Mean Cell Volume (fL) | HbF (%) |
|----------------------------|---------------------------------|-----------------------|---------|
| HbAA (normal)*             | 12-18                           | 80-100                | 1       |
| HbAS*                      | 12-16                           | 82-92                 | 1       |
| HbSS                       | 6.5-9.5                         | 80-98                 | 2-20    |
| HbS/ $\beta^0$ thalassemia | 6.0-12.5                        | 63-88                 | 1.4-20  |
| HbS/ $\beta^+$ thalassemia | 6.5-14.0                        | 62-84                 | 1-15    |
| HbSC                       | 8.5-12                          | 82-92                 | 1-8     |
| HbS/HPFH†                  | 7-18                            | 75-89                 | 15-85   |
| HbSS/ $\alpha$ -thal trait | 7.5-10                          | 60-80                 | 5-20    |

\*No associated clinical disease; included for comparison.

†Hereditary persistence of fetal hemoglobin.

However, patients with HbSC disease have a higher percentage of HbS in their erythrocytes than do individuals with sickle cell trait (HbAS). In addition, HbSC erythrocytes have a membrane defect that leads to intracellular dehydration, causing a further increase in the intraerythrocytic hemoglobin concentration.<sup>17</sup> Because of both these factors, HbSC erythrocytes are far more likely to undergo sickling than are HbAS cells. As would be predicted from these differences, the relative expected disease severity is: HbSS, HbS/ $\beta^0$  thalassemia > HbSC, HbS/ $\beta^+$  thalassemia > HbS/HPFH > HbAS. Concomitant  $\alpha$ -thalassemia in individuals with HbSS disease does not appear to impose a significant change in the frequency of pain crises. However, some forms of chronic organ damage are increased in this disorder because of higher hemoglobin levels, which could lead to increased blood viscosity.<sup>18</sup> Characteristic hematologic indices of some of the important sickle syndromes are shown in Table 29-1.

### Transfusion Therapy in Sickle Cell Disease

The chronic anemia of SCD is usually well tolerated, but during intercurrent illnesses RBC transfusions may be required. Transfusions may also be indicated in order to limit or prevent vasoocclusive complications, either acute or chronic. As indicated in Table 29-2, some of the complications of SCD are characterized by both anemia and vasoocclusive manifestations. In general, for complications in which anemia is the predominant concern, traditional transfusion goals such as adequate hemoglobin concentration are appropriate. In contrast, for complications in which sickle cell vasoocclusion is the overriding concern, the primary objective of RBC transfusion is to achieve a favorable balance between the relative concentrations of normal and sickle red cells.

### Transfusion in Patients with Sickle Cell Vasoocclusion

The purpose of transfusion in the management of sickle cell vasoocclusion is to diminish the likelihood of intravascular sickling through the dilution and replacement of the recipient's sickle cells by transfused, nonsicklable cells. Clinical experience has shown that vasoocclusion is unlikely to occur with mixtures of AA (normal) and SS (sickle) cells if the relative concentration

**Table 29-2.** Acute and Chronic Complications of Sickle Cell Disease that May Require Transfusion Because of Anemia or Vasoocclusion

|         | Anemia                                                             | Anemia and Vasoocclusion                                                                                                                  | Vasoocclusion                                                                                                          |

of HbS-containing cells is less than 30% to 40%. This finding is supported by in-vitro data from Lessin et al,<sup>19</sup> who showed that the relative resistance to flow of mixtures of AA and SS red cells rose sharply when the proportion of SS cells exceeded 40%. Schmalzer et al<sup>20</sup> showed that at a fixed concentration of sickle cells ( $H_S/H_T$  or  $H_S$  alone, where  $H_T$  is the total hematocrit and  $H_S$  is the hematocrit of sickle cells), the viscosity ( $\eta$ ) rose with the hematocrit ( $H_T$ ), because of the addition of AA cells (Figs 29-3 and 29-4). These authors also showed that deoxygenation does not change the viscosity of AA cells but causes appreciable increases in the viscosity of SS cells, especially at higher hematocrits (Fig 29-3). The rise in viscosity was steepest with higher  $H_S$  values, and at fixed absolute ( $H_S$ ) or relative ( $H_S/H_T$ ) concentrations of sickle cells the effective oxygen delivery ( $H_T/\eta$ )<sup>20</sup> declined when  $H_T$  rose through the physiologic range (20% to 40%) (Fig 29-5). This effect, too, was more pronounced with higher  $H_S$  (or  $H_S/H_T$ ). These results indicate that in suspensions of normal cells ( $H_S$  or  $H_S/H_T = 0$ ), as  $H_T$  rises, the benefit provided by increased oxygen-carrying capacity is nearly equally

**Figure 29-3.** The rise of viscosity ( $\eta$ ) with  $H_T$  at given proportions of sickle cells to total cells ( $H_S/H_T$ ) in the suspension. (See text for definition of terms.)  
(A) Oxygenated cell suspensions. (B) Deoxygenated suspensions.<sup>20</sup>

**Figure 29-4.** The data from Fig 29-3 (B) replotted to show the rise in viscosity ( $\eta$ ) with  $H_T$  at various hematocrit levels of sickle cells ( $H_S$ ).<sup>20</sup>

**Figure 29-5.** The  $H_T/\eta$  ratio for suspensions containing mixtures of AA and SS cells. (A) Increasing  $H_S/H_T$  ratios cause a lowering of the  $H_T/\eta$  curve. (B) The same data as in A is plotted with constant levels of  $H_S$ . The relative merits of simple vs exchange transfusion can be analyzed by using the curves for  $H_T/\eta$  (B) to illustrate a hypothetical patient. *Point S* represents a patient with sickle cell disease with  $H_T = H_S = 20\%$  before transfusion treatment. After simple transfusion to raise the  $H_T$  to  $35\%$ , *Point S* moves along the same  $H_T/\eta$  curve ( $H_S = 20\%$ ) to *Point T*, and there is a drop of about 11% in oxygen delivery ( $H_T/\eta$ ). However, if an exchange transfusion is carried out to lower the  $H_S$  level of the patient to 5%, although the  $H_T$  is raised to  $35\%$  with AA cells, the result would be at *Point E*, where the  $H_T/\eta$  is 11% more than at *Point S* and about 23% more than at *Point T*.<sup>20</sup>

offset by the adverse effect of increased viscosity, so that the effective oxygen delivery remains nearly constant (Fig 29-5). Conversely, in the presence of sickle cells (higher  $H_S$  or  $H_S/H_T$ ), the effect upon viscosity predominates and a net decrease in the effective oxygen delivery results. These data strongly emphasize the rheologic advantages of exchange transfusion over simple transfusion when used in the management of patients with sickle cell vasoocclusion. Either type of transfusion produces relative enrichment of normal over sickle cells, but the exchange method has the added benefits of rapidly diminishing  $H_S$  and limiting the rise in  $H_T$ . Both effects are helpful in reducing viscosity and improving oxygen delivery to tissues (Fig 29-5).

The distribution of HbS among the erythrocytes significantly influences the overall likelihood of sickling. For example, in mixtures of AA and SS erythrocytes, the SS cells fully retain the capacity to sickle, whereas AA cells, of course, lack any potential to sickle. Similarly, in HbSC disease or other clinically significant compound heterozygous condition, each HbS-containing cell retains the potential to sickle under suitable physiologic conditions. When planning transfusions for managing sickle vaso-occlusion in individuals with compound heterozygous conditions, it is therefore most prudent not to focus on the percentage of the HbS, but rather to consider the percentage of cells that are sicklable. For example, if the recommendation for a particular indication in HbSS disease is to achieve a HbS concentration of 30%, it should be reinterpreted in HbSC disease to mean that transfusion should achieve 30% sicklable cells (yielding approximately 15% HbS) or an HbA concentration of 70%.

### Clinical Features

At birth, infants with homozygous (HbSS) SCD are clinically and hematologically normal because of the predominance of HbF during this period. During the ensuing several months, as the percentage of HbF naturally declines, anemia and other hematologic abnormalities become increasingly apparent. Susceptibility to clinical sequelae of SCD typically begins at 3 to 6 months of age. Various clinical findings in young children with SCD, including early onset of dactylitis (“hand-foot syndrome”), severity of anemia, and presence of leukocytosis, may be predictive for disease severity and mortality,<sup>21,22</sup> but some of these relationships (eg, early onset dactylitis) have not been found consistently.<sup>23</sup>

### Acute Sick Cell Crises

The hallmark clinical expressions of SCD are acute sickle cell “crises.”

**Acute Pain Crisis.** These episodes, which are believed to result from vasoocclusion, account for the majority of hospitalizations of sickle cell patients in the United States. Pain crises may involve practically any area of the body but most often are musculoskeletal or soft tissue in origin. These episodes may be brought on by a variety of initiating conditions, including fever, infection, acidosis, and hypoxia, but frequently there is no identifiable precipitant. Occasionally, pain crises are so severe as to be unresponsive to high-dose narcotic analgesia, and they often occur with great enough frequency to be debilitating and severely disruptive of school or work. Acute dactylitis involves the distal extremities and characteristically occurs in infancy. Frequently, this complication represents the initial identifiable clinical event in children with SCD.

RBC transfusions are rarely indicated for the treatment of severe or protracted episodes of acute pain crisis or for the prevention of frequent recurrences. When severe acute pain crisis is unresponsive to the standard therapy of intravenous hydration and analgesia, exchange transfusion designed to lower the HbS to less than 40% to 50% may produce relief. Debilitating cycles of frequent pain crises may be arrested by regular courses of

transfusion that maintain the HbS at less than 40% to 50%. However, this approach is associated with a high risk of recurrence when the transfusions are stopped.

**Acute Splenic Sequestration Crisis.** In patients with SCD, repetitive microocclusive events occur in the spleen throughout early childhood, so that by adulthood the spleen is often “autoinfarcted” and lacks any appreciable blood circulation. Before reaching this state, and primarily in early childhood, the spleen is subject to acute obstruction by sickle cells in the efferent circulation. In about one-half of reported cases, there is a history of infectious illness. The period of risk for acute splenic sequestration is typically prolonged until the early adult years in patients with the milder sickle syndromes (eg, HbSC and HbS/ $\beta^+$ -thalassemia).

Splenic sequestration is a rapidly progressive and potentially fatal process. The clinical course may progress from a state of relative well-being to circulatory shock within just a few hours. Upon presentation, the hemoglobin concentration may be as low as 2 g/dL. Volume resuscitation can be initiated with crystalloid solution followed by prompt transfusion of RBC units. The volume of RBC transfusions should be sufficient to restore baseline hemoglobin levels. One or 2 days following transfusion, splenomegaly will typically diminish and the hemoglobin will spontaneously rise, indicating resolution and liberation of formerly sequestered blood cells into the circulation.

In contrast to the typical, rapidly progressive course of acute splenic sequestration crisis (ASSC), subacute, minor episodes may be seen, especially in children with chronic hypersplenism. If splenectomy is being considered to avert recurrence of ASSC or hypersplenism, a limited transfusion program of 1 year may resolve the disease process and avoid surgery. At the least, transfusion can stave off surgery until the patient reaches an age when splenectomy would pose less risk of sepsis. As in other long-term transfusion programs intended to prevent sickle vasoocclusion, the HbS concentration should be maintained at less than 30% to 40%. However, repeated ASSC episodes have even been reported with HbS concentrations as low as 14% to 16%.<sup>24</sup>

**Aplastic Crisis.** This complication typically occurs in children of an age and history similar to those of children who experience splenic sequestration. Aplastic crisis is a transient, self-limited cessation of erythrocyte production caused in most, if not all, cases by infection with human parvovirus.<sup>25</sup> Because the life span of sickle red cells is only 5 to 20 days, any temporary cessation of erythrocyte production can lead to severe anemia within a short time.

Aplastic crisis is characteristically self-limited, and spontaneous recovery usually occurs within a few days of onset. Decisions regarding transfusion must take into account the patient’s clinical status as well as the hemoglobin concentration and any evidence of recovery, as reflected by the reticulocyte count. When possible, an early decision about transfusion helps to diminish the period of mandatory close observation and shorten the hospital stay. Transfusion to or near the baseline hemoglobin level is sufficient, and under such circumstances there need not be concern that transfusion will delay the recovery from marrow aplasia.

### Stroke

In addition to the pain episodes that apparently result from vasoocclusion, patients with SCD may also experience major, in some cases catastrophic, ischemic events. Sick cell vasoocclusion in the cerebral circulation may cause cerebrovascular accidents, producing hemiplegia, seizures, coma, or death. In children, strokes usually are caused by cerebral infarction, whereas subarachnoid or cerebral hemorrhages become more prevalent with advancing age. Over two-thirds of strokes in patients with SCD occur during childhood, and approximately 11% of children with SCD suffer from stroke.<sup>26</sup> In the absence of further intervention, approximately two-thirds of sickle cell patients with stroke will have a recurrent episode, usually within 3 years.<sup>26</sup> Functional recovery after a first stroke is variable, and subsequent episodes may produce additional and frequently more devastating sequelae. The acute mortality in adult patients is especially high and may approach 50%. Acute cerebral events that produce focal neurologic deficits lasting less than 24 to 48 hours—transient ischemic attacks (TIAs)—may be a harbinger of stroke in these patients. In sickle cell patients, chronic neurologic damage, manifest as silent cerebral infarcts (SCIs) on magnetic resonance imaging, is twice as common as overt stroke, and is associated with impaired cognitive function.<sup>27</sup> SCI is a risk factor for the development of stroke.

The primary acute therapy for stroke in patients with SCD is exchange transfusion to limit further intracerebral sickling. Exchange transfusion is preferred rather than simple transfusion because it allows a greater reduction in the fraction of circulating sickle cells, and it more rapidly improves the rheologic properties of circulating blood. In addition, the risk of stroke recurrence appears to be lower with exchange rather than simple transfusion.<sup>28</sup> At a minimum, a single-volume exchange should be performed, with the aim of achieving a HbS concentration of approximately 30%. In more severe cases, a greater level of protection may be desirable during the acute phase; a double-volume exchange would be expected to reduce the level of HbS to approximately 10%.

The recurrence rate of stroke in sickle cell patients is high. Chronic transfusion to maintain the HbS concentration below 30% to 40% has been effective in reducing the incidence and severity of recurrent neurologic events.<sup>29</sup> However, this beneficial effect may be temporary, lasting only for the duration of transfusion therapy. For example, the incidence of recurrence is reduced to approximately 10% during transfusion therapy but increases again within 1 year after the cessation of transfusions.<sup>30</sup> When transfusions are stopped after 5 to 12 years, the risk of stroke recurrence still remains elevated.<sup>31</sup> The appropriate duration of therapy, therefore, remains a vexing clinical question. Common practice is to continue transfusion until 18 years of age, if not longer.<sup>32</sup>

The following management of stroke is advised. Acute exchange transfusion aims to achieve rapid reduction of circulating sickle cells to less than 30%. If cerebral angiography is planned, a further decrease of HbS to 20% should be achieved.

Chronic transfusion therapy to maintain the HbS concentration at less than 30% is advised for at least 5 years. In order to diminish the transfusion load, it may be possible to relax the transfusion criteria after 5 years and maintain the level of HbS at less than 50%.<sup>33</sup> Beyond that period, as noted above, transfusions should be continued at least until the patient is approximately 18 years of age, and possibly indefinitely. Transfusion therapy should be monitored by hemoglobin fractionation for determination of the percentage of HbA and HbS, as well as hemoglobin and reticulocyte determinations. If frequent fractionation measurements are impractical, it may be possible to estimate an individual's transfusion requirement with reasonable accuracy by measuring the reticulocyte count and hemoglobin level after the patient's individual pattern has been established.<sup>34</sup> Complications resulting from transfusions, such as hepatitis, alloimmunization, and iron overload may necessitate early cessation of chronic transfusion. Improvements in cerebral radiographic findings should not be misinterpreted as evidence that risk of stroke recurrence has abated.

All these treatment considerations unfortunately underscore a great deficiency in the attempt to prevent stroke in sickle cell patients—they are designed to prevent a second stroke, but ignore the considerable morbidity that occurred as a result of the first event. Is there a reliable means to identify prospectively those patients who are at high risk for developing a first stroke, so that they can be offered prophylactic therapy? Children with elevated cerebral blood flow velocity, as measured by transcranial Doppler (TCD) ultrasonography, have an increased risk for developing stroke during the several years following abnormal studies. On the basis of this screening method, the Stroke Prevention Trial in Sickle Cell Anemia ("STOP") tested the hypothesis that regular prophylactic transfusions in patients with abnormal TCD findings could prevent a first stroke.<sup>35</sup> A total of 1934 children ages 2 to 16 years were screened using TCD, and 206 were found to have abnormal results. Of 130 children who were deemed suitable for the study, 63 patients were randomly assigned to receive regular transfusions designed to maintain the concentration of HbS at less than 30%, and 67 patients were assigned to receive standard care (no transfusions). During the course of the trial, 10 patients dropped out of the transfusion group, and two patients assigned to standard care transferred to the transfusion group. After a follow-up period of up to 30 months, there were 10 cerebral infarctions and one intracerebral hematoma in the standard care group, compared with one infarction in the transfusion group. Because of the obvious benefit afforded by prophylactic transfusion, this study was terminated early in order to allow patients in the standard care group to elect to receive regular transfusions.

Patients who received such primary stroke prophylaxis were more likely to revert to normal TCD findings,<sup>36</sup> suggesting that chronic transfusion can actually aid in the healing of abnormal vasculature. Is it safe to stop prophylactic transfusion after TCD velocities have normalized? A follow-up study ("STOP 2") addressed that question, and found that once preventive transfusions were stopped, many patients again developed abnormal TCD

results, or even stroke, within just a few months.<sup>37</sup> A recommended duration for primary stroke prevention has not been established. In patients with abnormal TCD results and evidence of SCI, chronic transfusion has also been demonstrated to lower the risk of new SCI.<sup>38</sup> Whether transfusion of patients with a history of SCI but normal TCD results could lower the incidence of new SCI is currently under study (“Silent Infarct Transfusion or SIT Trial”).<sup>39</sup>

Despite these promising results, many questions remain unanswered. That regular transfusions are highly effective in preventing stroke is hardly surprising. The crucial question is, given the limitations of TCD methodology, do the benefits of primary stroke prevention via chronic transfusion outweigh the risks? The positive predictive value of high-risk TCD results is only about 35% to 40%,<sup>40,41</sup> implying that a majority of patients deemed as high risk for stroke by TCD testing would be subjected to the risks of chronic transfusion unnecessarily. A recent analysis employed computer modeling to hypothetically compare the projected benefits and risks of several common primary stroke prevention strategies.<sup>42</sup> The key parameter assessed in this study was life expectancy. Several assumptions were employed in this study, including an 80% participation rate of families for whom preventive transfusions were recommended, use of the oral medication deferasirox for iron chelation, and an 80% compliance rate with that treatment. This study found that all the commonly recommended primary stroke prevention strategies employing transfusion resulted in a shorter life expectancy than no transfusion at all. In all cases, but to varying extents, the life expectancy gain produced by averting strokes was outweighed by increased mortality from iron overload. The decision model highlighted the major adverse impact that iron accumulation has in any long-term transfusion regimen. Indeed, in the analysis, if 100% compliance with oral iron chelation was assumed instead of 80%, then the adverse impact of iron accumulation was averted in virtually all the analyzed regimens. Some limitations of this study should be recognized. Some of the assumed benefits of primary stroke prevention may have been overstated because the data employed were derived from controlled clinical trials, in which rates of adherence, monitoring, and follow-up are undoubtedly better than those that would be achieved in general clinical settings. Conversely, some benefits of chronic transfusion may have been understated, because this study focused on life expectancy as an outcome, and did not address any potential improvements in quality of life.

Ultimately, it is perhaps understandable that primary stroke prevention with chronic transfusion has met considerable resistance from physicians and sickle cell families.<sup>41</sup> Alternative, effective medical strategies certainly would be highly welcome. Hydroxyurea has been found capable of lowering TCD flow velocities,<sup>43</sup> but it may not be sufficiently reliable to be clinically useful.<sup>44</sup>

### Acute Chest Syndrome

The clinical picture of ACS includes new pulmonary infiltrates on chest radiograph, often accompanied by a combination

of fever, cough, chest pain, and hypoxia. Infection is the most common cause in young children, whereas vasoocclusion is probably the most likely etiology in adults.<sup>45</sup> Especially in children, one complication can precipitate the other. Regardless of the underlying cause, the clinical course can be extremely variable; the most severe cases can progress to an acute respiratory distress syndrome (ARDS)-like picture within just a few hours.

Among those patients with an infectious etiology of ACS, the most common pathogens are *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and respiratory syncytial virus. Pulmonary fat embolism, presumably caused by infarction of bone during a vasoocclusive event, is another important cause of ACS.<sup>46</sup> Serum levels of secretory phospholipase A<sub>2</sub> (sPLA<sub>2</sub>), an enzyme that hydrolyzes phospholipids into free fatty acids and lysophospholipids, has been described as a useful biochemical marker that is markedly elevated during episodes of ACS, and correlates with its clinical severity.<sup>47</sup> sPLA<sub>2</sub> levels rise 24 to 48 hours before clinical presentation of ACS, and thus it is a useful tool to predict impending disease<sup>48</sup>; serum levels of C-reactive protein, a much more readily available test, appear to parallel those of sPLA<sub>2</sub>.<sup>49</sup>

RBC transfusions are often necessary for the treatment of this complication if it is associated with hypoxemia. Prompt treatment helps to avert clinical deterioration. In critical situations, a single-volume exchange transfusion is recommended, because this approach poses no risk of volume overload and achieves a rapid replacement of sickle cells with normal red cells. In less urgent situations, simple transfusions are usually satisfactory.

### Hepatic Crisis

Sickling in the liver produces sharp right upper quadrant abdominal pain, hyperbilirubinemia, and other abnormal liver function values. The clinical picture often resembles that seen in acute cholelithiasis. Because asymptomatic gallstones are coincidentally seen in approximately one-half of all young adult patients with SCD, it is important to distinguish between the two conditions. Treatment with supportive care generally suffices.

Acute hepatic sequestration has been rarely described, and is characterized by a rapidly enlarging liver accompanied by a significant decrease in the hemoglobin concentration. RBC transfusion may be required; in order to prevent hyperviscosity stemming from release of sequestered cells, exchange transfusion is preferred.

### Priapism

Prolonged, painful, and unwanted penile erection occurs in up to 89% of male patients with SCD<sup>50</sup> and appears to be most prevalent in sickle cell patients who have unusually high rates of hemolysis.<sup>51</sup> Common clinical pictures include prolonged erection (lasting more than 4 hours), which often results in severe pain, difficulty in urination, and even impotence, or brief episodes lasting only a few hours, which may be only moderately painful with no long-term sequelae, and which may occur in clusters (“stuttering priapism”).

Two types of priapism have been described based on blood flow patterns in the penile vasculature. High-flow priapism is caused by dysregulated arterial inflow stemming from cavernosal arterial injury, and is uncommonly associated with ischemia or pain. High-flow priapism rarely requires urgent treatment. In contrast, low-flow priapism is thought to be caused by venous sickle vaso-occlusion within the corpora cavernosa, and is often associated with localized ischemia and pain. This type is much more common in SCD, and requires prompt attention to avert long-term sequelae.<sup>52</sup>

In milder priapism of very recent onset, intravenous hydration and analgesia are the mainstays of therapy, but this approach is often insufficient. If priapism has lasted longer than 4 hours, then aspiration of the corpora cavernosa under local anesthesia with instillation of epinephrine, a mixed  $\alpha$ - and  $\beta$ -agonist, has proven to be effective.<sup>53</sup> Instillation of phenylephrine, which primarily has  $\alpha$ -agonist activity, can be used instead of epinephrine, and might be preferable.<sup>52</sup>

Simple and exchange transfusion have been employed in the management of acute priapism, but their role is unclear. Seeler<sup>54</sup> obtained satisfactory results by transfusing sufficient RBC units to double the hemoglobin concentration. In more severe or prolonged episodes (those lasting longer than 6 to 12 hours), a single-volume exchange transfusion may be considered. If this is successful, relief of pain occurs relatively soon, but complete detumescence may take several days or even weeks. If this approach is unsuccessful, a surgical shunt between the corpora cavernosa and corpus spongiosum may relieve the circulatory obstruction. If surgery is required, an exchange transfusion will have prepared the patient for anesthesia and surgery (see Special Indications for Transfusion). However, acute neurologic events, including seizure and stroke, have been reported in children who have undergone partial exchange transfusion for priapism, and the association between the two has been termed the ASPEN syndrome (association of sickle cell disease, priapism, exchange transfusion, and neurologic events).<sup>55</sup> This complication frequently begins with acute onset of severe headache. The etiology of these neurologic complications is not well understood, but it has been speculated that release of vasoactive substances is involved.<sup>52</sup> If RBC transfusions are used in the management of acute priapism, it is important to ensure that they not delay the use of more definitive therapies, such as intracavernosal injection, or shunt placement.

### **Hematuria**

Significant urinary blood loss from acute papillary necrosis in patients with SCD may require transfusions for correction of anemia. It is unclear whether transfusion accelerates healing of the renal papillae in these patients. Acute papillary necrosis has also been described in patients with sickle cell trait.

### **Infection**

Patients with SCD have impaired host defense function and increased susceptibility to infections, particularly to *Streptococcus pneumoniae* and *Haemophilus influenzae b*. In addition, bouts of infection are considerably more severe and protracted in patients

with SCD, compared to normal individuals. Sepsis may hinder erythropoiesis, as well as accelerate hemolysis. In severe infections, the red cell T cryptantigen may be exposed, leading to red cell polyagglutination.<sup>56</sup> Transfusions may be indicated in sickle cell patients with sepsis in order to improve oxygen-carrying capacity and to prevent widespread sickling that might result from associated hypoxia or acidosis.

### **Acute Multiorgan Failure Syndrome**

This relatively uncommon but life-threatening complication typically occurs after an episode of unusually severe pain crisis, and is probably caused by widespread vasoocclusion. Acute failure develops in at least two of three organs: lungs, liver, or kidney. The onset of organ failure is often accompanied by fever, rapid decrease in hemoglobin concentration and platelet count, nonfocal encephalopathy, and rhabdomyolysis.<sup>57</sup> It is curious that this catastrophic complication seems to preferentially affect patients who previously had relatively mild disease, relatively high steady-state hemoglobin levels, and no prior chronic organ damage. Aggressive transfusion therapy, either through the use of repeated simple transfusions, and/or exchange transfusions, is associated with improved survival in this severe complication.<sup>57,58</sup>

### **Chronic Effects of Sickle Cell Disease**

Chronic organ damage from SCD produces an additional spectrum of disease manifestations. RBC transfusions play a role in the management of these complications.

**Cardiac Effects.** Cardiomegaly, especially left ventricular hypertrophy, most often reflects chronic anemia, but may also result from sickle cardiomyopathy. Even though the coronary circulation is a site of high oxygen extraction, the incidence of myocardial infarction is diminished in sickle cell patients. Apparently, the short transit time through the coronary circulation is less than the delay time for sickling.

**Pulmonary Effects.** Pulmonary arterial hypertension (PAH) affects about a third of adult patients with SCD, and is associated with a significantly increased risk of death.<sup>59</sup> PAH is diagnosed by Doppler echocardiography, with a finding of tricuspid regurgitant jet velocity of at least 2.5 m/second. This condition is strongly associated with increased rates of hemolysis, a finding which supports the pathophysiologic process alluded to previously (see Molecular and Cellular Pathophysiology). Hemolysis is injurious to endothelium, and contributes to increased vascular tone by lowering levels of NO.<sup>9</sup> Chronic lung disease with ventilation-perfusion mismatch or reduction in lung volume may result from repeated or severe episodes of pneumonia or pulmonary infarction.

Sickle cell patients with the most severe PAH are treated with a variety of medical therapies, including oral selective pulmonary artery vasodilators, prostacyclin analogues, hydroxyurea, and inhaled NO.<sup>60</sup> In addition, they are often treated with exchange transfusions.<sup>59</sup> Preliminary data indicate that early stages of PAH may be reversed by transfusion therapy.<sup>61</sup>

**Hepatobiliary Effects.** Cholelithiasis occurs in approximately 40% to 50% of patients with SCD by the time they reach young adulthood, but in the majority of cases it is asymptomatic. Cholecystectomy is required for those patients who are symptomatic, but many have managed asymptomatic patients expectantly; some however, do advocate elective cholecystectomy for those with cholelithiasis who are asymptomatic.<sup>62</sup>

**Renal Effects.** The renal medulla is a hypertonic, acidotic environment that readily encourages intravascular sickling. Beginning in early childhood, intrarenal ischemia leads to an impaired ability to concentrate urine maximally (hyposthenuria). Infrequently, patients with SCD also develop nephrotic syndrome and overt renal failure. Their anemia may also worsen in the face of frank renal failure.

**Skeletal Effects.** Avascular necrosis of the femoral head produces Legg-Perthes-like radiographic changes, and is a common cause of chronic pain and debilitation in patients with SCD. This complication is associated with higher hemoglobin levels and concomitant presence of  $\alpha$ -thalassemia. Sick cell-induced infarction of the vertebral bodies is a cause of severe back pain, and is seen as a “fishmouth” appearance of the vertebrae on radiographic examination.

**Dermal Effects.** Adolescent and adult sickle cell patients are prone to develop leg ulcers, usually in the anterior tibial region or adjacent to the medial malleolus. Infection is common, and healing occurs slowly; the recurrence rate is high. When severe, leg ulcers adversely affect mobility, employability, and overall quality of life.

When local measures are unsuccessful in the management of severe ulcers, a transfusion program lasting several months may achieve satisfactory results.<sup>63</sup> However, the role of transfusion in the management of skin ulcers is debatable.<sup>58</sup>

**Ophthalmic Effects.** Patients with SCD are at increased risk for ophthalmic disease, which occurs in numerous forms.<sup>64</sup> Nonproliferative lesions, which frequently can be identified by direct ophthalmoscopic examination, affect a variety of structures, including the retina, macula, choroid, and optic disc. Proliferative retinopathy occurs primarily in adolescent or older patients with HbSC or HbS/ $\beta^+$ -thalassemia, and indirect ophthalmoscopy and fluorescein angiography are used to detect the characteristic retinal vascular changes. In severe cases, there can be progression to vitreous hemorrhage and retinal detachment, and even blindness. However, spontaneous resolution of milder disease occurs quite commonly,<sup>65</sup> and so optimal management of proliferative sickle retinopathy is not always clear. Early stages of sickle eye disease may not produce obvious vision changes; therefore, routine examinations are advised.

## Special Indications for Transfusion in Sickle Cell Patients

### Pregnancy

Pregnancy poses special risks to the mother with SCD and to her fetus. Potential maternal complications include an increased frequency of painful vasoocclusive crises, worsening of anemia, increased infection (especially urinary tract infections), toxemia,

and death. The fetus is at increased risk for growth retardation, premature birth, stillbirth, and spontaneous abortion. In mothers with HbSS disease, maternal complications and fetal death occur most frequently in the third trimester, whereas fetal death is more frequent in the first trimester in mothers with HbSC disease.<sup>66</sup> In 1971, Fort et al<sup>67</sup> reported an overall maternal death rate of more than 6% and an infant perinatal mortality rate of approximately 45% in mothers with SCD. These authors concluded that measures should be taken to prevent pregnancies in these women, including sterilization or abortion. Since 1972, the maternal death rate has been less than 2% and the perinatal death rate has been less than 5%.<sup>68</sup>

Recommendations for the prenatal care of the mother with SCD have included prophylactic transfusion at the onset of pregnancy or at the beginning of the third trimester, prophylactic transfusion only in those pregnancies considered high risk, or obstetric management without transfusion. Many of the earlier studies of transfusion in pregnant women with SCD are difficult to evaluate because of differences in design and the use of historical controls.

The most informative study to date is that of Koshy et al.<sup>69</sup> In this prospective study, 72 pregnant women with SCD were randomly assigned to receive either prophylactic RBC transfusions or only therapeutically indicated transfusions for defined medical or obstetric emergencies. Those patients assigned to the prophylactic transfusion study arm received an average of 12 RBC units during the course of pregnancy, while nearly one-half of the controls received an average of only 6.5 RBC units. When patients with high-risk factors (ie, multiple gestation or a history of previous perinatal mortality) were excluded, there were no significant differences in maternal and fetal outcome between the prophylactic transfusion and control groups, except (as might be expected) that the number of pain crises in the prophylactic transfusion group was significantly reduced. These findings suggest that prophylactic transfusion therapy may be unnecessary, and better avoided, in pregnant women with SCD who lack underlying high-risk factors.

Prophylactic transfusions have been advised for pregnancies in women with SCD who have high-risk features such as multiple gestation or history of perinatal loss.<sup>70</sup> Other indications for transfusion include toxemia, septicemia, acute renal failure, hypoxemia, and ACS.<sup>71</sup> It is important to recognize that even when high-risk features are absent, and prophylactic transfusions are avoided, between one-quarter and one-half of pregnant women with SCD will require RBC transfusion on an emergency basis because of major complications.<sup>70,72</sup> This should serve as a sobering reminder that all pregnant women with SCD require meticulous care.

### Surgery

The patient with SCD is at increased risk for perioperative complications including sudden death, pulmonary infarction, infection, and pain crisis. Changes in regional perfusion, accidents of anesthesia (eg, aspiration, difficulty in intubation, etc), or a variety of surgical circumstances may alter oxygenation, hydration,

temperature, or acid-base balance and lead to localized or generalized sickle cell vasoocclusion.

Some studies have reported favorable surgical results without the use of prophylactic transfusion. Homi et al<sup>73</sup> avoided transfusion throughout the entire perioperative period in 137 of 200 sickle cell patients who underwent surgery with general anesthesia. In the remaining patients transfusions were given either to restore the hemoglobin to baseline levels or to combat anticipated or actual blood loss. Six patients died, all during the postoperative period. Detailed transfusion information related to these fatalities was not provided, but five of the six patients had undergone emergency surgery and were in poor physical condition preoperatively. In a nonrandomized study of 66 patients with sickle syndromes (50 HbSS, 13 HbSC, 3 HbS/ $\beta$  thalassemia) who underwent 82 surgical procedures, no major differences in perioperative morbidity and mortality were seen, regardless of whether transfusions were given preoperatively, intraoperatively, postoperatively, or not at all.<sup>74</sup>

Other groups have routinely employed elective preoperative transfusion with good results. Janik and Seeler<sup>75</sup> described 32 patients with HbSS disease who underwent 46 operations following preparative RBC transfusions of 15 to 20 mL/kg, designed to increase the hematocrit to a minimum of 36%. The posttransfusion level of HbS was between 32% and 55%. In this series, there was no reported morbidity or mortality. Prophylactic exchange transfusions designed to achieve hematocrit values of more than 35% and HbA concentrations of more than 40% were administered in another study of 42 patients with SCD.<sup>76</sup> There were no reported deaths, and postoperative complications were infrequent and unremarkable; there were no apparent cases of vasoocclusive crisis or pulmonary embolus. Preoperative exchange transfusions have also been given successfully to patients with SCD before vitreoretinal surgery in order to diminish the risk of anterior segment ischemia.<sup>77</sup>

The Preoperative Transfusion in Sickle Cell Disease Study Group has provided the most comprehensive comparison of conservative and aggressive transfusion regimens. In 1995, this group reported results from a prospective study of 551 patients (a total of 604 operations), some of whom were randomly assigned to one of two transfusion regimens.<sup>78</sup> The aggressive transfusion regimen was intended to achieve a HbS concentration of 30% or less, while the conservative transfusion regimen sought to attain a minimum hemoglobin concentration of 10 g/dL. Although some overlap existed in the hematologic features of the two groups, data were analyzed on an intent-to-treat basis. Cholecystectomies, and otolaryngologic and orthopedic procedures accounted for more than three-fourths of the operations performed. A serious or life-threatening complication, most commonly ACS, was experienced by about 20% of the patients in each group. The aggressively transfused group used twice as many RBC units and had twice the alloimmunization rate, in comparison with the conservatively managed group.

The study group reported a subset of 364 patients who underwent cholecystectomy, using either traditional (58% of patients)

or laparoscopic techniques (42% of patients).<sup>79</sup> In this study, 110 patients were randomly assigned to receive aggressive preoperative transfusion, 120 patients were randomly assigned to receive conservative transfusion, 37 patients were nonrandomly assigned to receive no transfusion, and 97 patients were nonrandomly assigned to receive transfusion. Among all groups combined, the total complication rate was 39%, and sickle cell events occurred in 19%. However, patients who were nonrandomly assigned to receive no transfusion had a sickle cell complication rate of 32%. Patients who underwent laparoscopic procedures had longer anesthesia time but shorter duration of hospitalization, compared with those who had an open abdominal procedure. The incidence of complications did not differ between these two groups.

In a review of 118 patients who underwent elective tonsillectomy and adenoidectomy or myringotomy, and who were randomly assigned to either conservative or aggressive preoperative transfusion protocols, the study group found no major differences in complication rates.<sup>80</sup> About one-third of all patients experienced serious, nontransfusion-associated complications.

In all these reports, the study group concluded that a conservative preoperative transfusion regimen had equivalent efficacy to an aggressive transfusion regimen in preventing perioperative complications. Furthermore, the conservative transfusion regimen was associated with one-half the transfusion-associated complications. Therefore, a conservative preoperative transfusion approach was advocated. However, other interpretations of the data should be considered as well. For example, because of the overlap in percentage of HbS achieved between the aggressively and conservatively transfused groups, the two groups may not have differed from each other sufficiently to produce clinically distinct outcomes. Also, the aggressively transfused group may not have been transfused intensely enough to provide adequate physiologic protection from sickle cell events. The experience from Duke University supports the latter hypothesis: a very low complication rate was experienced by sickle cell patients there who were preoperatively transfused to mean hemoglobin values of 11.2 g/dL and an average of 21% HbS.<sup>81</sup>

Based upon all these results, the following guidelines would seem to be appropriate for most sickle cell patients who are undergoing surgery:

1. The most critical aspect of perioperative management is meticulous anesthetic and surgical care, avoiding hypoxemia, dehydration, acidosis, and hypothermia.
2. Preoperative RBC transfusions are warranted when prolonged general anesthesia is used or anticipated (ie, when there is reasonable likelihood that local anesthesia will prove to be inadequate). For uncomplicated minor procedures in which brief inhalation anesthetic is used (eg, some dental procedures), transfusion is seldom necessary.
3. The specific method of transfusion—regular or partial exchange—is not as important as the hematologic endpoint. A preoperative HbS of 30% to 40% and hemoglobin concentration in an intermediate range (10 to 12 g/dL) are desirable,

based upon empirical clinical experience and data cited previously. Special surgical situations characterized by low regional blood flow, especially if in a critical anatomic site (eg, major cardiac, orthopedic, or neurosurgery), may warrant even more aggressive preoperative transfusion. The choice of the method of transfusion largely depends upon the clinical circumstance. When surgery is urgent, a single-volume exchange transfusion (60 to 70 mL/kg) will rapidly achieve the hematologic goal, but when sufficient time is available before elective surgery, repeated regular transfusions over 2 to 4 weeks can be employed, with the attendant benefits of greater technical ease, lower procedural risk, and possibly a lower overall transfusion requirement.

4. In the various compound heterozygous sickle syndromes (with the exception of HbS/ $\beta^0$  thalassemia, which has a hemoglobin pattern similar to that of HbSS disease) it is safest not to monitor the percentage of HbS per se, but to consider the percentage of sicklable cells.

5. In most circumstances no special measures need to be taken in the preoperative management of patients with sickle cell trait. Patients with sickle cell trait probably do not even require transfusion before cardiopulmonary bypass.<sup>82</sup> However, prophylactic transfusion may well be appropriate for patients with sickle cell trait who will be undergoing orthopedic surgery requiring prolonged tourniquet application, although this view is not universally held.<sup>83</sup>

### Radiologic Imaging

Cerebral or coronary angiography in patients with SCD should be performed only after prophylactic transfusion has achieved a HbS concentration of less than 20% and with adequate hydration.<sup>84</sup> Magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) have largely supplanted catheter angiography for neuroimaging in SCD, and can be safely performed using gadolinium contrast without concern for inducing vasoocclusion.<sup>85</sup> Intravenous urography may be performed without preparative transfusion, but vigorous hydration should be maintained both before and after the procedure.

## Donor Selection and Transfusion-Related Complications in Patients with Sickle Cell Disease

### Alloimmunization

Sensitization to transfused red cell antigens (alloimmunization) may lead to an inconvenient and costly delay or even a life-threatening inability to find compatible blood. In addition, significant alloimmunization in patients with SCD may result in delayed hemolytic transfusion reactions (DHTRs) that are often serious and occasionally even lethal. Whenever there is a prolonged or repeated requirement for transfusion, it is prudent to obtain a full red cell antigen profile (including, for example, C, E, K, Fy<sup>a</sup>, and Jk<sup>b</sup> phenotypes) of the recipient before transfusion therapy is initiated. This information will be very useful later if alloimmunization is suspected.

Studies of adult and pediatric patients who have been transfused suggest that the overall risk of alloimmunization in SCD is

about 20% to 30%. Many of these studies, however, were retrospective and did not examine the patients' transfusion histories before the study.

Patients who are frequently transfused appear to be somewhat more likely to develop alloantibodies than those who receive infrequent transfusions. Chronically transfused patients who develop alloantibodies often appear to do so early in their transfusion courses<sup>86</sup> and are also more likely to develop multiple alloantibodies. In this regard, patients with SCD appear to be similar to the population at large: there is a subpopulation of "hyperresponders" who readily become alloimmunized, but the majority are nonresponders in spite of numerous transfusions.<sup>87</sup> Approximately one-half to two-thirds of alloantibodies identified in patients with HbSS disease have been directed at antigens of the Rh blood group system, and the majority of these are anti-Rh(E). Anti-Kell (K) and anti-Kidd (Jk<sup>a</sup> and Jk<sup>b</sup>) account for approximately 20% of alloantibodies in transfused patients with SCD.<sup>87</sup> Lewis antibodies account for up to one-third of alloantibodies, but as in the general population these are generally regarded as "naturally occurring" and do not appear to be clinically significant.

The impact of racial differences between donors and recipients on the rates of alloimmunization of patients with HbSS disease has been examined in several studies. Overall, approximately 20% to 30% of transfused patients with SCD become alloimmunized, in comparison with 5% to 10% of thalassemia patients who are transfused in the United States.<sup>88</sup> The increased incidence of alloimmunization in patients with SCD has been attributed to the greater disparity in race and red cell phenotypic profile that exists between typical blood donors and sickle cell recipients, in comparison with other recipients.<sup>88,89</sup> In many urban centers, often 90% to 95% of blood donors are of European ancestry<sup>88,89</sup> and often possess a variety of Rh, Duffy, Kell, and Kidd antigens that are less frequently found in recipients of African ancestry.<sup>90</sup> Orlina et al<sup>89</sup> calculated that a Black recipient has a 33% chance of compatibility for these antigens from a Black donor pool, in comparison with an only 3% chance of compatibility with the typical urban donor pool of 90% White and 10% Black donors. However, 70% to 80% of Black populations are Fy(a-b-), whereas more than 99% of White populations are positive for one or both antigens, yet the frequency of Duffy alloimmunization in transfused sickle cell patients is only 15% or less.<sup>87</sup> When the blood donor and recipient belong to different racial groups, the risk of alloimmunization depends not only on whether the two populations have different frequencies of blood group antigens but also on the intrinsic antigenicity of each blood group antigen.

Previous recommendations have included selecting donors 1) according to an extended red cell antigen profile, so that compatibility is achieved for Kell and secondary Rh group antigens (ie, C and E), 2) according to race, and 3) according to no special criteria other than the standard ABO group and Rh(D) type.

If any special preselection of donors is performed, it should be maintained on a regular basis, because hyperresponders often

become immunized after only 10 to 20 transfusions. Under most circumstances, it is not cost effective or feasible to pre-select donors for sickle cell patients. Routine donors are usually acceptable. If a patient with SCD has clinically significant alloantibodies, then specific compatibility testing must, of course, be performed. Because of the existence of hyperresponders, it is advisable to match as closely as possible all individuals who have developed one or more alloantibodies. In such cases, the search for compatible blood is hastened by screening units obtained from same-race donors.<sup>88</sup>

### ***Delayed Hemolytic Transfusion Reaction***

This complication is caused by acute destruction of transfused red cells beginning several days after transfusion. It is typically caused by an alloantibody to a blood group antigen produced in anamnestic fashion in a previously sensitized patient. Clinically, delayed hemolytic transfusion reaction (DHTR) is characterized by fever and a precipitous decrease in hemoglobin, often to levels lower than those that existed before transfusion. Hemoglobinuria is often seen, resulting from intravascular hemolysis. DHTR has distinctive features when present in patients with SCD, and thus it may even constitute a unique syndrome in this setting.<sup>91</sup> It occurs in about 5% to 20% of regularly transfused patients with SCD, an incidence considerably higher than that seen in other multitransfused populations.<sup>92</sup> Pain is commonly experienced by sickle cell patients with DHTR and it may be readily confused with that from vasoocclusive crisis. Marked reticulocytopenia is occasionally seen, which contributes to the anemia. When DHTR is suspected, serial hemoglobin fractionation may be a useful means to document alloimmune hemolysis, by showing a rapid fall in donor-cell-derived HbA. However, although hemolysis of donor red cells is typically the principal concern, destruction of autologous cells can occur as well through a phenomenon that has been referred to as “bystander hemolysis.”<sup>93</sup> In this process, antigen-negative red cells are destroyed by autoantibodies with an indeterminate specificity, or by deposition of antigen-antibody complexes on red cell membranes, causing complement activation and lysis of red cells. These reactions are an especially serious threat, because this potentially life-threatening complication is not always prevented by the use of phenotypically matched blood. Corticosteroids, intravenous immune globulin, and erythropoietin have been used to treat this complication. In the face of a DHTR, additional transfusion should be avoided whenever possible in order to prevent exacerbation of the hemolytic process.

### ***Blood from Sickle Cell Trait Donors for Patients without Sickle Cell Disease***

The oxygen-carrying capacity of HbAS blood is comparable to that of normal (HbAA) blood, and in the great majority of general, elective transfusion settings, HbAS blood may be transfused without any untoward consequence. However, this blood should be avoided in neonates (especially ventilator-dependent premature infants), in patients with severe cardiopulmonary illness or shock, and in those who require high-volume

blood transfusions (eg, in cases of severe acute hemorrhage). All of these conditions are sometimes associated with hypoxemia and acidosis severe enough to cause sickling of sickle trait erythrocytes. Leukocyte reduction filters often are unsuccessful, and HbAS erythrocytes sometimes hemolyze during the process of deglycerolization.<sup>94,95</sup> *Accordingly, RBC units destined for leukocyte reduction or frozen storage should be screened to detect, and possibly eliminate, units containing sickle cell trait.*

Because HbAS blood is acceptable for routine transfusion to individuals without sickle cell disease, there should be no objection to using autologous transfusion in patients with sickle cell trait, as long as none of the risk factors cited above is present.<sup>96</sup>

### ***Blood from Sickle Cell Trait Donors for Patients with Sickle Cell Disease***

Blood obtained from donors with sickle cell trait is undesirable for use in patients with SCD, primarily because the resultant mixture of HbSS and HbAS cells will obfuscate hemoglobin fractionation results that are generally used to monitor the progress of transfusion therapy. In addition, in nearly all sickle cell conditions requiring transfusion therapy, there is a danger of progressive sickling. As noted above, even HbAS blood can sickle under severely unfavorable physiologic conditions and thus should be avoided.

## **Thalassemias**

### ***Epidemiology***

The frequency of thalassemia genes in world populations is surprisingly high, with the thalassemias in aggregate representing the most prevalent of all known genetic diseases.<sup>97</sup> Occasional individuals with thalassemia have been observed in native populations in virtually all areas of the world where they have been sought, but most cases are concentrated within a broad subtropical “thalassemia belt” extending from Western Europe to Southeast Asia (Fig 29-1). Within this region there are areas with especially high frequencies of thalassemia genes, with as many as 50% of some populations having one or more forms of thalassemia.

The characterization in recent years of the underlying mutations of the thalassemia syndromes has added considerably to our understanding of the population genetics of these disorders. In general, each of the geographic areas with a high prevalence of thalassemia, particularly the  $\beta$  form, has a characteristic and often unique group of thalassemia mutations. In most of these populations, a small number of mutations account for most of the observed cases. These mutations probably arose independently in each population, and they achieved high frequency because of strong selective pressure. There is considerable information suggesting that resistance to *P. falciparum* malaria is the selective force responsible for the high frequency of thalassemia. One line of evidence in support of this hypothesis is the geographic concurrence of the “thalassemia belt” and the areas where malaria was formerly endemic (Fig 29-1).

Molecular Basis for the Thalassemia Syndromes

More than 200 distinct thalassemia mutations are now known. A summary of the major categories of these molecular abnormalities is shown in Table 29-3; a detailed description is given elsewhere.<sup>1(pp194-195)</sup> In spite of the considerable diversity of forms and sites of mutations in the globin genes, as well as the variety of mechanisms by which they lead to inhibition of globin-chain synthesis, the clinical phenotypes of most forms of thalassemia are similar (see below). For most clinical purposes, therefore, the identification of the specific mutations of thalassemia patients is of little importance. However, for prenatal diagnosis, and because of the potential for ameliorating the effects of thalassemia genes, this information may eventually assume fundamental significance.

Pathophysiology

In most of the symptomatic forms of thalassemia, the pathophysiology follows the same mechanism. The pathogenesis of homozygous  $\beta$ -thalassemia (“Cooley anemia”) serves as a representative example.

Marrow erythroid cells of affected individuals exhibit a diminution or absence of hemoglobin  $\beta$ -chain synthesis. Although this defect is partially compensated for by an increase in the synthesis of HbF  $\gamma$  chains, a major disparity nevertheless exists between  $\alpha$ -chain and non- $\alpha$ -chain synthesis (Fig 29-6), with  $\alpha$ -chain synthesis occurring in considerable excess. The deficiency of  $\beta$  and  $\gamma$  chains results in severe underhemoglobinization of the red cells because of insufficient quantities of HbA ( $\alpha_2\beta_2$ ) or HbF ( $\alpha_2\gamma_2$ ).

The excess of uncombined  $\alpha$  chains that accumulate in the red cells of these patients is also responsible for other deleterious effects. Uncombined  $\alpha$  subunits are unstable and precipitate within erythrocytes. This process, which is accompanied by oxidation of heme iron, releases superoxide ions, which in turn inflict oxidative damage on intracellular, and particularly membrane, components of the red cell.<sup>98,99</sup> In severe forms of  $\beta$ -thalassemia, the latter process results in destruction of a major fraction of erythroid cells, even before they are released from the marrow, producing what has been termed “ineffective erythropoiesis.” In compensation for this process, these patients

develop an enormous expansion of their marrow, a change that produces characteristic bony deformities most apparent in the skull and face. The resulting anemia in the most severe forms of homozygous  $\beta$ -thalassemia ( $\beta^0$ ) is incompatible with long-term survival unless periodic transfusions are given.

Compound Heterozygous Forms

In geographic areas with high frequencies of thalassemia, both  $\alpha$ - and  $\beta$ -thalassemia alleles may coexist in the same population, and both types of abnormalities may therefore occur in the same individual. The combination of homozygous  $\beta^0$ -thalassemia with concomitant  $\alpha$ -thalassemia produces a clinically mild form of

**Figure 29-6.** Synthesis of globin chains by erythroid cells from a normal individual (top), a patient with  $\alpha$ -thalassemia (middle), and a patient with severe  $\beta^0$ -thalassemia (bottom).<sup>1(p192)</sup>

**Table 29-3.** Examples of Molecular Abnormalities of Thalassemia Genes

| Abnormality                                                             | Consequence                                                                        |
|-------------------------------------------------------------------------|------------------------------------------------------------------------------------|
| Globin-gene deletions, partial or complete                              | Absence of globin synthesis; formation of fusion genes; elevated expression of HbF |
| Nucleotide substitutions in the promoter regions                        | Inhibition of globin-gene transcription                                            |
| Nucleotide substitutions or deletions at splice-junction sites          | Prevention of the formation of normal globin messenger RNA (mRNA)                  |
| Nucleotide substitutions in the coding segments or introns              | Abnormally spliced globin mRNA                                                     |
| Nucleotide substitutions in the transcription-termination signal region | Formation of abnormal globin mRNA                                                  |
| Nucleotide substitutions in translation-initiation codons               | Inhibition of mRNA translation                                                     |
| Nucleotide deletions or insertions                                      | Formation of premature termination codons                                          |
| Nucleotide substitutions in the translation-termination codons          | Production of extended-length globin chains                                        |
| Mutations that produce highly unstable globin chains                    | Rapid degradation of globin chains within the erythrocytes                         |

Cooley anemia,<sup>100</sup> undoubtedly because a more nearly normal balance is achieved between  $\alpha$ -chain and  $\beta$ -chain synthesis, so that the harmful series of events described above is attenuated.

Hemoglobin E, an abnormal hemoglobin prevalent in Southeast Asia, produces thalassemia-like hematologic effects, possibly by two separate mechanisms. First, HbE is an unstable variant and may undergo  $\beta$ -chain loss by intracellular precipitation or degradation or both. Second, the HbE mutation produces an aberrant splicing site, leading to a decreased production of  $\beta^E$  messenger RNA (mRNA).<sup>101</sup> Large series of patients with the compound heterozygous combination of HbE and  $\beta^0$  thalassemia have been reported.<sup>102</sup> This syndrome has variable expression, with more severely affected individuals requiring periodic transfusions to maintain adequate hemoglobin levels.

### Homozygous $\beta$ -Thalassemia (Cooley Anemia)

#### Clinical Features and Natural History

The clinical and hematologic features of the major forms of  $\beta$ -thalassemia are summarized in Table 29-4. Because the molecular abnormalities that cause these disorders are within, or in close proximity to, the  $\beta$ -globin genes, the onset of expression of  $\beta$ -thalassemia occurs some months after birth when HbF is replaced by HbA. Affected infants are therefore normal at birth, and evidence of the disease first appears by the middle or end of the first year. Anemia gradually develops, accompanied by progressive enlargement of the liver and spleen and cardiovascular changes related to congestive heart failure. A large fraction of the cardiac output is shunted through the hypertrophied marrow of untransfused thalassemia patients and this change contributes to an expansion of the plasma volume, resulting in increasing

hemodilution and worsening cardiac failure. Before the introduction of modern transfusion methods, the size of the spleen and the liver in these patients progressed to a massive degree, primarily because of reticuloendothelial cell proliferation. Hyperexpanded marrow also results in a thinning of cortical bone, predisposing these children to fractures. Craniofacial bone deformities are variable in degree but often severe, frequently resulting in considerable malocclusion caused by maxillary hyperplasia. In the absence of transfusion support, children with severe  $\beta$ -thalassemia succumb to the effects of anemia and heart failure within the first years of life. Milder forms of  $\beta$ -thalassemia are accompanied by a slower rate of progression and correspondingly longer survival.

#### Transfusion Therapy for Patients with $\beta$ -Thalassemia

The earliest transfusion regimens for patients with  $\beta$ -thalassemia consisted of administering mainly whole blood as infrequently as possible and only when severe anemia developed.<sup>102</sup> This form of management protected these children from early death from progressive heart failure but did not mitigate the full expression of the disease. A critical turning point in the approach to the transfusion management of  $\beta$ -thalassemia patients came in 1964, when reports by Schorr and Radel<sup>103</sup> and Wolman<sup>104</sup> compared the clinical status of patients whose hemoglobin levels had been maintained at different levels. The principal finding was that children with thalassemia fared better if their hemoglobin levels were maintained above 8 g/dL. Compared with other  $\beta$ -thalassemia patients, the group with a high hemoglobin level exhibited more normal growth, a lesser extent of liver and spleen enlargement, less bony deformity and orthodontic abnormalities,

**Table 29-4.** Clinical and Hematologic Features of the Major Forms of  $\beta$  Thalassemia

| Type                             | Hemoglobin Findings                                                                 | Hematologic Changes                                                                                         | Clinical Features                                                                                          |

| <b>Homozygous</b>                |                                                                                     |                                                                                                             |                                                                                                            |
| $\beta^+$                        | F, 30-95%                                                                           | Markedly abnormal red cell morphology with microcytosis and hypochromia, nucleated red cells; severe anemia | Pallor, jaundice, bone deformities with abnormal facies, hepatosplenomegaly, usually transfusion-dependent |
| $\beta^-$                        | F, 40-80%                                                                           | Poikilocytosis, anisocytosis, target cells; moderate anemia                                                 | Pallor, hepatosplenomegaly, jaundice; transfusions not usually required                                    |
| $\delta\beta$ (high F)           | F, 100%                                                                             | Poikilocytosis, anisocytosis, hypochromia, microcytosis; mild to moderate anemia                            | Mild jaundice, hepatosplenomegaly usually present                                                          |

and a considerably lower frequency of cardiac enlargement. Although these patients had received a larger number of transfusions and had correspondingly higher levels of iron stores, their considerably improved clinical status demonstrated that, at least in younger children, the hemoglobin level was more important than iron overload as a determinant of clinical status.<sup>104</sup>

The findings from these studies led rapidly to the introduction of transfusion regimens that sought to maintain higher hemoglobin levels, usually higher than 9.5 or 10 g/dL. This approach, frequently referred to as “hypertransfusion,” usually consists of RBC transfusions of about 20 mL/kg, given whenever the patient’s hemoglobin falls below the targeted level. Once these patients are fully transfused, the requirement to maintain them on the hypertransfusion regimen is no greater than that needed to maintain patients at a lower hemoglobin level.<sup>105</sup> Immediate posttransfusion hemoglobin levels typically average 14 g/dL, returning to baseline after 3 to 6 weeks. Hypertransfusion is also accompanied by a reduction in gastrointestinal absorbance of iron.<sup>106</sup> The rate of iron accumulation can therefore be lessened while maintaining a more desirable hemoglobin level.

In addition to improved clinical status, the correction of anemia by hypertransfusion also exerts a suppressive effect on the erythropoietic drive that causes marrow hypertrophy. The bony abnormalities, which in the past were so characteristic of this disease, are now entirely preventable,<sup>107</sup> and these patients now experience no increased risk of fractures. In addition, the marrow suppressive effect of hypertransfusion prevents the release of the deformed, short-lived Cooley anemia erythrocytes and delays the onset of hypersplenic changes, permitting splenectomy to be postponed safely until an older age.

Appropriately transfused patients with Cooley anemia gradually experience increasing splenomegaly caused by reticuloendothelial proliferation. Although this process is considerably delayed by hypertransfusion, it cannot be totally prevented. The development of hypersplenism shortens the transfusion interval and increases transfusion requirements. Piomelli and Loew<sup>108</sup> have suggested that RBC transfusion of more than 200 mL/kg per year in these patients is usually an indication for splenectomy.

Propper et al<sup>109</sup> have proposed a transfusion regimen for Cooley anemia that maintains the hematocrit above 35%, but this “supertransfusion” approach is no longer recommended.<sup>97</sup> Indeed, moderate transfusion regimens that target a baseline hemoglobin level of 9 to 10 g/dL appear to offer the best combination of preventing the long-term adverse consequences of anemia and excessive erythropoiesis, while minimizing iron accumulation.<sup>110</sup>

Individuals with heterozygous  $\beta$ -thalassemia ( $\beta$ -thalassemia trait) ordinarily have no special need for transfusions. An exception is during pregnancy, when women with thalassemia trait often develop more severe anemia<sup>111</sup> and occasionally require transfusion support.<sup>112</sup> Those who have inherited a combination of both mild and more severe  $\beta$ -thalassemia mutations, termed thalassemia intermedia, exhibit a variable clinical course; some experience a mild clinical course that rarely requires intervention,

while others may require regular RBC transfusions, at least for some period.<sup>113</sup>

### $\alpha$ -Thalassemia

Wasi et al,<sup>102</sup> in summarizing their experience in Thailand with a large number of patients with HbH disease (Table 29-5), showed that this syndrome often produced Cooley anemia-like changes, with anemia, bony deformities, and splenomegaly. However, these changes appear to reflect, in part, the effects of infections and other environmental factors superimposed upon the genetic abnormality. HbH disease in the United States generally exhibits a relatively mild thalassemia-intermedia-like syndrome and seldom requires blood transfusion except during surgery.

The hydrops fetalis form of  $\alpha$ -thalassemia, in which  $\alpha$ -chain synthesis is totally lacking, has until recent years been invariably fatal, the infants surviving no longer than a few hours after birth.

A few recent examples have been reported of such infants who received vigorous resuscitative measures, including transfusions at birth, with survival beyond the neonatal period.<sup>114</sup> This syndrome is characterized by the production almost exclusively of homotetramers of  $\gamma$  and  $\beta$  chains (Table 29-5). These abnormal hemoglobins have virtually no physiologically useful oxygen-transporting capacity because of their very high oxygen affinity. Infants who survive are therefore at great risk of developing hypoxic encephalopathy during the neonatal period and are totally dependent on transfused RBC units throughout their lives.

### Effects and Management of Chronic Transfusion Therapy Hemosiderosis

Each RBC unit contains approximately 250 mg of iron. Unfortunately, physiologic mechanisms for the elimination of excess iron are lacking. Signs of clinical toxicity often become apparent when total body iron reaches 400 to 1000 mg/kg of body weight, and levels in excess of this are potentially lethal.<sup>115</sup>

Once reticuloendothelial sites of iron storage become saturated, parenchymal deposition increases and tissue damage ensues. The primary targets of iron toxicity are the heart, liver, pancreas, and other endocrine organs. Hepatotoxicity, expressed initially by fibrosis and subsequently cirrhosis, is the most common early manifestation of transfusion-related iron overload. Cardiac toxicity, causing cardiomyopathy and arrhythmia, has been the most frequent cause of death in chronically transfused patients.

The most practical measurement of body iron stores is the serum ferritin concentration, which is in equilibrium with storage iron up to a level of approximately 4000  $\mu$ g/L.<sup>115</sup> However, in the face of a high total body iron burden, and in a variety of disease states (eg, acute inflammatory conditions, hepatocellular damage), the reliability of serum ferritin as a marker for the total body iron burden diminishes. Serum ferritin is probably even less reliable as a marker of total body iron in patients with SCD.<sup>116</sup> The hepatic iron concentration determined from liver biopsy specimens is an excellent indicator of total body iron stores in

patients with thalassemia major.<sup>116</sup> Despite the relative difficulty in obtaining such specimens, this method is recommended for the reliable measurement of the total amount iron stored in the body.<sup>117</sup> A superconducting quantum interference device susceptometer measures body iron noninvasively and produces results equivalent to those obtained by liver biopsy, but this method is available in just a few centers worldwide.<sup>116</sup> MRI has been used to assess levels of iron in the liver, has recently been standardized, and may soon become the optimal method for the indirect measurement of iron in the liver.<sup>118</sup> MRI measurement of iron in the heart has also been studied, but this technique has not been fully standardized.<sup>116,117</sup>

When faithfully administered, treatment with daily subcutaneous deferoxamine has been shown to arrest or even reverse hepatic<sup>119</sup> and cardiac<sup>120</sup> iron toxicity in thalassemia patients, especially when started early in the course of transfusion therapy. This drug has also been effective in patients with sickle cell anemia.<sup>121</sup> Deferoxamine is usually prescribed in a daily dose of 50 to 75 mg/kg of body weight, administered subcutaneously over 8 to 12 hours (usually overnight) via a portable infusion pump. Because of the parenteral route of administration and the special measures required to use the pump, this agent is cumbersome to administer. The infusion may also be painful, especially for children. Not surprisingly, compliance is often poor, thus limiting the effectiveness of this therapy.

Oral iron chelators have been developed that offer the promise of far greater ease of administration, and hopefully, improved compliance. Deferiprone has been studied for over 20 years, and is currently available in Europe. Concerns were initially raised that deferiprone could be linked to an increased incidence of hepatic fibrosis, but further studies appear to have relieved that concern. Its main toxicity appears to be agranulocytosis, and so patients

receiving this medication should undergo frequent blood counts. Deferiprone may have only partial efficacy in reducing liver iron concentrations, but it actually might be superior to deferoxamine in lowering cardiac iron.<sup>116</sup> Deferasirox is the first oral iron chelator licensed in the United States, and is almost exclusively excreted in the bile, in contrast to deferoxamine and deferasirox, which are primarily excreted in the urine. Deferasirox is generally well tolerated, but it may cause nephrotoxicity. Studies to date have demonstrated that deferasirox is effective in reducing liver iron content, while only preliminary data show that it can lower cardiac iron. Both oral iron chelators, deferiprone and deferasirox, appear to be more effective than deferoxamine in binding to intracellular iron, while deferoxamine may have an advantage in chelating extracellular iron. Attempts have been made to combine therapy with both deferoxamine and either deferiprone or deferasirox. Early data seem to suggest that this type of combination indeed offers some additive benefit.

The transfusion regimen employed for the long-term management of chronically transfused patients can significantly affect the rate of iron accumulation. In sickle cell patients who require protracted courses of transfusion, exchange procedures can considerably decrease the rate of accumulation.<sup>122</sup>

## Erythrocyte Enzyme Abnormalities

Enzyme-mediated metabolic pathways in the red cell function to maintain the hemoglobin and the cell membrane in a reduced state. These objectives are accomplished primarily through the reactions linked to the pentose phosphate shunt and, for metabolic energy requirements, through the glycolytic pathway. Many enzyme deficiencies in these metabolic pathways have

been described. The majority are inherited as autosomal recessive abnormalities. Two exceptions—glucose-6-phosphate dehydrogenase (G6PD) deficiency and phosphoglycerate kinase deficiency—are transmitted in an X-linked recessive mode.

G6PD deficiency is prevalent in the same geographic areas in which there is a high frequency of hemoglobin disorders. In common with many of the hemoglobinopathies and thalassemia syndromes, hemizygous carriers of G6PD abnormalities are more resistant to *P. falciparum* malaria. Two common clinical forms of G6PD deficiency are the African variant, designated Gd<sup>A</sup>, and the Mediterranean variant, Gd<sup>Mediterranean</sup>. Both are characterized by an accelerated age-dependent decrease in red cell G6PD activity. In the cells of affected males or homozygous females with the African Gd<sup>A</sup> variant, there is a comparatively slow decline in enzyme activity with age, so that only a minority of cells, the most senescent, are substantially lacking in enzyme activity. The Gd<sup>Mediterranean</sup> variant has much less enzyme activity, and in affected males even newly released reticulocytes have a substantial deficiency in enzyme activity; the mature circulating erythrocytes are essentially devoid of measurable G6PD activity.

G6PD catalyzes the initial step in the pentose phosphate shunt pathway, which is essential in the mature red cell for the regeneration of reduced nicotinamide adenine dinucleotide phosphate (NADPH) from nicotinamide adenine dinucleotide phosphate (NADP). The reduced form is a required cofactor for the enzyme glutathione reductase, which together with glutathione peroxidase protects the hemoglobin, the supporting structures, and the enzymes of the red cell against oxidative damage. In the face of G6PD deficiency, erythrocytes may be extremely vulnerable to oxidant stress, resulting from exposure to certain drugs, chemicals, and infectious agents. During periods of oxidant stress, the hemoglobin may undergo intracellular precipitation to form Heinz bodies. These precipitates, which become associated with the cell membrane, are normally removed in the spleen, but in the process the cell may become damaged and undergo rapid destruction.

Both the African and the Mediterranean types of G6PD deficiency are associated with little or no hematologic abnormality under normal circumstances. In individuals with the African variant, only a comparatively small fraction of circulating red cells are significantly deficient in G6PD at any given time, and even though severe hemolysis and anemia may result from an episode of oxidative stress, the process is typically self-limited. The younger population of red cells that remains after hemolysis has occurred retains a higher level of enzyme activity, and these cells are thus relatively protected from further oxidative challenge. In individuals with the Mediterranean variant, all of the circulating erythrocytes are severely G6PD deficient and hence susceptible to oxidant challenge. Patients with this variant are at risk for acute, life-threatening hemolysis if exposed to a significant oxidant challenge. Transfusions are often lifesaving during episodes of acute hemolysis.

Pyruvate kinase (PK) deficiency occurs most often in northern Europeans and is the most prevalent enzyme deficiency

disorder affecting the glycolytic pathway. Impaired synthesis of adenosine triphosphate in PK-deficient red cells results in potassium depletion, intracellular dehydration, and impaired passage of the erythrocytes through the spleen. Premature destruction ensues in the spleen, liver, or marrow, resulting in variable degrees of anemia. In severe forms of the disease, splenectomy may ameliorate the degree of hemolysis, but ongoing transfusion support may nevertheless be required to maintain an adequate hemoglobin level in these patients.

---

## Disorders of the Red Cell Membrane

The primary functions of the red cell membrane are to maintain the structural integrity of the cell and to regulate cation transport and permeability. The most prevalent of the red cell membrane disorders include hereditary spherocytosis (HS) and hereditary elliptocytosis (HE). Rarer membrane-related disorders include a group of hereditary stomatocytosis syndromes and hereditary pyropoikilocytosis. Hereditary spherocytosis predominates in individuals of northern European extraction, whereas HE has been found in numerous population groups. There are numerous variants of each of these disorders, and in most cases inheritance follows an autosomal dominant pattern.

The extent of hemolysis in HS and HE varies considerably among the different variants. In some cases hemolysis is fully compensated and barely perceptible, whereas in more severe forms anemia may be pronounced. The underlying defects in these disorders are structural abnormalities of the red cell membrane cytoskeleton, but this alone is not the direct cause of hemolysis. Rather, the misshapen cells have impaired deformability and difficulty in traversing the splenic circulation, and undergo destruction within the spleen. Accordingly, splenectomy is frequently effective in ameliorating the hemolysis and the anemia, especially in HS.

Before splenectomy, patients with these hemolytic disorders are also at risk of developing acute episodes of aplasia accompanied by reticulocytopenia and a rapid decrease in hemoglobin levels. These episodes typically follow a trivial viral illness, and they have been linked to the same parvovirus agent that causes aplastic episodes in patients with SCD.<sup>25</sup> During these aplastic crises, as in sickle cell disease, RBC transfusions may be required to sustain life.

**Ronald G. Strauss**

Professor Emeritus, Pathology and Pediatrics, University of Iowa College of Medicine, Iowa City, Iowa, USA

Many aspects of hematopoiesis are either incompletely developed in preterm infants or are adapted to serve the fetus (ie, the intrauterine counterpart to a live-born preterm neonate). This lack of development and/or adaptation to extrauterine life diminishes the capacity of the neonate to produce red cells, platelets, and neutrophils—particularly during the stress of life-threatening illnesses encountered after preterm birth such as sepsis, severe pulmonary dysfunction, necrotizing enterocolitis, and immune cytopenias. Similarly, hepatic function is immature, and the result is low levels of plasma clotting proteins. The serious medical and surgical problems of preterm birth can be further complicated by phlebotomy blood losses, bleeding, hemolysis, and consumptive coagulopathy. Thus, preterm infants begin life with quantities of blood cells and clotting proteins that are barely adequate. Furthermore, these infants have a diminished ability to increase production adequately to compensate for the hematologic problems they experience. These circumstances lead to the need for blood component transfusions.

Preterm infants, especially those with a birthweight less than 1.0 kg and with respiratory distress, are given numerous red cell transfusions early in life because of several interacting factors. Neonates delivered before 28 weeks of gestation (birthweight <1.0 kg) are born before the bulk of iron transport has occurred from mother to fetus via the placenta and before the onset of marked erythropoietic activity of fetal marrow during the third trimester. Hence, preterm infants of very low birthweight enter extrauterine life with low iron stores and a small circulating volume mass of red cells. Soon after preterm birth, severe respiratory disease can lead to repeated blood sampling for laboratory studies and, consequently, to replacement red cell transfusions. As a final factor, preterm infants are unable to mount an effective erythropoietin (EPO) response to decreasing numbers of red cells, and this factor contributes to the diminished ability to compensate for anemia and enhances the need for transfusions.

The physiology of hematopoiesis in the fetus and newborn is discussed in detail in Chapter 25, hemolytic disease of the fetus and newborn in Chapters 26 and 27, congenital hemolytic anemias in Chapter 29, and the physiology and disorders of plasma clotting and anticoagulant proteins in Chapter 28. Accordingly, only the aspects of physiology and pathophysiology that pertain to neonatal transfusion medicine, in general, are included here. The emphasis is on transfusion management during the first several weeks after birth.

---

## Red Cell Transfusion

### Pathophysiology of Anemia of Prematurity

During the first weeks of life, all infants experience a decline in the number of circulating red cells caused by physiologic factors. In sick preterm infants, phlebotomy blood losses also contribute to the decline. In healthy term infants, the nadir blood hemoglobin value rarely decreases to less than 9 g/dL (mean = 11 to 12 g/dL) at an age of approximately 10 to 12 weeks.<sup>1</sup> Because this postnatal decrease in hemoglobin level is universal and is well tolerated by term infants, it is commonly called the *physiologic anemia of infancy*. Among preterm infants, this decline occurs at an earlier age and is more pronounced in severity. Mean hemoglobin concentration decreases to approximately 8 g/dL in infants of 1.0 to 1.5 kg birthweight and to 7 g/dL in infants weighing less than 1.0 kg.<sup>2</sup> In preterm infants, this marked decline in hemoglobin frequently is exacerbated by phlebotomy blood losses and may be associated with symptomatic anemia that necessitates red cell transfusions, making the *anemia of prematurity* unacceptable as a “purely physiologic” event.

Physiologic factors that influence erythropoiesis and the biologic characteristics of EPO are critical in the pathogenesis of the anemia of prematurity. Growth is extremely rapid during the first weeks of life, and red cell production by neonatal marrow must increase commensurately to avoid a decreasing hematocrit caused by an insufficient number of circulating red cells being diluted within the expanding blood volume. It is widely accepted that the

circulating life span of neonatal red cells in the bloodstream is shorter than that of adult red cells. This shorter survival of neonatal red cells, quite possibly, is an artifact, in part, because studies of transfused autologous red cells labeled with biotin or radioactive chromium may underestimate red cell survival in the infant's bloodstream for technical reasons. In healthy adults—when body size is stable so that blood and red cell volumes are constant (ie, not increasing with growing body size and commensurate increase in erythropoiesis), when no transfusions are given, and when large volumes of blood are not being taken for laboratory studies—the gradual disappearance of transfused labeled red cells, caused by dilution with red cells produced endogenously by the marrow, accurately reflects red cell survival in the bloodstream. In contrast, one or more of these confounding factors (ie, growth, red cell transfusions, phlebotomy) exists in infants—particularly, sick preterms—thus introducing error into the calculations performed when red cell survival is determined, based on disappearance of labeled red cells.

In addition, a key clinical factor is the need for repeated blood sampling to monitor the condition of critically ill neonates. Small preterm infants are the most critically ill, require the most frequent blood sampling, and suffer the greatest proportional loss of red cells because their circulating cell volumes are smallest. In the past, the mean volume of blood removed for sampling has been reported to range from 0.8 to 3.1 mL/kg/day during the first few weeks of life for preterm infants requiring intensive care. Promising “in-line” devices that withdraw blood, measure multiple analytes, and then reinfuse the sampled blood have been reported.<sup>3,4</sup> They have decreased the need for red cell transfusions. However, until these devices are proven more extensively to be practical, effective, and safe, replacement of blood losses from phlebotomy will remain a critical factor responsible for transfusions given to critically ill neonates—particularly, transfusions given during the first 4 weeks of life.

A key reason that the nadir hemoglobin values of preterm infants are lower than those of term infants is that preterm infants have a relatively diminished EPO plasma level in response to anemia.<sup>5</sup> Although anemia provokes EPO production in premature infants, the plasma levels achieved in anemic infants, at any given hematocrit, are lower than those observed in comparably anemic older persons.<sup>6</sup> Erythroid progenitor cells of preterm infants are quite responsive to EPO *in vitro*—a finding suggesting that inadequate production of EPO (not marrow unresponsiveness) is the major cause of physiologic anemia.<sup>7</sup>

The mechanisms responsible for the diminished EPO output by preterm neonates are only partially defined and, likely, are multiple. One mechanism is that the primary site of EPO production in preterm infants is in the liver, rather than kidneys.<sup>8</sup> This dependency on hepatic EPO is important because the liver is less sensitive to anemia and tissue hypoxia—resulting in a relatively sluggish EPO response to the decreasing hematocrit. The timing of the switch from the liver to kidneys is set at conception and is not accelerated by preterm birth. Viewed from a teleologic perspective, decreased hepatic production of EPO under in-utero

conditions of tissue hypoxia may be an advantage for the fetus. If this were not the case, normal levels of fetal hypoxia in utero could trigger high levels of EPO and produce erythrocytosis and consequent hyperviscosity. Following birth, however, diminished EPO responsiveness to tissue hypoxia is disadvantageous and leads to anemia because it impairs compensation for low hematocrit levels caused by rapid growth and red cell losses caused by phlebotomy, clinical bleeding, hemolysis, etc.

Diminished EPO production cannot entirely explain low plasma EPO levels in preterm infants, because extraordinarily high plasma levels of EPO have been reported in some fetuses and infants.<sup>9,10</sup> Moreover, macrophages from human cord blood produce normal quantities of EPO messenger RNA and protein.<sup>11</sup> Thus, additional mechanisms contribute to diminished EPO plasma levels. For example, plasma levels of EPO are influenced by metabolism (clearance) as well as by production. Data in human infants<sup>12</sup> have demonstrated low plasma EPO levels resulting from increased plasma clearance, increased volume of distribution, more rapid fractional elimination, and shorter mean plasma residence times than comparative values in adults. Thus, accelerated catabolism accentuates the problem of diminished EPO production, so that the low plasma EPO levels are a combined effect of decreased synthesis plus increased metabolism.

### Red Cell Transfusion Practices

Red cell transfusions are given to maintain the hematocrit at a level judged best for the clinical condition of the infant.<sup>13</sup> General guidelines acceptable to most neonatologists are listed in Table 30-1. However, many aspects of neonatal red cell transfusion therapy are controversial and vary from center to center. This lack of consistency stems from incomplete knowledge of the cellular and molecular biology of erythropoiesis during the perinatal period, of the pathophysiologic effects of neonatal anemia, and of the infant's response to red cell transfusions. In some instances the value of red cell transfusions is clear (eg, to manage anemia that has caused congestive heart failure), but in others it is not (eg, to correct irregular patterns of heart or respiratory rates), and practices are based largely on logical assumptions. Although well-designed clinical trials are being reported,<sup>14,15</sup> they are not completely mutually supportive and questions

**Table 30-1.** Guidelines for Small-Volume Red Cell Transfusions

- 
- Maintain >40% to 45% hematocrit for *severe* cardiopulmonary disease
  - Maintain >30% to 35% hematocrit for *moderate* cardiopulmonary disease
  - Maintain >30% to 35% hematocrit for *major* surgery
  - Maintain >20% to 25% hematocrit for infants with *stable* anemia, especially with:
    - Unexplained breathing disorders
    - Unexplained tachycardia
    - Unexplained poor growth
- 

Words in *italics* must be defined locally. For example, “severe” pulmonary disease may be defined as requiring mechanical ventilation with >0.35 FiO<sub>2</sub> and “moderate” as less intensive assisted ventilation.

remain. Therefore, it is important that pediatricians critically evaluate the guidelines in Table 30-1 and apply them in light of neonatal practice at their respective institutions.

An important controversy that is still unresolved is the wisdom—or lack, thereof—of prescribing Red Blood Cell (RBC) units for neonates using restrictive guidelines (ie, low pretransfusion hematocrit values) vs liberal guidelines (ie, conventional, relatively high pretransfusion hematocrit values). Two randomized controlled trials have been published<sup>14,15</sup> and, although many of their results agree, they disagree in one extremely important way—specifically, whether preterm infants are at increased risk of brain injury when given RBCs per restrictive guidelines (ie, due to undertransfusion). In both trials, preterm infants were randomly assigned to receive small-volume RBC transfusions per either restrictive or liberal guidelines—with guidelines based on a combination of the pretransfusion hematocrit or hemoglobin level, age of the neonate, and clinical condition at the time each transfusion was given. Both studies found that neonates in the restrictive transfusion group received fewer transfusions, without an increase in mortality or in morbidity based on several clinical outcomes. However, one critical discrepancy was present. Bell et al<sup>14</sup> found increases in apnea, intraventricular bleeding, and brain leukomalacia in infants transfused per restrictive guidelines, whereas Kirpalani et al<sup>15</sup> found no differences between infants in the restrictive vs liberal groups. Moreover, rates of serious outcomes were fairly high in both groups of the Kirpalani study—perhaps, a result of the extreme prematurity of the infants. However, because neonates in the liberal transfusion group of Bell et al likely had substantially higher hematocrit/hemoglobin levels than neonates in the liberal group of Kirpalani et al (an average hematocrit of 6% or hemoglobin level of 2 g/dL higher), it is reasonable to speculate that the higher hematocrit levels, in some way, protected liberally transfused infants in the Bell study.<sup>14,15</sup> Until more information is available, it seems wise to transfuse preterm neonates using conventional, relatively liberal guidelines (ie, do not place infants at possible risk of undertransfusion by strict conservative practices). The rationale for the conventional, relatively liberal guidelines (Table 30-1) follow in the paragraphs below.

#### **Maintain Hematocrit >40% to 45% for Severe Cardiopulmonary Disease**

In neonates with severe respiratory disease, such as those requiring high volumes of oxygen with ventilator support, it is customary to maintain the hematocrit above 40% to 45% (hemoglobin concentration above 13-14 g/dL)—particularly when blood is being drawn frequently for testing. This practice is based on the belief that transfused donor red cells, containing adult hemoglobin with its superior interaction with 2,3-diphosphoglycerate (2,3-DPG), will provide optimal oxygen delivery throughout the period of diminished pulmonary function. Consistent with this rationale for ensuring optimal oxygen delivery in neonates with pulmonary failure, it seems logical to maintain the hematocrit

above 40% in infants with congenital heart disease that is severe enough to cause either cyanosis or congestive heart failure.

#### **Maintain Hematocrit >30% to 35% for Moderate Cardiopulmonary Disease**

Following similar logic, it seems reasonable to maintain the hematocrit above 30% to 35% for moderate cardiopulmonary disease (Table 30-1).

#### **Maintain Hematocrit >30% for Major Surgery**

Definitive studies are not available to establish the optimal hematocrit for neonates facing major surgery. However, it seems reasonable to maintain the hematocrit >30% because of limited ability of the neonate's heart, lungs, and vasculature to compensate for anemia. Additional factors include the inferior off-loading of oxygen to tissues by the infant's own red cells because of the diminished interaction between fetal hemoglobin and 2,3-DPG plus the developmental impairment of neonatal pulmonary, renal, hepatic, and neurologic function. Because this transfusion guideline is simply a recommendation—not a firm indication—it should be applied with flexibility to individual infants facing surgical procedures of varying complexity (ie, minor surgery may be judged not to require a hematocrit >30%). The amount of anticipated blood loss must be strongly considered in preoperative transfusion decisions—with a likelihood of large blood loss, some physicians might like the preoperative hematocrit to be relatively high.

#### **Maintain Hematocrit >20% to 25% for Stable Infants with Symptomatic Anemia**

The clinical recommendations for red cell transfusions in preterm infants who are not critically ill but, nonetheless, develop moderate anemia (hematocrit <25% or hemoglobin level <8 g/dL) are extremely variable. In general, infants who are clinically stable with modest anemia do not require red cell transfusions, unless they exhibit significant clinical problems that are ascribed to the presence of anemia or are predicted to be corrected by donor red cells.<sup>16,17</sup> As an example, proponents of red cell transfusions to treat disturbances of cardiopulmonary rhythms believe that a low blood level of red cells contributes to tachypnea, dyspnea, apnea, and tachycardia or bradycardia because of decreased oxygen delivery to the respiratory center of the brain. Red cell transfusions might decrease the number of apneic spells by improving oxygen delivery to the central nervous system. However, results of clinical studies have been contradictory.<sup>14,16,17</sup>

Another controversial clinical indication for red cell transfusions is to maintain a reasonable hematocrit level as treatment for unexplained growth failure. Some neonatologists consider poor weight gain to be an indication for transfusion, particularly if the hematocrit is <25% and if other signs of distress are evident (eg, tachycardia, respiratory difficulty, weak suck and cry, and diminished activity).<sup>18</sup> In this setting, growth failure has been ascribed to the increase in metabolic expenditure required to support the work of labored breathing. In the past, a

hematocrit below 30% was of concern and often led to transfusion. However, results of clinical studies have not supported this practice,<sup>16,17</sup> and no apparent rationale exists to justify maintaining any predetermined hematocrit level by prophylactic, small-volume red cell transfusions in stable, growing infants who seem to be otherwise healthy.

In practice, the decision of whether to transfuse is based on the desire to maintain the hematocrit concentration at a level judged to be most beneficial for the infant's clinical condition. Investigators who believe this "clinical" approach is too imprecise have suggested the use of "physiologic" criteria such as red cell mass,<sup>19</sup> available oxygen,<sup>20</sup> mixed venous oxygen saturation, and measurements of oxygen delivery and utilization<sup>21</sup> to develop guidelines for transfusion decisions. In one study of 10 human infants with severe (oxygen-dependent) bronchopulmonary dysplasia, improvement of physiologic endpoints was shown (increased systemic oxygen transport and decreased oxygen use) as a consequence of small-volume red cell transfusions.<sup>21</sup> However, these promising but technically demanding methods are, at present, difficult to apply in the day-to-day practice of neonatology. The application, in infants, of data obtained from studies of animals and adult humans that correlate tissue oxygenation with the clinical effects of anemia and the need for red cell transfusions is confounded by the differences between infants and adults in hemoglobin oxygen affinity, ability to increase cardiac output, and regional patterns of blood flow.

Another physiologic factor considered in transfusion decisions is use of the circulating red cell volume/mass rather than the hematocrit or hemoglobin level. Although circulating red cell volume/mass is a potentially useful index of the blood's oxygen-carrying capacity, it cannot be predicted accurately from hematocrit or hemoglobin concentration levels; hence, it must be measured directly.<sup>22</sup> Unfortunately, circulating red cell volume/mass measurements and other "physiologic" criteria for transfusions are not widely available for clinical use.

### Red Blood Cell Products to Transfuse

Most transfusions are given to preterm infants as small-volume transfusions (10 to 20 mL/kg body weight) of RBCs in extended-storage media (additive solution AS-1, AS-3, AS-5) at a hematocrit of approximately 55% to 60% (Table 30-2). Alternatively, some neonatologists prefer RBCs in citrate-phosphate-dextrose-adenine (CPDA) solution at a hematocrit of approximately 70%—although the superiority of this last solution over extended-storage media has not been shown. Some centers prefer to centrifuge RBC aliquots before transfusion to prepare a uniformly packed RBC concentrate (hematocrit >80%).<sup>23</sup> Most RBC transfusions are infused slowly over 2 to 4 hours. Because of the small quantity of extracellular fluid (storage media) infused very slowly with small-volume transfusions, the type of anticoagulant-preservative solution used poses no risk for most premature infants.<sup>24,25</sup> Accordingly, the traditional use of relatively fresh RBCs (<7 days of storage) has been replaced in many centers by the practice of transfusing aliquots

**Table 30-2.** Formulation of Red Cell Anticoagulant-Preservative Solutions

| Constituent                       | CPDA | AS-1             | AS-3             | AS-5             |
|-----------------------------------|------|------------------|------------------|------------------|
| Volume (mL)                       | 63*  | 100 <sup>†</sup> | 100 <sup>†</sup> | 100 <sup>†</sup> |
| Sodium chloride (mg)              | None | 900              | 410              | 877              |
| Dextrose (mg)                     | 2010 | 2200             | 1100             | 900              |
| Adenine (mg)                      | 17.3 | 27               | 30               | 30               |
| Mannitol (mg)                     | None | 750              | None             | 525              |
| Trisodium citrate (mg)            | 1660 | None             | 588              | None             |
| Citric acid (mg)                  | 206  | None             | 42               | None             |
| Sodium phosphate (monobasic) (mg) | 140  | None             | 276              | None             |

\* Approximately 450 mL of donor blood is drawn into 63 mL of citrate-phosphate-dextrose-adenine (CPDA) solution. One Red Blood Cell unit (hematocrit, ~70%) is prepared by means of centrifugation and removal of most plasma. Results of calculations will be slightly different if 500 mL of donor blood is drawn.

<sup>†</sup> When additive solution AS-1 or AS-5 is used, 450 mL of donor blood is first drawn into 63 mL of CPD, which is identical to CPDA except it contains 1610 mg dextrose per 63 mL and has no adenine. When AS-3 is used, donor blood is drawn into CP2D, which is identical to CPD except it contains double the amount of dextrose. After centrifugation and removal of nearly all plasma, the cells are resuspended in 100 mL of the additive solution (AS-1, AS-3 or AS-5) at a hematocrit of approximately 55% to 60%.

of RBCs from a dedicated unit (or part of a unit) of RBCs stored up to 42 days in efforts to diminish the high donor exposure rates among infants who undergo numerous transfusions.<sup>23,25</sup> Neonatologists who object to prescribing stored RBCs and insist on transfusing fresh RBCs generally express the following four concerns: 1) the increase in the level of potassium in the plasma (ie, supernatant fluid); 2) the decrease in the level of 2,3-DPG; 3) the possible risks of additives such as mannitol and the relatively large amounts of glucose (dextrose) and phosphate present in extended-storage preservative solutions; and 4) the changes in red cell shape and deformability that may lead to poor flow through the microvasculature. Although these concerns often are legitimate for large-volume ( $\geq 25$  mL/kg) transfusions, particularly when infusion is rapid, they do not apply to small-volume transfusions for the following reasons.

After 42 days of storage in extended-storage media (AS-1, AS-3, AS-5) at a hematocrit of approximately 60%, extracellular ("plasma") potassium levels in RBC units approximate 50 mEq/L (0.05 mEq/mL), a value that at first glance seems alarmingly high. Simple calculations, however, show the actual dose of ionic potassium transfused in the extracellular "plasma" fluid is small. An infant weighing 1 kg given a 15-mL/kg transfusion of RBCs stored 42 days in extended-storage media at a hematocrit of 55% to 60% receives only 0.3 mEq. The potassium concentration of RBCs stored in CPDA solution at a hematocrit of 70% increases to 70 to 80 mEq/L after the 35 days of permitted storage, and the dose of potassium infused with a 15-mL/kg transfusion to a 1-kg infant is 0.3 to 0.4 mEq. These doses are quite small when compared to the usual daily potassium requirement of 2 to 3 mEq/kg and have been shown in several clinical studies not to cause hyperkalemia.<sup>25</sup>

**Table 30-3.** Quantity (Total mg/kg) of Additives Infused During a Transfusion of 15 mL/kg AS-1, AS-3, or AS-5 RBCs at Hematocrit 60%

| Additive        | AS-1  | AS-3 | AS-5  | Toxic Dose*    |
|-----------------|-------|------|-------|----------------|
| Sodium chloride | 54.0  | 24.6 | 52.6  | 137 mg/kg/day  |
| Dextrose        | 132.0 | 66.0 | 54.0  | 240 mg/kg/hour |
| Adenine         | 1.6   | 1.8  | 1.8   | 15 mg/kg/dose  |
| Citrate         | Trace | 37.8 | Trace | 180 mg/kg/hour |
| Phosphate       | Trace | 16.6 | Trace | >60 mg/kg/day  |
| Mannitol        | 45.0  | None | 31.5  | 360 mg/kg/day  |

\*The accuracy of toxic dose is difficult to predict because infusion rates are slow, allowing metabolism and distribution of additives from blood into extravascular sites. In addition, dextrose, adenine, and phosphate enter red cells and are somewhat sequestered and not immediately “available” in the extracellular solution. Data on potential toxic doses from Luban et al.<sup>24</sup>

Calculations for quantity of additives infused assumed the following: 1) total volume of RBC unit = 300 mL, consisting of 100 mL additive solution + 180 mL completely packed red cells + 20 mL of primary anticoagulant trapped between the red cells; 2) 15 mL/kg transfusion = 9 mL red cells + 6 mL additive solution; 3) quantity of additive solution infused per single RBC transfusion = quantity in 100 mL/(100 × 6); 4) trace amounts of trisodium citrate, citric acid, and phosphate were carried over by primary anticoagulant trapped between red cells.

By 21 days of storage, 2,3-DPG is totally depleted from RBCs as reflected by a  $P_{50}$  value that decreases from approximately 27 mm Hg in fresh blood to 18 mm Hg in stored red cells at the time of outdate. Because of the effects of high fetal hemoglobin levels in neonatal red cells, the 18 mm Hg value of red cells transfused after maximum storage corresponds to the expectedly low  $P_{50}$  value obtained from studies of red cells produced by many healthy preterm infants at birth. Thus, both older stored red cells and endogenous red cells from neonates have a similarly reduced ability to off-load oxygen compared with fresh adult red cells. However, older adult red cells in banked RBC units provide an advantage over the infant’s own cells because 2,3-DPG and the  $P_{50}$  of transfused adult cells (but not endogenous infant red cells) increase rapidly after transfusion. When studied in the setting of small-volume (15 mL/kg) transfusion, 2,3-DPG levels were maintained in infants given stored RBCs.<sup>26</sup>

The quantity of additives present in RBCs in extended-storage media is unlikely to be dangerous for neonates given small-volume transfusions (15 mL/kg).<sup>24,25</sup> Regardless of the type of suspending solution, the quantity of additives is quite small in the clinical setting in which a neonate would receive a single, small-volume transfusion over 2 to 4 hours. With AS-1, AS-3, and AS-5 as examples (Table 30-3), the dose of extended-storage media additives transfused during a typical small-volume transfusion is estimated to be far less than levels believed to be toxic.<sup>24</sup> This assumption was proved correct in clinical studies in which infants received one or more transfusions.<sup>24</sup> The safety and efficacy of transfusing stored RBCs is documented by the results of several laboratory tests performed before and after small-volume RBC transfusions in preterm infants (Table 30-4).

During storage in conventional preservative solutions, red cells sustain decreases in 2,3-DPG and adenosine triphosphate, and

**Table 30-4.** Mean Change in Blood Chemistry Levels During RBC Transfusions<sup>27,28</sup>

| Value             | Change*                          |                                   |

\*Change (± SD) is posttransfusion value minus pretransfusion value. Statistical tests used were *t* test for pH, sodium, potassium, and glucose (normal distribution) and Wilcoxon rank sum test for hematocrit, calcium, and lactate (abnormal distribution). No statistically significant differences were found (p values all >0.05) comparing 1 to 21 days vs 22 to 42 days of storage.

they undergo membrane and cytoskeletal changes that lead to the formation of echinocytes and microvesicles and to decreased deformability. The last changes may lead to diminished perfusion of the microvasculature and, consequently, to tissue and organ dysfunction. For the past few years, the argument has raged over whether critically ill adult patients are harmed by receiving “old” RBC units (usually defined as stored ≥15 or ≥21 days), and whether mortality, multi-organ failure, infections, need for mechanical ventilation, length of stay in intensive care units and in the hospital, etc could be diminished by transfusing only fresh RBC units. Older, largely observational, studies generally support the idea that “old” RBC units put critically ill patients at risk, particularly if they receive multiple transfusions. Several more recent studies have challenged this concept and have cautioned against insisting on transfusions of fresh RBCs.<sup>29,30</sup> Well-designed clinical trials are needed to resolve this question.

The situation is similar for neonatal RBC transfusions (ie, neonates are often critically ill and questions about morbidity caused by transfusing stored RBCs have been raised). However, well-designed trials have addressed efficacy and safety and, within the limits of the number of infants studied, fresh and stored cells have been documented to be equivalent.<sup>14,25,26</sup> Moreover, the intravascular recovery 24 hours after transfusion and long-term survival of stored red cells is normal, when measured in human infants using biotinylated red cells.<sup>31</sup> Because the risks of multiple donor exposure can be nearly eliminated by giving infants cells taken from dedicated, stored RBC units and because increased risks of transfusing stored vs fresh cells have not been demonstrated, it seems prudent to continue transfusing stored RBCs for small-volume transfusions.

**Approach to Anemia of Prematurity**

For many infants with a birthweight less than 1.0 kg, anemia of prematurity is severe and necessitates therapy with red cell

transfusions and/or the administration of recombinant human erythropoietin (rHuEPO) plus iron.

For decades, red cell transfusion has been the standard of care and continues to be so. A key principle is that allogeneic donor exposure should be minimized by transfusing cells from dedicated RBC units stored as long as permitted (eg, 42 days for extended-storage anticoagulant-preservative solutions). At the University of Iowa DeGowin Blood Center, preterm infants who need transfusions are assigned to dedicated RBC units suspended in extended-storage (42-day) solutions. At the time the first transfusion is ordered, one-half of a freshly collected unit (stored  $\leq 7$  days) is dedicated to a preterm infant with a birthweight of 1.0 kg or less. The rest of the unit can be assigned to another infant. Thus, one complete unit can serve two very-low-birthweight infants simultaneously. When transfusions are ordered, aliquots are removed sterily and issued.<sup>23</sup> Although units are used throughout 42 days of storage, if a unit has been stored 14 days without an infant being assigned to it, it has become relatively aged (14 of its 42 storage days have lapsed), and it enters the general inventory to be used for older patients as needed. This plan has been demonstrated to be cost-effective.<sup>32</sup>

Recognition of low plasma EPO levels and adequate erythropoietic activity in preterm infants provides a rational basis to consider rHuEPO as treatment for the anemia of prematurity. Because the inadequate quantity of EPO is the major cause of anemia—not a subnormal response of erythroid progenitors to EPO—it is logical to assume that rHuEPO will correct EPO deficiency and will effectively treat the anemia of prematurity. Unfortunately, rHuEPO has not been widely accepted in clinical neonatology practice because its efficacy is incomplete. On one hand, clonogenic erythroid progenitors from neonates respond well to rHuEPO in vitro and rHuEPO and iron effectively stimulate erythropoiesis in vivo as evidenced by increased blood reticulocyte and red cell counts in recipient infants (ie, efficacy successful at the marrow level). On the other hand, when the primary goal of rHuEPO therapy is to eliminate transfusions, rHuEPO often fails (ie, efficacy at the clinical level has not been consistently successful).<sup>13,33</sup>

By 2000, over 20 controlled clinical trials assessing the efficacy of rHuEPO to eliminate RBC transfusions in the anemia of prematurity were published with inconsistent results. To investigate the extent and reasons for the inconsistencies, a meta-analysis was conducted of the controlled clinical studies published between 1990 and 1999.<sup>33</sup> To be included, a reported study had to prospectively enroll a treatment group of preterm infants under 4 months of age treated with rHuEPO and a concurrent control group not given rHuEPO. Twenty-one reports were eligible for inclusion in the meta-analysis. However, because the experimental design and conduct of the studies were extremely variable, only four reports were judged to fulfill all of the highly desired characteristics of being effectively blinded, having high-quality experimental design (ie, randomized, placebo-controlled, all dropouts well-explained, etc), using conservative transfusion practices (rather than liberal transfusions, which suppress

endogenous erythropoiesis), and enrolling a majority of very preterm infants with birthweights  $< 1.0$  kg.

Two major conclusions emerged from the meta-analysis.<sup>33</sup> First, the controlled trials of rHuEPO to treat the anemia of prematurity differed from one another in multiple ways and, consequently, produced markedly variable results that could not be adequately explained. Hence, it was judged impossible to make firm recommendations regarding use of rHuEPO in clinical practice to treat the anemia of prematurity. Second, when the four studies with highly desired characteristics were analyzed separately, rHuEPO was found to be efficacious in significantly reducing transfusion needs. However, the magnitude of the effect of rHuEPO on reducing the total red cells transfusions given to infants throughout their initial hospitalization was, in fact, relatively modest and of questionable clinical importance. Although the meta-analysis was unable to recommend how to use rHuEPO in clinical practice, it was apparent that: 1) relatively large or stable preterm infants, shown to respond best to rHuEPO plus iron at the marrow level, are given relatively few red cell transfusions with today's conservative transfusion practices and, accordingly, have little need for rHuEPO when the goal is to avoid transfusions; and 2) extremely small preterm infants, who are critically ill and unstable, have not consistently responded to rHuEPO plus iron when the outcome measure is to reduce need for transfusions.

Several reports published after 2000 have provided useful information. Donato et al,<sup>34</sup> assessing the effects of rHuEPO very early in life, randomly assigned 114 neonates with birthweights  $< 1.25$  kg to receive either rHuEPO or placebo during the first 2 weeks of life, followed by a 6-week treatment period during which *all infants* were given rHuEPO, iron, and folic acid. During the first 3 weeks of life, rHuEPO increased reticulocytes and hematocrit values, but there was no difference in red cell transfusions. However, at the end of all treatment (8 weeks), a subgroup of infants with birthweights  $< 0.8$  kg and phlebotomy losses  $> 30$  mL/kg who were given rHuEPO shortly after birth received fewer total red cell transfusions than infants initially given placebo ( $3.4 \pm 1.1$  vs  $5.4 \pm 3.7$ ,  $p < 0.05$ ). Similarly, Yeo et al<sup>35</sup> found a modest advantage for a subgroup of very-low-birthweight infants given rHuEPO. Infants with birthweights 0.8 to 0.99 kg were given fewer transfusions with rHuEPO than control infants not given rHuEPO ( $2.1 \pm 1.9$  vs  $3.5 \pm 1.6$ ,  $p < 0.04$ ). A randomized blinded trial by Meyer et al<sup>36</sup> found an advantage for very-low-birthweight infants given rHuEPO. Neonates with birthweights  $< 1.7$  kg plus criteria that predicted a likely need for red cell transfusions were randomly assigned either to receive rHuEPO beginning shortly after birth or to experience a sham treatment to simulate placebo injections. Iron was given to all infants, but at a much lower dose (unfortunately) to control infants not given rHuEPO than to infants given rHuEPO—thus, creating two variables/differences (rHuEPO and iron dose, rather than just rHuEPO) being assessed in treated vs control infants. There was no overall difference in red cell transfusions, but in a subset of infants with birthweights  $< 1.0$  kg, transfusions given

late (ie, after 30 days of age) were reduced by rHuEPO vs transfusions given to controls ( $0.5 \pm 0.7$  vs  $1.6 \pm 1.1$ ,  $p = 0.01$ ).

Two reports defined rHuEPO “success” as maintaining a hematocrit of  $\geq 30\%$  without need for any transfusions. Maier et al<sup>37</sup> randomly assigned 219 neonates with birthweights 0.5 to 0.99 kg to receive early rHuEPO (from the first week of life for 9 weeks), late rHuEPO (from the fourth week of life for 6 weeks), or no rHuEPO. “Success” was modest (13% with early rHuEPO, 11% with late rHuEPO, and 4% with no rHuEPO). Only early rHuEPO administration was significantly superior to no rHuEPO ( $p = 0.026$ ). Avent et al<sup>38</sup> randomly assigned 93 neonates with birthweights 0.9 to 1.5 kg to receive low-dose rHuEPO (250 units/kg), high dose rHuEPO (400 units/kg), or no rHuEPO. Treatment began within 7 days of life and continued until discharge (median 32 days and maximum 74 days). “Success” was met by 75% of low-dose rHuEPO infants, 71% of high-dose rHuEPO infants, and 40% of no rHuEPO infants ( $p < 0.001$ ). The number of red cell transfusions given to all infants treated with rHuEPO vs those with no rHuEPO was not significantly different. The authors concluded that rHuEPO does not significantly further decrease red cell transfusions in infants with birthweights of 0.9 to 1.5 kg, when phlebotomy losses are small and relatively few transfusions are given per stringent transfusion guidelines.

The observation by Avent et al<sup>38</sup> that the benefits of rHuEPO in reducing the number of red cell transfusions given can be equalled by stringent or conservative transfusion guidelines has been made by others. Franz and Pohlandt<sup>39</sup> assessed both the number of red cell transfusions given and red cell transfusion guidelines in four prospective, randomized trials of rHuEPO given to preterm neonates. To be selected for analysis, the clinical trials had to include ventilated infants (ie, sick infants likely to receive red cell transfusions). The authors found that, when restrictive transfusion guidelines were followed, the number of red cell transfusions and the volume of red cells transfused were similarly low in infants either given or not given rHuEPO.<sup>36</sup> Similarly, Amin and Alzahrani<sup>40</sup> found no difference in the number of red cell transfusions, whether or not rHuEPO was given to preterm infants with birthweights  $\leq 1.0$  kg, when transfusions were given per strict transfusion guidelines.

Another alternative to allogeneic transfusions is use of placental blood as a source of autologous red cells.<sup>41,42</sup> Although collection, storage, and transfusion of placental blood after delivery deserves careful consideration, at least three obstacles must be overcome before autologous transfusions of stored placental red cells can be adopted for clinical use. One concern is that a sufficient quantity of red cells will not be obtained consistently from placentas of preterm infants to avoid a significant number of allogeneic transfusions. The second issue is the sterility of placental blood. Because bacterial contamination of placental blood is a distinct possibility,<sup>41</sup> extensive testing will be needed to ensure absolute safety. Finally, acceptable quality of stored placental blood must be maintained.<sup>42</sup> Because of these concerns, collection and storage of placental blood has not been encouraged.<sup>43</sup>

Instead, interest has been renewed in delayed clamping of the umbilical cord immediately following delivery to expand neonatal blood volume and red cell volume/mass to, possibly, improve circulatory hemodynamics and increase tissue perfusion and oxygenation.<sup>22,44</sup>

## Platelet Transfusion

### Pathophysiology of Neonatal Thrombocytopenia

Blood platelet counts of  $\geq 150,000/\mu\text{L}$  are present in normal fetuses (as early as 17 weeks of gestation) and in normal neonates. Thus, platelet counts are in the normal range, regardless of gestational age at birth. Low platelet counts indicate potential problems. Preterm neonates commonly have thrombocytopenia (eg, in one neonatal intensive care unit, 22% of infants had platelet counts  $< 150,000/\mu\text{L}$ ).<sup>45</sup> In contrast, thrombocytopenia is documented in  $< 1\%$  of term neonates.<sup>46</sup> Blood platelet counts  $< 100,000/\mu\text{L}$  pose significant clinical risks. In one study, neonates with birthweights less than 1.5 kg and a platelet count  $< 100,000/\mu\text{L}$  were compared with neonates of similar size who did not have thrombocytopenia.<sup>47</sup> The bleeding time was prolonged when platelet counts were  $< 100,000/\mu\text{L}$ , and platelet dysfunction was suggested by bleeding times that were disproportionately long for the degree of thrombocytopenia present. The incidence of intracranial hemorrhage was 78% among thrombocytopenic neonates with a birthweight less than 1.5 kg vs 48% for similar neonates without thrombocytopenia. In addition, the extent of hemorrhage and neurologic morbidity was greater among infants with thrombocytopenia.<sup>47</sup>

Although multiple pathogenetic mechanisms underlying thrombocytopenia likely are involved in these sick neonates, accelerated platelet destruction frequently is implicated by shortened platelet survival time, increased level of platelet-associated immunoglobulin G, increased platelet volume, normal number of marrow megakaryocytes, and an inadequate response to platelet transfusions.<sup>45,48</sup> Another mechanism that contributes to neonatal thrombocytopenia is diminished platelet production. This is evidenced by neonatal megakaryocytes that are smaller and of lower ploidy than those of adults.<sup>49</sup> In addition, some investigators have reported decreased numbers of megakaryocyte progenitors,<sup>50</sup> while others have not.<sup>49</sup> The response to thrombocytopenia in adults is to increase megakaryocyte number, volume, and ploidy—mediated primarily by thrombopoietin—all of which leads to increased platelet production. Thrombocytopenic neonates either fail to increase, or increase inadequately, megakaryocyte number, volume, and ploidy when compared to adults and, consequently, they cannot increase platelet counts sufficiently to correct thrombocytopenia.<sup>49,51</sup> Moreover, thrombopoietin seems to increase neonatal megakaryocyte proliferation, but inhibit endoreduplication,<sup>52</sup> in contrast, both are increased in adults.

As is reminiscent of neonatal red cell and neutrophil production, where basal erythropoiesis and myelopoiesis are adequate,

basal platelet production and thrombopoiesis are adequate. However, under the stress of cytopenia, none of the three cell lines is capable of increasing production to completely and promptly correct low blood counts (ie, the infants lack sufficient hematopoietic reserve).

### Recommendations for Platelet Transfusion during Infancy

The relative risks of different degrees of thrombocytopenia in various clinical settings during infancy remain largely unanswered. Prophylactic platelet transfusions to prevent bleeding in preterm neonates were studied systematically several years ago, and the results still seem relevant.<sup>53</sup> No randomized clinical trials of therapeutic platelet transfusions have been reported for bleeding thrombocytopenic neonates. Recognizing the need for more data, it seems logical in the interim to transfuse thrombocytopenic neonates per the guidelines presented in Table 30-5.

Two firm indications for platelet transfusions are either to control hemorrhage that has already occurred or to prevent it from complicating an invasive procedure. No disagreement exists over using a pretransfusion platelet count of 50,000/ $\mu$ L as a minimum transfusion trigger in these instances. However, platelet transfusions are given at platelet counts  $>50,000/\mu$ L by some physicians to neonates to control bleeding or in hopes of reducing either the threat of, or the worsening of, intracranial hemorrhage in high-risk preterm neonates.<sup>47</sup> No data exist to clearly establish the efficacy of platelet transfusions at these relatively high platelet levels.

Conventional prophylactic platelet transfusions are given to prevent bleeding when severe thrombocytopenia poses a likely risk of spontaneous hemorrhage. Prophylactic platelet transfusions are given by some physicians to maintain the presence of a normal platelet count in hopes of preventing the neonate from slipping into high-risk situations that might lead to spontaneous bleeding. Regarding the first circumstance, most experts agree that it is reasonable to give platelets to any infant with a platelet count,  $<20,000/\mu$ L because spontaneous hemorrhage is a likely risk at this platelet count. Severe thrombocytopenia occurs most commonly among sick infants who, because of the illness, often receive medications that can compromise the function of their already diminished number of platelets. Because these factors are more pronounced in extremely preterm infants, who are clinically unstable, some neonatologists favor prophylactic platelet transfusion whenever the platelet count decreases to  $<50,000/\mu$ L, or even to  $<100,000/\mu$ L, in critically ill infants.<sup>47</sup>

**Table 30-5.** Guidelines for Neonatal Platelet Transfusions

- Maintain  $>50,000$  to  $100,000/\mu$ L platelets for *significant* bleeding
- Maintain  $>50,000/\mu$ L platelets for *invasive* procedures
- Maintain  $>20,000/\mu$ L platelets prophylactically for *clinically stable* neonates
- Maintain  $>50,000$  to  $100,000/\mu$ L platelets prophylactically for *clinically unstable* neonates

Words in italics must be defined locally. For example, consider bleeding site, extent and degree of prematurity, and underlying medical condition.

It is not efficacious to maintain a completely normal platelet count ( $\geq 150,000/\mu$ L) in preterm neonates without bleeding.<sup>53</sup> Moreover, such a practice can place infants at increased risk from more platelet donor exposures. Intracranial hemorrhage occurs commonly among sick preterm infants. Although neither a causative role for thrombocytopenia nor a therapeutic benefit for platelet transfusion has been established in this disorder, it seems logical to presume thrombocytopenia might be a risk factor.<sup>54</sup> Accordingly, in a randomized trial designed to address this issue, transfusion of platelets whenever the platelet count decreased below the normal value of  $150,000/\mu$ L (which maintained the average daily platelet count  $>200,000/\mu$ L) was compared with transfusion of platelets only when the platelet count decreased below  $50,000/\mu$ L.<sup>53</sup> There was no difference in the incidence of intracranial hemorrhage (28% vs 26%) in the two groups. Thus, there is no documented benefit to transfusing “prophylactic platelets” to maintain a completely normal platelet count in preterm neonates vs transfusing “therapeutic platelets” to treat thrombocytopenia when it actually occurs.

### Platelet Product to Transfuse

The ideal goal of platelet transfusions for many thrombocytopenic neonates is to increase the low pretransfusion platelet count to a posttransfusion count  $>50,000/\mu$ L and for sick preterm infants to  $>100,000/\mu$ L. This can be achieved consistently by transfusing 5 to 10 mL/kg of *unmodified* platelet concentrates (withdrawn from a unit of platelets collected either by centrifugation of fresh units of whole blood or plateletpheresis and transfused directly). Platelet concentrates should be transfused as rapidly as the neonate’s condition allows, certainly within 2 hours.

Routinely reducing the volume of platelet concentrates for infants by means of additional centrifugation steps is both unnecessary and unwise—unless a specific reason exists to do so. To illustrate, transfusion of 10 mL/kg platelet concentrate, taken directly from the unit and transfused, provides approximately 10,000/ $\mu$ L platelets. If the blood volume of an infant is 70 mL/kg body weight and the plasma volume is 40 mL/kg, the platelet dose of 10 mL/kg increases the platelet count 100,000 to 150,000/ $\mu$ L above the pretransfusion baseline—assuming a posttransfusion platelet recovery of 60%. This calculated increment is consistent with the increment actually achieved after transfusing this dose as reported in clinical studies.<sup>53</sup> With modest thrombocytopenia, a 5 mL/kg dose may be sufficient. In general, 5 to 10 mL/kg is not an excessive transfusion volume even for sick neonates, as long as the intake of other intravenous fluids, medications, and nutrients is adjusted. If volume reduction is to be achieved, the method of reduction *and* the efficacy of platelet transfusions after reduction must be validated *locally* to ensure the quantity and quality of platelets (both *ex vivo* and *in vivo*) remaining after modification.

In the selection of platelet units for transfusion, it is desirable for the infant and the platelet donor to be of the same ABO blood group. It is important to minimize repeated transfusions of group O platelets to group A or B recipients, because large quantities of

passive anti-A or anti-B can lead to hemolysis. This should be avoided easily, with the exception of a directed-donor situation in which the infant receives—usually after an emotional rather than medical decision—platelet transfusions from an out-of-group donor. Directed-donor platelets should not be used in this situation; ABO-identical platelets from the general inventory should be selected. Proven methods exist to reduce the volume of platelet concentrates when truly warranted (eg, multiple transfusions anticipated in which several doses of passive anti-A or anti-B may lead to hemolysis, or failure to respond to a transfusion of 10 mL/kg of unmodified platelet concentrate). However, additional processing should be performed with great care—using a method that is well-validated *locally*—because of probable platelet loss, clumping, and dysfunction caused by the additional handling.

Approach to Infants with Thrombocytopenia

Thrombocytopenia exists wherever the blood platelet count is <150,000/μL. Every infant with thrombocytopenia needs an evaluation—if nothing more than a repeated complete blood count, a review of the medical history, and a physical examination. Definitive management of thrombocytopenia depends on the underlying disorder and is beyond the scope of this discussion (see Chapter 23). Correction of the thrombocytopenia per se by means of platelet transfusions is based on maintaining a platelet count deemed appropriate for the infant’s clinical condition (Table 30-5).

There are no alternatives to platelet transfusion in the care of neonates with thrombocytopenia. Recombinant thrombopoietin (c-Mpl ligand or megakaryocyte growth and differentiation factor) and interleukin-11 are promising agents in older patients. However, neither is recommended for use during infancy, and both have potential toxicities that can preclude their use in the care of sick preterm infants. Thrombopoietin has broad actions on the early precursors of all three major lineages in the marrow and may produce effects in excess of those expected on megakaryocytes and platelets. Moreover, its interactions with fetal/neonatal megakaryocytes may be quite different from those with adults.<sup>52</sup> Interleukin-11 may cause anemia. Clearly, these agents must not be prescribed in the treatment of infants, except in experimental settings with parental consent and institutional oversight. As noted in the plasma transfusion section, recombinant activated Factor VII has been used “off-label” to treat life-threatening bleeding during infancy.

Plasma Transfusion

Pathophysiology of Neonatal Clotting Proteins

Hemostasis in a neonate is quantitatively and qualitatively different from that in an older child or adult, and the risk exists of either serious hemorrhage or thrombosis. Thus, some important facts about neonatal clotting proteins are summarized before issues of plasma transfusion are addressed. (See Chapters 17, 20, and 28 for more detailed discussions of hemostasis.)

Table 30-6. Guidelines for Neonatal Plasma Transfusions

- High risk of bleeding because of acquired deficiency of clotting proteins
  - Exchange transfusion
  - Extracorporeal membrane oxygenation
  - Cardiac bypass surgery
  - Disseminated (consumptive) coagulation
- Bleeding because of congenital clotting protein deficiency, if specific concentrate is unavailable
- Bleeding because of vitamin K deficiency
- Thrombosis because of anticoagulant protein deficiency

Dose depends on severity of the deficiency, but a satisfactory starting dose is 10 to 15 mL/kg body weight of Fresh Frozen Plasma or Plasma Frozen within 24 Hours After Phlebotomy.

Maternal clotting factors do not cross the placenta. Therefore, fetal levels depend on endogenous production. Clotting proteins are synthesized by the fetus beginning in the first trimester, with concentrations gradually increasing throughout gestation.<sup>55</sup> At birth, the mean levels of the contact factors (Factors XII and XI, prekallikrein, and high-molecular-weight kininogen) are approximately 40% to 50% of adult values in term neonates and approximately 30% to 40% of adult values in preterm neonates. The vitamin-K-dependent factors (II, VII, IX, and X) are present at approximately 40% to 50% of adult values in term neonates and at approximately 20% to 50% of adult values in preterm neonates. Strikingly low levels are present in very immature neonates. Neonatal levels of Factors VIII and XIII and fibrinogen are comparable with adult levels, although the level of Factor XIII can be quite low in some infants at birth. The natural anticoagulant proteins (antithrombin and proteins C and S) are 30% to 50% of adult values. Fibrinolysis is less well studied but probably is diminished to a considerable degree because the plasminogen level is moderately low.

Plasma Transfusion Practices

Clotting times are prolonged in neonates compared with results of older children and adults because of developmental deficiency of clotting proteins. Plasma should be transfused only after reference to normal values that take into account the birthweight and age of the infant. Guidelines for neonatal transfusion of plasma are presented in Table 30-6. Fresh Frozen Plasma (FFP) and Plasma Frozen within 24 Hours after Phlebotomy (PF24), whether prepared from whole blood units or by plasmapheresis, are used interchangeably. PF24 has up to a 25% loss of Factor VIII and less loss of Factor V; neither has clinical importance for the vast majority of patients receiving plasma transfusions.

The indications for plasma transfusion include reconstitution of RBC concentrates to simulate whole blood for use in massive transfusions (eg, exchange transfusion, extracorporeal membrane oxygenation, or cardiovascular surgery), provision of multiple clotting factors for bleeding caused by disseminated intravascular coagulation or vitamin K deficiency, and treatment of congenital factor deficiencies when more specific treatment

(purified and virus-inactivated factor concentrates) is not available or the diagnosis of a specific factor deficiency has not been made (ie, multiple factors may need replacement).

The use of prophylactic plasma transfusions to prevent intraventricular hemorrhage in preterm neonates is not recommended. Use of plasma as a suspending agent to adjust the hematocrit of RBC concentrates before small-volume transfusions (15 mL/kg) should be discouraged because plasma offers no medical benefit over simply transfusing red cells suspended in the preservative solution in which they are stored. Similarly, the use of plasma in partial exchange transfusion for the management of neonatal hyperviscosity syndrome (erythrocytosis) is unnecessary, because safer colloid solutions (eg, 5% albumin) are available.

In the treatment of bleeding neonates, cryoprecipitate often is considered as an alternative to plasma because of its small volume. However, cryoprecipitate contains only fibrinogen, von Willebrand factor, and Factors VIII and XIII. It is not effective for managing the more extensive multi-factor clotting deficiencies that are commonly encountered—despite the desirability of a small infusion volume. Discussion of the transfusion of clotting factor concentrates is presented in detail in Chapter 28. However, it is important to point out that recombinant activated Factor VII has been effective in treating life-threatening bleeding in infants with deficiency and/or dysfunction of clotting proteins or platelets.<sup>56</sup>

## Neutrophil Transfusion

### Pathophysiology of Neonatal Neutropenia

Neonates are unusually susceptible to severe bacterial infections, and multiple abnormalities of neonatal body defenses contribute to their pathogenesis. Neonatal neutrophils have both quantitative and qualitative abnormalities related to the increased incidence, morbidity, and mortality of bacterial infections. These abnormalities include absolute and relative neutropenia, diminished chemotaxis, abnormal adhesion and aggregation, defective cellular orientation and receptor capping, decreased deformability, inability to alter membrane potential during stimulation, imbalances of oxidative metabolism, and a diminished ability to withstand oxidant stress.<sup>57</sup>

Neutropenia can occur during fulminant bacterial infection. Because physiologic neutrophilia occurs soon after birth, it is quite unusual for the absolute blood neutrophil count to decrease to less than 2000/ $\mu$ L during the first week of life. Although an abnormally low neutrophil count can occur in neonates with disorders as diverse as sepsis, asphyxia, and maternal hypertension, suspicion of severe bacterial infection must always be high whenever relative neutropenia (neutrophil count  $<2000/\mu$ L) occurs in a sick neonate. The mechanisms responsible for abnormal neonatal granulopoiesis are only partially defined. One factor is that the postmitotic marrow neutrophil storage pool (metamyelocytes and mature, segmented neutrophils) is inadequate during fulminant infection. The neutrophil storage pool accounts for 26% to 60% of all nucleated cells in the marrow of normal

neonates, whereas neonates with sepsis may have a storage pool numbering less than 10% of nucleated marrow cells. Thus, they have severely diminished marrow neutrophil reserves.<sup>58</sup> Second, storage pool neutrophils are released at an excessively rapid and apparently poorly regulated rate from the marrow during stress. Third, committed (clonogenic) neutrophil precursors in neonatal marrow are fewer in number in neonates than in older patients, and most of these cells are actively proliferating even when studied at an apparently basal state.<sup>58,59</sup> Thus, neonatal marrow functions at near capacity in basal state and is unable to either rapidly expand production or release stored neutrophils to meet the increased demands of infection. Additional discussion of fetal and neonatal hematopoiesis is presented in Chapter 25.

### Neutrophil Transfusion Practices

Because both quantitative and qualitative abnormalities of neonatal neutrophils occur, neutrophil transfusions have been reported to successfully treat neonatal sepsis.<sup>60</sup> Neutrophil transfusions generally were given to neonates with fulminant sepsis and relative neutropenia (neutrophil count  $<2000$  to  $3000/\mu$ L during the first week of life or  $<1000/\mu$ L thereafter). Unfortunately, neutrophil transfusions have not provided a satisfactory solution to neonatal sepsis, and they are used rarely, if at all, for several reasons.<sup>60</sup> Although neutrophil transfusion is efficacious for some infants with neutropenia and fulminant sepsis, only neutrophil concentrates obtained by means of automated leukapheresis for transfusion have demonstrated effectiveness. The controlled trials contain scientific flaws, and in many instances, conventional supportive care with antibiotics seemed equally efficacious.

### Approach to Infants with Sepsis and Neutropenia

Each institution must assess its own experience with neonatal sepsis. If nearly all infants survive without apparent long-term morbidity when treated only with antibiotics, neutrophil transfusions are unnecessary, and attention should be focused on prompt diagnosis and optimal antibiotic therapy. If the outcome of standard therapy is not optimal, alternative therapies must be considered to improve the outlook. Such therapies include intravenous immunoglobulin (IVIG) and/or myeloid cytokines such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF).

Most studies evaluating prophylactic IVIG to prevent neonatal infections have shown either little or only modest benefit, whereas several therapeutic studies have shown a benefit to adding IVIG to antibiotics to treat neonatal infections.<sup>61</sup> Data are insufficient to justify the use of IVIG as a standard of care for all preterm neonates to prevent or manage sepsis. However, it seems reasonable to give “physiologic” doses of IVIG (0.3 to 0.4 g/kg) to septic very-low-birthweight neonates because they are likely to have hypogammaglobulinemia as a result of extremely premature birth (ie, being born before major placental transport of immunoglobulin G has taken place). To date, properly designed clinical studies of recombinant myeloid growth factors given to

human neonates are limited,<sup>62,63</sup> and firm recommendations cannot be made for use of these agents in the management of neonatal neutropenia or sepsis.

There is no universally accepted role for neutrophil transfusions, IVIG, or myeloid growth factors as a standard of practice to treat neonatal sepsis. Until more information becomes available, it seems reasonable to manage fulminant sepsis in neonates with neutropenia (neutrophil counts  $<2000/\mu\text{L}$  during the first week of life or  $<1000/\mu\text{L}$  thereafter) as follows. For infants born before 30 weeks of gestation, give one dose of 0.4 g/kg of IVIG to correct possible hypogammaglobulinemia plus 5  $\mu\text{g/kg}$  of G-CSF or 10  $\mu\text{g/kg}$  GM-CSF on 3 consecutive days. For infants born at 30 weeks of gestation or after, give 5  $\mu\text{g/kg}$  of G-CSF or 10  $\mu\text{g/kg}$  GM-CSF on 3 consecutive days. This therapy should be adjunctive to optimal antibiotic and supportive care, and it must be given with parental consent and the understanding that its efficacy and potential toxicity are not completely understood. Actually, because of high plasma levels of endogenous G-CSF already present in some septic neonates, it has been cautioned that adding additional exogenous recombinant G-CSF offers no benefit.<sup>64</sup>

## Transfusion Support for the Oncology Patient

**Christopher A. Tormey<sup>1</sup> & Edward L. Snyder<sup>2</sup>**<sup>1</sup> Instructor, Department of Laboratory Medicine, Yale University School of Medicine, Yale-New Haven Hospital, New Haven, Connecticut, USA<sup>2</sup> Professor of Laboratory Medicine, Yale University School of Medicine, and Director, Blood Bank/Apheresis Service, Yale-New Haven Hospital, New Haven, Connecticut, USA

Transfusion support for patients with cancer is a complicated, multifaceted medical therapy meant to overcome complications related to chemotherapy, radiation, transplantation, or widespread metastatic disease. Oncology patients are often substantially immunosuppressed and may require chronic transfusion support. For these patients, greater attention must be paid to the preparation, modification, and response to blood components to help ensure better outcomes. Furthermore, with recent evidence that drugs such as erythropoietin may be particularly harmful to oncology patients, heavier reliance on allogeneic blood transfusion may be necessary in the immediate future. This chapter highlights the most challenging aspects of transfusion therapy for oncology patients encountered by clinicians and transfusion services on a routine basis.

## Red Cell Transfusion

### Indications

Red cell transfusions should be used to increase the oxygen-carrying capacity of whole blood for oncology patients with anemia. Unfortunately, there are no oncology-specific evidence-based target laboratory criteria for the transfusion of Red Blood Cell (RBC) units. Therefore, oncology patients should be transfused on a symptomatic basis or at predetermined hemoglobin or hematocrit measurements as defined by oncology services. When clinicians apply standards used in other critically ill populations, and consider the underlying comorbid diseases, most oncology patients should tolerate hemoglobin levels of 7 to 10 g/dL without the need for allogeneic transfusions.<sup>1</sup> There is no evidence to show that sustained increases in hemoglobin over 10 g/dL provide any therapeutic benefit for ill patients; in fact, “hypertransfusion” strategies may actually be harmful to patient outcome.<sup>2</sup>

### Selection of ABO Group for RBC Transfusion

For the majority of oncology patients, no specific consideration is given to selection of ABO group of RBC units so long as the unit is ABO compatible with the recipient. However, for patients who have undergone allogeneic hematopoietic stem cell transplantation (HSCT), the choice of ABO group can be difficult, particularly if there is an ABO mismatch between hematopoietic progenitor cell (HPC) donor and recipient. ABO incompatibility, although not a barrier to HSCT, does complicate posttransplant management. Patients receiving ABO-mismatched transplants are known to require more transfusions because of delayed cellular engraftment and red cell aplasia. These patients are also at risk for acute and delayed red cell hemolysis caused by ABO incompatibility during HPC reinfusion and as engraftment takes place.<sup>3-7</sup> Despite these complications, numerous studies have shown that ABO-mismatched HSCT does not adversely affect long-term survival or outcome in either pediatric or adult populations.<sup>3,8,9</sup>

Although ABO mismatch does not seem to have long-term drawbacks, providing appropriate blood component support immediately following transplantation can be a complex endeavor for a transfusion service. In the setting of allogeneic transplantation, there are several possibilities for ABO antibody mismatch. Patients may have a minor mismatch, wherein the donor possesses antibodies against recipient cells. This would occur when a patient with group A red cells receives HPCs from a group O donor. Another possibility is a major mismatch, wherein a recipient harbors antibodies directed against donor cells. This would occur when a patient with group O red cells receives HPCs from a group A donor. For minor incompatibility, a strategy to reduce hemolysis during HPC infusion is plasma reduction to remove, or significantly lower, titers of offending antibodies.<sup>10</sup> Similarly, for major mismatches, techniques for red cell depletion can prevent immediate hemolysis during infusion.<sup>11</sup>

After transplantation, the selection of blood components can be difficult, because antibodies can persist for weeks or months after stem cell rescue.<sup>12,13</sup> Additionally, following HSCT,

patients may present as chimeras with two distinct blood group populations seen on routine type and screening tests.<sup>12</sup> Thus, strategies have been developed to provide the most appropriate ABO component for these patients. For major incompatibility, with recipient anti-A or anti-B directed against donor red cells, it is necessary to use recipient-type RBC units until ABO antibodies are no longer detectable.<sup>10,14,15</sup> For minor incompatibility, recipient-type plasma and platelets are necessary until the recipient's red cells are no longer detectable. Donor-type RBC units can be used immediately after HSCT for minor incompatibility.<sup>10,14,15</sup> For a patient with both major and minor incompatibility ("two-way" incompatibility), group O RBC units and group AB plasma and platelets should be used until offending antibodies and cells are no longer detectable. Tables 31-1 and 31-2 summarize major and minor incompatibility by blood group and provide a transfusion protocol for ABO-mismatched HSCT.<sup>10,14,15</sup> Table 31-2 provides a suitable protocol to follow.

### Alloimmunization to Red Cell Antigens

Despite significant immunosuppression, patients with malignancies may still mount immune responses to "foreign" red cell antigens.<sup>16</sup> This not only complicates transfusion, but

also may increase the risk for hemolysis in patients undergoing allogeneic HSCT.<sup>17</sup> Rates for red cell alloimmunization have been most extensively studied in patients with hematologic malignancies undergoing HSCT and range from 2% to 8% in these populations.<sup>18,19</sup> Other retrospective or prospective studies are necessary to better define the red cell alloimmunization rate for patients with solid tumors and other oncologic problems.

### Alternatives to Allogeneic Red Cell Transfusion

For patients unwilling, or unable, to undergo allogeneic transfusion, several alternatives are available (see Chapter 37). In theory, red cell alternatives should reduce infectious and immunologic complications of allogeneic transfusion while providing similar therapeutic benefit. Several perioperative techniques have been developed to curb allogeneic blood use in the operative setting (see Chapter 38). Acute normovolemic hemodilution (ANH) involves the removal of whole blood immediately before a surgical procedure with crystalloid or colloid volume replacement.<sup>20</sup> If bleeding occurs, the blood is readily available for reinfusion at the bedside. ANH has been shown to reduce the need for allogeneic transfusion in multiple studies.<sup>20</sup> Intraoperative blood recovery—a process whereby shed whole blood is centrifuged, washed of contaminants and debris, and then reinfused to the patient—is also of benefit in reducing allogeneic blood usage.<sup>21</sup> Although some concerns about promotion of tumor cell metastasis with the use of blood recovery and reinfusion have been raised, several trials conducted in the setting of surgery for hepatobiliary and genitourinary cancers have shown no evidence of decreased survival in these patients.<sup>22-24</sup> Furthermore, irradiation of the recovered blood has also been shown to prevent poor outcome in oncology patients undergoing surgery.<sup>25</sup> The use of preoperatively donated autologous whole blood can also be considered, although this is often not feasible for oncology patients who are too anemic and who can require surgery at unpredictable times. Despite the irregular scheduling of oncologic surgery, autologous whole blood donation has been successfully utilized for patients with prostate cancer and

**Table 31-1.** Compatibility by ABO Group in Hematopoietic Stem Cell Transplantation

| Recipient ABO Blood Group | Donor ABO Blood Group |    |    | AB |
|---------------------------|-----------------------|----|----|----|
|                           | O                     | A  | B  |    |
| O                         | C                     | M  | M  | M  |
| A                         | m                     | C  | Mm | M  |
| B                         | m                     | mM | C  | M  |
| AB                        | m                     | m  | m  | C  |

C = compatible; M = major incompatibility; m = minor incompatibility; mM = both major and minor incompatibility ("two-way" incompatibility).

| Recipient | Donor O  |              |                | Donor A  |              |                | Donor B  |              |                | Donor AB |              |                |
|-----------|----------|--------------|----------------|----------|--------------|----------------|----------|--------------|----------------|----------|--------------|----------------|
|           | RBC type | FFP/PLT type | 2nd choice PLT | RBC type | FFP/PLT type | 2nd choice PLT | RBC type | FFP/PLT type | 2nd choice PLT | RBC type | FFP/PLT type | 2nd choice PLT |
| O         | O        | O            | A or           | O        | A            | O              | O        | B            | O              | O        | AB           | A              |
| A         | O        | A            | O              | A        | A            | O              | O        | AB           | A              | A        | AB           | A              |
| B         | O        | B            | O              | O        | AB           | A              | B        | B            | O              | B        | AB           | B              |
| AB        | O        | AB           | A              | A        | AB           | A              | B        | AB           | B              | AB       | AB           | A or B         |

NOTE: Rh positive recipients with Rh negative donors receive Rh negative products. Rh negative recipients with Rh positive donors receive Rh positive products.

gynecologic malignancies.<sup>26,27</sup> It is recommended, however, that the use of preoperative autologous donation be restricted to oncology patients undergoing major surgery, because it is not necessarily a cost-effective therapy for all patients.<sup>28</sup>

The routine administration of erythropoietin-stimulating agents (ESAs) to patients with cancer-related anemia was a strategy developed to reduce allogeneic transfusion within oncology populations.<sup>29</sup> However, the chronic use of ESAs for anemia in patients with cancer, as well as for those with other critical illnesses, has come under scrutiny. Several large trials have demonstrated that ESA administration may lead to decreased patient survival and increased risk for thrombosis.<sup>30-32</sup> It has been postulated that erythropoietin administration accelerates tumor growth, accounting for decreased survival trends.<sup>33</sup> It has also been found that ESAs do not necessarily significantly decrease the need for allogeneic transfusion in critically ill patients.<sup>30-32,34</sup> The results of these trials prompted the Food and Drug Administration (FDA) to issue a “black box warning” for the use of ESAs in the setting of cancer-related anemia.<sup>35</sup> More data and clinical trials will be necessary to ascertain the ultimate safety and efficacy profile for the use of ESAs in oncology patients.

**Component Modification: Irradiation and Leukocyte Reduction**

Because of their immunosuppressed state, many oncology patients are at high risk for transfusion-associated graft-vs-host disease (TA-GVHD), wherein donor lymphocytes generate a profound

immune response against the recipient’s cells.<sup>36</sup> The causes and manifestations of TA-GVHD are discussed below (see Adverse Reactions to Blood Transfusion). Prevention of TA-GVHD can be accomplished with gamma irradiation of cellular blood components.<sup>36</sup> Table 31-3 summarizes disorders for which gamma irradiation is prudent.<sup>37</sup> Some within the field of transfusion medicine have argued for a policy of universal blood component irradiation. The process has few side effects and broad application of irradiation may help to eliminate TA-GVHD in the occasional patient who is at risk for TA-GVHD, but whose high-risk status is not known to the physicians or other caregivers. The practicality and cost-effectiveness of such a policy has not been determined.<sup>38</sup> Irradiation of red cells does have the disadvantage of inducing a red cell membrane potassium leak, which shortens the shelf life of the RBC unit to no more than 28 days from the date of irradiation.

In addition to irradiation, blood collection centers and blood banks have implemented prestorage leukocyte reduction techniques to improve transfusion outcomes. Leukocyte reduction of blood components is particularly beneficial for oncology patients. By decreasing the absolute numbers of white cells in RBC units, alloimmunization to HLA antigens is reduced. Leukocyte reduction has also had an ameliorating effect on immunologic refractoriness to platelet transfusions, a significant problem for chronically transfused oncology patients.<sup>39,40</sup> Unfortunately, prestorage leukocyte reduction has not shown a benefit in the reduction of red cell antigen alloimmunization.<sup>41</sup> Beyond alloimmunization, leukocyte reduction has the potential

**Table 31-3.** Indications for Gamma Irradiation of Cellular Blood Components

|                         |                                          |                                                         |

to prevent passage of some transfusion transmitted diseases—cytomegalovirus (CMV) and other pathogens residing within white cells are efficiently filtered via leukocyte reduction.<sup>39</sup> Furthermore, studies have shown a reduction in febrile transfusion reactions associated with leukocyte filtration of blood components.<sup>39</sup> According to the 2007 National Blood Collection and Utilization Survey, approximately 72% of all RBC units in the United States in 2006 were leukocyte reduced, most of them before storage.<sup>42</sup>

## Platelet Transfusion

### Indications

Platelet transfusion for oncology patients is intended to stop or prevent bleeding in the setting of thrombocytopenia. The use of platelet transfusion for acute hemorrhage in the patient with low platelet counts, or receiving antiplatelet medication, is a first-line therapy.<sup>43</sup> Much greater controversy exists, however, in the consideration of platelet transfusion for bleeding prophylaxis. Historically, the practice of providing platelet transfusions on a prophylactic basis arose out of studies involving patients with leukemia who were noted to have decreased bleeding episodes following platelet transfusion.<sup>44</sup> Until the early 1990s, routine bleeding prophylaxis included platelet transfusions for oncology patients with platelet counts less than 20,000/ $\mu$ L.<sup>45</sup> However, as clinical experience and evidence mounted, it was found that oncology patients could tolerate much lower platelet counts without development of severe bleeding. A number of clinical trials, beginning in 1991, demonstrated that spontaneous hemorrhage was unlikely even at platelet counts as low as 5000 to 10,000/ $\mu$ L. Bleeding episodes and morbidity in these patients were no worse than for those individuals transfused at higher “trigger” platelet counts.<sup>46–51</sup> These studies also found that stringent transfusion criteria led to a significant reduction in transfused platelet products, thereby reducing the risks associated with chronic transfusion exposure.

The evidence provided by these clinical trials led to the implementation of more conservative platelet transfusion triggers. Most oncology and hematology guidelines now recommend platelet transfusion only in patients with platelet counts less than 10,000/ $\mu$ L in the absence of bleeding.<sup>52,53</sup> It is important to recognize that clinical history, presentation, and comorbid states influence the decision to transfuse platelets. For instance, a patient undergoing a major surgical procedure or one who has a history of platelet dysfunction may require higher baseline platelet counts or more frequent platelet transfusion. For patients undergoing major invasive procedures (eg, central venous catheter placement before HPC collection) goals of platelet counts of 40,000 to 50,000/ $\mu$ L are an appropriate target, while procedures such as marrow aspiration can be safely performed at platelet counts less than 20,000/ $\mu$ L.<sup>54</sup>

Of note, although clinical trials have shown no increased bleeding complications associated with stringent platelet

transfusion criteria, a recent study suggests that persistent and profound thrombocytopenia leads to greater patient mortality. This retrospective analysis of patients following HSCT showed greater risk for mortality for those individuals who received platelets according to stringent (ie, <10,000/ $\mu$ L) criteria.<sup>55</sup> Mortality in these cases, not associated with bleeding episodes, may imply some other protective benefit to increased platelet counts in oncology patients. Prospective studies on long-term patient survival and outcome with conservative approaches to platelet transfusion may yet again change the landscape for the treatment of thrombocytopenic oncology patients.

### Selection of ABO Group and Rh Type for Platelet Transfusion

The ABO antigens are expressed on several platelet proteins and lipids, although the interactions between these antigens and circulating host antibodies do not mediate clinically significant transfusion reactions.<sup>56</sup> Thus, most blood banks will transfuse ABO-mismatched platelets to adults without significant concern for incompatibility. However, for the oncology patient, the use of ABO-mismatched platelet products could result in poor outcome and decreased therapeutic benefit. For instance, a form of platelet refractoriness is mediated by ABO antibodies, with mismatched platelets cleared from circulation minutes to hours after infusion.<sup>56</sup> Furthermore, there is some evidence to suggest that ABO incompatibility can promote the development of HLA alloimmunization in multitransfused patients.<sup>56</sup> Another concern is the possibility for hemolytic transfusion reactions secondary to high-titer or high-avidity ABO antibodies present in the plasma fraction of platelet pools. Although rare, there are several case reports of high-titer ABO antibodies mediating severe hemolysis in patients with hematologic and oncologic diseases receiving apheresis platelet products.<sup>57–60</sup> Children in particular may demonstrate clinically significant hemolysis to ABO-incompatible platelet transfusions given their small blood volume. Therefore, it is advisable that oncology patients with low platelet counts receive ABO-compatible platelet products if at all feasible. For populations undergoing HSCT, other considerations regarding major and minor mismatches are also relevant. Table 31-2 summarizes guidelines for platelet transfusion therapy in the peritransplant period.

Although there are no Rh antigens on platelets, the concern for Rh alloimmunization during platelet transfusion arises secondary to the presence of residual D-antigen-positive red cells in platelet products collected from Rh-positive donors. Even a few milliliters of red cells are sufficient to cause alloimmunization in Rh-negative recipients, because of the immunogenicity of the D-antigen. There is evidence to suggest that, in part due to immunosuppression, both adult and pediatric patients with hematologic malignancies are unlikely to form anti-D responses to Rh-incompatible platelet transfusions.<sup>61,62</sup> Thus, the provision of Rh-incompatible platelet products is likely a safe procedure and unlikely to cause D alloimmunization in oncology populations. Nonetheless, it is still advisable to prevent Rh

alloimmunization in children and females of childbearing potential, because of the consequences of anti-D development in these populations. Alloimmunization can be prevented with a dose of 250 IU (50 µg) of intravenous Rh Immune Globulin provided within 72 hours of D antigen exposure.<sup>63</sup>

Platelet Refractoriness and Alloimmunization

In the chronically transfused oncology patient, increases in platelet count may be lower than expected following transfusion. This phenomenon, known as platelet refractoriness, can be attributed to both immune and nonimmune causes. In oncology patients, approximately 70% to 80% of cases of platelet refractoriness are caused by nonimmunologic factors.<sup>43</sup> Table 31-4 provides a list of the most common variables associated with nonimmune platelet refractoriness. For the patient with non-immunologic platelet refractoriness, few clinical management options exist. Addressing the underlying cause (eg, splenectomy for hypersplenism, removal of an offending medication) can often alleviate refractoriness. For the acutely bleeding patient or for hemorrhage prophylaxis, strategies of continuous platelet infusion (“platelet drip”) have been attempted with moderate success.<sup>54,64</sup> The “platelet drip,” wherein a dose of platelet concentrate is infused slowly over a 4-hour period, is intended to provide an ongoing source of platelets to maintain vascular integrity, while addressing the practical concern of blood bank platelet inventory conservation.

An underlying antibody to platelet antigens is most often responsible for the remaining 20% to 30% of platelet refractoriness in oncology patients. Platelets express Class I HLA and numerous other platelet-specific antigens. Most commonly, HLA antigens mediate immunologic platelet refractoriness, although the chronically transfused patient may develop alloantibodies to any platelet antigen.<sup>43,65</sup> Treatment strategies for immune-mediated platelet refractoriness center on providing antigen-negative components. The first and simplest strategy for managing immune platelet refractoriness is to provide ABO-compatible units. The next option would be

to obtain crossmatch-compatible platelets from the hospital blood bank or donor center. This process involves crossmatching of patient serum against a variety of donor platelets and selection of those products for which no agglutination reaction is observed.<sup>66</sup> Platelet count responses to crossmatch-compatible platelets may be sustainable for 2 to 3 days, but this is also dependent on the age of the unit and other underlying clinical factors.

If the majority of tested donors are incompatible with recipient serum, HLA typing of the recipient and provision of HLA antigen-matched platelet products is likely necessary.<sup>43,65</sup> Polymorphisms of HLA Class I antigens can complicate compatibility testing and make the process of finding fully matched donors very difficult. The Duquesnoy grading system was developed to allow for the most advantageous use of partially mismatched donations.<sup>67</sup> Newly developed computerized algorithms, based on characterization of HLA polymorphisms, are paving the way for broader matches that may help reduce the need to provide partially incompatible platelet products.<sup>68</sup>

Crossmatch-compatible platelets have been proven to be as efficacious as HLA-matched platelets in raising platelet counts in alloimmunized patients.<sup>43,65,66</sup> Thus, the decision to provide HLA-matched platelets should depend upon factors such as quality of the HLA match, severity of alloimmunization, and availability of crossmatched platelet products. In many cases, crossmatch-compatible platelets can be more quickly and easily obtained and are available at lower cost than HLA-matched products.

The best strategy to reduce immune-mediated platelet refractoriness is prevention of HLA and platelet antigen exposures. The trend toward universal leukocyte reduction has helped reduce the incidence of alloimmune platelet refractoriness by limiting exposure to HLA antigens.<sup>40</sup> Conservative transfusion strategies also help to prevent exposure to various HLA and platelet-specific antigens and may play a role in reducing the frequency of alloimmunization. Unfortunately, once alloimmunization has occurred, immune-modulation with corticosteroids, plasmapheresis, and intravenous immune globulin have been of little benefit.<sup>69</sup>

Table 31-4. Most Common Causes of Refractoriness to Platelet Transfusion

| Category                      | Cause                                                             |
|-------------------------------|-------------------------------------------------------------------|
| Nonimmunologic refractoriness | Acute bleeding/consumption                                        |
|                               | Fever (any cause)                                                 |
|                               | Infection                                                         |
|                               | Medications (eg, amphotericin B)                                  |
|                               | Microangiopathy or disseminated intravascular coagulation         |
|                               | Splenomegaly                                                      |
| Immunologic refractoriness    | ABO-mismatched transfusion                                        |
|                               | HLA and/or platelet-specific alloantibodies                       |
|                               | Autoimmune thrombocytopenia (eg, immune thrombocytopenic purpura) |

Alternatives to Platelet Transfusion

For patients unwilling to undergo platelet transfusion, or for severe platelet refractoriness, several medical therapies can aid in bleeding episodes. A commonly prescribed drug, 1-deamino-8-D-arginine vasopressin (DDAVP), acts to stimulate the release of von Willebrand factor from endothelial cells, which can enhance platelet activity even at very low platelet counts.<sup>70</sup> DDAVP is also of proven benefit for platelet dysfunction and bleeding associated with uremia.<sup>71</sup> Antifibrinolytic therapies have also been employed as an adjunct to platelet transfusions for the bleeding patient. Medications such as aminocaproic acid, tranexamic acid, and aprotinin have all been successfully used to reduce hemorrhage and allogeneic transfusion requirements in the bleeding patient.<sup>72,73</sup>

Chemical and cytokine-based stimulation of the marrow to endogenously increase platelet production has also been attempted. Agents such as thrombopoietin (TPO) and megakaryocyte growth factors have been synthesized, but clinical trials with some of these drugs led to the development of neutralizing antibodies and thrombocytopenia in recipients.<sup>74,75</sup> TPO and TPO-like growth factors are finishing clinical trials and may be considered for FDA licensure in the near future. One such agent, AMG531 (Nplate, Amgen, Thousand Oaks, CA), has been licensed by the FDA. Interleukin (IL)-11, a cytokine that drives megakaryocyte production and division, also has been approved for use in thrombocytopenia.<sup>74,75</sup> The development of other similar cytokine agents is currently under way.<sup>74,75</sup>

### Selection of Platelet Products

Platelet products in the United States, Canada, and Europe can be prepared in several ways. In the past, the majority of platelet units available for transfusion were derived, via centrifugation, from whole blood.<sup>43</sup> These individual units are pooled in groups of four to five to yield a product intended to raise platelet counts by approximately 50,000/ $\mu$ L. Thus, platelet pools consist of individual units from multiple donors. Since the 1970s, apheresis techniques have been developed to allow for the collection of full doses of platelet products from one donor.<sup>76</sup> Apheresis platelets have grown in popularity and usage, and provide a platelet dose virtually equivalent to pooled platelets.<sup>43</sup> Thus, the decision to use platelet pools or platelets from one donor relates more to concerns about exposures to multiple donors, risks for alloimmunization, and platelet quality rather than increases in baseline platelet count.

The primary consequence of transfusions obtained from multiple donors is an increased risk for transfusion-transmitted disease.<sup>77</sup> For the heavily immunosuppressed oncology patient, this fact alone would seemingly favor the use of apheresis platelets. However, with more rigorous donor screening and sensitive nucleic acid testing, the risk of transfusion-transmitted disease is virtually the same between platelet product options. In addition, even with the use of apheresis products, chronically transfused oncology patients are likely to be exposed to a multitude of donors over the course of their disease. Thus, the use of one apheresis platelet unit in an overall transfusion strategy has minimal benefit in reducing infectious disease risks. Thus, from an infectious disease standpoint, apheresis platelets are not necessarily preferred.

Another consideration in exposure to multiple donors is increased risk for platelet alloimmunization. In the era before leukocyte reduction, this was a significant concern for pooled products. However, with the advent of leukocyte reduction, a patient is as likely to become alloimmunized to a platelet pool as to a platelet product from an individual donor.<sup>40</sup> Thus, there is minimal advantage in using apheresis platelets to prevent alloimmunization. Once a patient has become alloimmunized, the use of platelet pools may be advantageous until crossmatch-compatible or HLA-matched units are available. In this scenario, an

alloimmunized thrombocytopenic patient may be more likely to respond to one of the four or five donors whose units constitute a platelet pool. For the alloimmunized patient, apheresis platelets should be employed only if the unit is crossmatch-compatible or HLA-matched.<sup>43</sup>

The quality of platelet products does differ somewhat between pooled and apheresis units. Markers of platelet activation, such as P-selectin, are increased in whole-blood-derived platelet concentrates as compared to apheresis platelets.<sup>78</sup> These changes, however, have not correlated with poor in-vivo platelet recovery. Thus, current evidence does not suggest that apheresis platelets are a more viable platelet option. From the standpoint of adverse reactions to platelet transfusion, large trials have revealed no difference in adverse events between apheresis and whole-blood-derived products.<sup>79</sup> Bacterial contamination does remain an outstanding concern for pooled platelets given the number of donors and various manipulations of the unit before issuance of the final product. Methods to address the contamination of pooled products, such as prestorage pooling with sampling for bacterial cultures, may help to identify contaminated units.<sup>80</sup> By comparison, apheresis products do offer a lower risk for bacterial contamination, but the risk for contamination has not been completely eliminated.<sup>81,82</sup> Indeed, 7-day apheresis platelets have been reported to be associated with greater bacterial contamination than 5-day apheresis platelets. Thus, from the standpoint of platelet quality, apheresis platelets seem to offer little advantage when compared to platelet concentrate pools.

### Platelet Product Modification: Irradiation, Leukocyte Reduction, and Volume Reduction

As is the case with RBC units, platelets can be modified to maximize safety for oncology patients. Despite leukocyte reduction, platelet units contain small amounts of white cells. Thus, patients at risk for TA-GVHD should receive irradiated platelets.<sup>36</sup> Table 31-3 summarizes those malignant conditions for which gamma irradiation is appropriate. As mentioned previously, leukocyte reduction of platelet products helps to reduce alloimmunization and refractoriness.<sup>40</sup> According to the 2007 National Blood Collection and Utilization Survey, approximately 40% of all whole-blood-derived platelet units were leukocyte reduced, and essentially all apheresis platelets were leukocyte reduced.<sup>42</sup> The movement toward universal leukocyte reduction in the United States should help ease the burden of alloimmunization in coming years.

Volume reduction of platelet products via centrifugation and resuspension in saline should be considered for oncology patients who have experienced severe allergic and/or anaphylactic reactions to platelet products.<sup>83</sup> Volume reduction is also efficient at removing the plasma fraction of platelet products to reduce the risk of hemolysis associated with ABO-incompatible transfusion.<sup>83</sup> Volume reduction and saline resuspension should be considered for ABO-mismatched platelet transfusions in infants and children with small blood volumes.

## Plasma and Cryoprecipitated AHF Transfusion

### Indications, Selection of ABO Group, and Product Modification

Plasma transfusions should be used to stop or prevent bleeding in patients with coagulopathy caused by vitamin K antagonists, factor consumption, or liver disease.<sup>84,85</sup> Cryoprecipitated AHF can be used to treat bleeding associated with uremia or Factor XIII deficiency associated with severe GVHD.<sup>71,86</sup> Plasma should not be used as the sole fluid for volume replacement because of limited supplies and the risks associated with blood transfusion. For the majority of oncology patients, no specific additional consideration is given to selection of ABO group for plasma or cryoprecipitate so long as the unit is ABO compatible with the recipient. Donor and recipient Rh types are not a consideration for infusion of plasma or cryoprecipitate. As mentioned previously, for patients who have undergone allogeneic HSCT, the choice of ABO group can be complex and should be based upon consideration of major and minor mismatches. Table 31-2 summarizes guidelines for plasma transfusion therapy in the peri-transplant period; guidelines for cryoprecipitated AHF are identical to those for plasma. Plasma and cryoprecipitated AHF are maintained at temperatures below  $-20^{\circ}\text{C}$ ; because they are acellular, there is no need for gamma irradiation.

### Alternatives to Plasma Transfusion

For some oncology patients, plasma transfusion may be contraindicated, may be ineffective, or (in the setting of acute hemorrhage) may not provide rapid enough reversal of coagulopathic states. For these conditions, there are several alternatives to plasma products, mostly consisting of recombinant coagulation factors. Among the most commonly used agents for acute moderate to severe bleeding is recombinant activated Factor VII, a potent activator of the coagulation cascade.<sup>87</sup> Successful use of Factor VIIa has been reported to help control massive bleeding in a variety of oncology patients.<sup>88-91</sup> There is also a role for use of Factor VIIa as a bypass agent for those oncology patients who acquire inhibitors to circulating coagulation factors, mainly Factor VIII.<sup>92</sup> Factor VIIa failures in bleeding oncology patients have also been reported; a patient with refractory gastrointestinal bleeding associated with GVHD following HSCT showed no improvement of hemorrhage following Factor VIIa administration.<sup>93</sup>

The instances of Factor VIIa usage cited above highlight the difficulty of recommending broad application of this therapy to the bleeding oncology patient. The most significant problem with making an evidence-based recommendation is that the vast majority of uses of Factor VIIa in the literature are in the form of case reports. Few adequate clinical trials have been conducted to determine the safety and efficacy of this drug in oncology populations. Furthermore, appropriate dosing regimens are imprecise and mostly based on data gathered in trials performed in other critically ill patient populations. Factor VIIa also carries a number of risks, chief of which is the possibility for development

of severe or even fatal thromboembolism.<sup>94</sup> Thus, Factor VIIa may be considered as an alternative to plasma infusion, but should be used only after other interventions have failed.

### Intravenous Immune Globulin

Intravenous immune globulin (IVIG) has become a very useful product in the management of oncology patients.<sup>95</sup> Consisting of human gamma globulins, IVIG has been used to provide passive immunity in highly immunosuppressed individuals. IVIG has also been successfully used as immunomodulatory therapy for patients with conditions such as immune thrombocytopenic purpura (ITP).<sup>96,97</sup> For recipients of HPC products, IVIG has been associated with improved immune defense against pathogens such as CMV and has helped to decrease the complications of acute GVHD.<sup>98,99</sup> The benefit from use of IVIG for chronic GVHD and infection prophylaxis in marrow transplantation is not clear and warrants further study.<sup>99</sup>

IVIG infusion is usually tolerated without significant adverse events in oncology patients. The common side effects of administration include myalgias, headache, fever, and fatigue.<sup>100</sup> A rare but serious complication of IVIG administration is acute renal failure seen with particular formulations using sucrose as a globulin stabilizer.<sup>100</sup> Thus, oncology patients with chronic renal insufficiency should be closely monitored during IVIG administration. Current IVIG products have not transmitted hepatitis B, hepatitis C, or human immunodeficiency virus; there are rare case reports of transmission of viruses such as parvovirus B19, a serious pathogen for oncology patients.<sup>101</sup> Plasma is now screened for this virus before being pooled for fractionation.

## Granulocyte Transfusion

### Indications

Granulocyte transfusion is a therapeutic option used almost exclusively in oncology patients. Classically, granulocyte infusions have been used to treat severe, antibiotic-refractory bacterial or fungal infections in patients with an absolute neutrophil count of less than  $500/\mu\text{L}$ . Only patients with a reasonable chance at sustainable marrow recovery after resolution of the underlying infection are candidates for granulocyte products.<sup>102</sup> Granulocyte infusion may be useful for patients who have received ablative chemotherapy regimens and who are not able to mount an adequate cellular response to infection. In general, to overcome a significant bacterial or fungal infection, humans should produce  $2$  to  $3 \times 10^{11}$  polymorphonuclear cells per day, numbers that often cannot be achieved for the immunosuppressed oncology patient.<sup>103</sup> The transfusion of exogenous granulocytes can provide additional innate immunity. Doses of  $1 \times 10^{11}$  granulocytes per square meter of body surface area have been reported to increase neutrophil counts by 1000 to 2000/ $\mu\text{L}$  are higher.<sup>103</sup>

In the past, the most significant barrier to the use of granulocytes was obtaining an adequate dose from a healthy donor. Trials performed in the 1970s and 1980s, using whole blood filtration

and centrifugation techniques, showed little clinical benefit likely secondary to suboptimal granulocyte doses.<sup>102</sup> By the mid-1980s granulocyte infusion therapy was largely abandoned. The technique gained renewed interest in the early 1990s primarily because of the development of granulocyte colony-stimulating factor (G-CSF).<sup>104</sup> The administration of G-CSF to healthy donors allowed for nearly 10-fold increases in granulocyte collection yield. G-CSF has led to higher granulocyte doses and has the added benefit of promoting persistent elevation in recipient white count after infusion, attributable to mobilization of both mature granulocytes and earlier myeloid precursors in donor products.<sup>102</sup> Improvements in apheresis technology have also helped to increase white cell collection efficiency.

Over the last 10 to 15 years, a number of trials have been performed to evaluate the safety and efficacy of granulocyte transfusion using G-CSF stimulation in healthy donors. Studies performed in both adult and pediatric populations have found that granulocyte transfusion leads to significant improvement in patients with fungal infections refractory to antimicrobial drugs.<sup>105–110</sup> Granulocyte doses in these studies were routinely 5 to  $10 \times 10^{10}$  with resultant increases in peripheral white count of 2000 to 5000/ $\mu\text{L}$ . There is also a growing body of literature on the prophylactic use of granulocyte transfusion to prevent onset or recurrence of severe infection.<sup>106,111–113</sup> While this therapy may have some efficacy in prevention of fungal infection recurrence, the role of granulocytes as an agent for primary infection prophylaxis remains unclear. To determine the true efficacy of granulocyte transfusion in these settings, future randomized, controlled trials will be necessary.<sup>102</sup>

### Selection of ABO Group and Donor Preparation

Healthy donors who qualify for granulocyte transfusion should be ABO-compatible with the intended recipient; products must be crossmatched before infusion because of high red cell content. A popular granulocyte mobilization regimen used in donors consists of the administration of 5 to 10  $\mu\text{g/kg}$  G-CSF subcutaneously, in combination with 8 mg oral dexamethasone, both administered approximately 12 hours before leukapheresis.<sup>114</sup> Granulocyte collections can be performed serially over 4 to 5 days to yield multiple doses for neutropenic patients. For granulocyte donors, side effects are usually mild and include bone pain, headache, fatigue, and fluid retention caused by G-CSF administration and apheresis.<sup>102,110,114</sup>

### Alloimmunization

The large number of white cells, red cells, and platelets contained within a granulocyte product increases the potential for red cell, HLA, and platelet antigen alloimmunization in oncology patients.<sup>115</sup> Unfortunately, most donor centers do not have the time to match donors and recipients according to HLA antigen expression given the urgent need to supply the granulocyte product. There is evidence to show that those patients previously alloimmunized to HLA antigens via chronic transfusion demonstrate reduced response to granulocyte infusion.<sup>116</sup> Thus, the

expectation for successful response to granulocyte therapy should be tempered in an individual who has previously demonstrated HLA alloimmunization. For these patients, HLA-antigen matching may be necessary to improve outcome of granulocyte transfusion.

### Alternatives to Granulocyte Transfusion

The decision to initiate granulocyte transfusion usually represents failure of other forms of therapy. In these cases, few other treatment options exist. The administration of G-CSF to the neutropenic patient may aid in the production of endogenous granulocytes and is a potential treatment strategy for infection prophylaxis.<sup>117</sup> For a reduction in fungal infection recurrence, at least one study has shown that the antifungal agent voriconazole is successful in preventing microorganism reactivation.<sup>118</sup>

### Granulocyte Product Storage, Modification, and Infusion

Granulocytes must be stored at 20 to 24°C without agitation.<sup>119</sup> Granulocytes must be infused within 24 hours of collection because of the limited life span of neutrophils and preferably should be given within 6 to 8 hours of collection. Before issuance, the granulocyte product should undergo gamma irradiation to prevent recipient TA-GVHD.<sup>120</sup> It is important to remind clinical staff that granulocytes should be infused through a 170- to 260-micron filter, but that leukocyte reduction filters should *never* be used.<sup>121</sup>

---

## Adverse Reactions to Blood Transfusion

Oncology patients undergoing transfusion therapy are subject to the same set of adverse reactions as any patient receiving blood components. However, in the oncology patient, discerning between an adverse transfusion event and worsening of an underlying condition can be difficult. Furthermore, the immunosuppressed oncology patient may be at greater risk for transfusion-transmitted infections and TA-GVHD when compared with immune-competent hosts. This section briefly explores those adverse reactions to transfusion that are most relevant to the oncology patient.

### Transfusion-Associated Graft-vs-Host Disease

The treatment of many malignant diseases relies heavily upon immunosuppressive drugs (eg, purine analogs such as fludarabine) and high-dose ablative chemotherapy. These therapies place oncology patients at particularly high risk for development of TA-GVHD.<sup>122,123</sup> In addition to immune suppression, transfusion of blood from HLA homologous donors places the recipient at increased risk for TA-GVHD.<sup>124</sup> This can be particularly problematic for HLA antigen-matched blood or directed donations from family members. TA-GVHD is common, with estimates that up to 1% of patients with hematologic malignancies can develop this condition at some point during their care.<sup>122</sup> In all cases of TA-GVHD, depletion of T-cell immunity allows donor lymphocytes to generate immune responses

against host tissue. TA-GVHD usually manifests within 2 weeks of transfusion as acutaneous rash with fever, diarrhea, liver function abnormalities, nausea, and vomiting.<sup>125</sup> Unfortunately, after the onset of TA-GVHD, there are few therapeutic options. Administration of corticosteroids, antithymocyte globulin, and cyclosporine have been attempted but to date have shown little efficacy. A diagnosis of TA-GVHD carries mortality approaching 100%.<sup>125</sup>

As mentioned previously, the best strategy to eliminate TA-GVHD is to prevent its occurrence. The most successful and proven mode of prevention is gamma irradiation of blood components. The AABB specifies a radiation dose of 2500 cGy directed at the center of the blood component with a minimum dosage of 1500 cGy achieved in all portions of the unit.<sup>126</sup> Only cellular components (ie, RBCs, platelets, and granulocytes) require irradiation. Leukocyte reduction is thought to contribute to prevention of GVHD.<sup>122</sup> However, leukocyte reduction must not be relied on as the sole modality for GVHD prophylaxis because the residual white counts at which GVHD is prevented are unknown.<sup>122</sup> If such cellular components are given to susceptible patients, the component(s) must be irradiated.

### Transfusion-Transmitted Diseases

Cytomegalovirus (CMV) is among the most problematic of the transfusion-transmitted agents for the oncology patient. It is a highly prevalent virus, with data indicating that 40% to 50% of healthy adults carry CMV antibodies.<sup>127</sup> Within blood donor populations, CMV has been detected in mononuclear cells of both seropositive *and* seronegative individuals, making the identification of true CMV-negative donors difficult.<sup>128</sup> For the immune-competent host, CMV can usually be controlled through various immune mechanisms and is rarely clinically significant. For the oncology patient, however, CMV infection can have serious consequences including pneumonia, gastrointestinal inflammation/infection, and delayed engraftment of myeloid cell lines for recipients of HSCT products. For the oncology patient who has never been exposed to CMV or for the severely immunosuppressed individual, there are several options for blood transfusion. CMV-seronegative blood components can be obtained from blood donor centers, although ABO-compatible components may be hard to find as the majority of urban adults are already CMV positive. Additionally, as mentioned above, even CMV-seronegative donors may harbor residual virus within their white cells. Leukocyte reduction of blood components is thus an excellent alternative to reduce the risk of CMV transmission. Studies have shown that leukocyte removal is equally efficient as CMV-seronegative blood components for prevention of viral transmission.<sup>129,130</sup> Despite these data, several other studies suggest that CMV virus transmission can occur even with leukocyte reduction efforts.<sup>131,132</sup> Currently, there is general consensus that in the absence of blood components that are definitively seronegative, leukocyte reduction is an acceptable alternative for reducing transmission of CMV to oncology patients.

Parvovirus B19, a nonenveloped, single-stranded DNA virus, infects erythroid precursors, leading to suppression of red cell production.<sup>133</sup> For immunosuppressed patients, parvovirus infection can result in severe erythroid hyperplasia and the development of red cell aplasia.<sup>133</sup> Fortunately, active parvovirus is not found in many healthy blood donors. Two recent European studies showed that less than 1% of blood donors actively carry parvovirus in peripheral blood as detected by polymerase chain reaction (PCR) methods.<sup>134-136</sup> There have been only occasional case reports documenting transmission of parvovirus B19 to hematology and oncology patients. In these cases, patients develop characteristic red cell aplasia and often remain chronically transfusion dependent.<sup>137-139</sup> The rarity of reports of transmission of this virus may indicate low infectivity via transfusion, or may represent lack of disease recognition on the part of clinicians and transfusion service personnel. A large retrospective study showed that the actual risk of parvovirus transmission to oncology patients is quite low. In this study, 1% of all blood components from a hospital blood bank tested positive for parvovirus DNA by PCR. Of all virus-contaminated units, 14 were received by patients with underlying hematologic malignancies and none developed signs, symptoms, or laboratory findings consistent with parvovirus infection.<sup>140</sup> Because of the low rates of transmission, the cost efficacy and clinical utility of screening all blood donors for this organism has yet to be determined.<sup>134,136</sup> In order to be most prudent in the application of parvovirus testing, screening of units intended for high-risk patients has been suggested as a strategy for prevention of disease transmission.<sup>141</sup>

West Nile virus (WNV) is a mosquito-borne pathogen that emerged in 1999 as a significant cause of morbidity and mortality in the United States. The presentation of WNV can be highly variable; patients can be completely asymptomatic or experience a spectrum of symptoms ranging from mild fever and fatigue to severe encephalitis.<sup>142</sup> In addition to mosquito-spread illness, transmission of WNV via blood transfusion has been repeatedly documented.<sup>143</sup> Although any transfusion recipient is susceptible to WNV infection, there is some evidence to suggest that immunosuppressed individuals, such as those undergoing chemotherapy and transplantation, are at higher risk for developing some of the more severe neurologic complications of WNV infection.<sup>144</sup> United States and Canadian blood centers have implemented routine nucleic acid testing of blood donors using advanced algorithms to match the seasonal nature of virus infectivity.<sup>145</sup> Current screening techniques should help to limit the exposure of oncology patients to WNV.

*Trypanosoma cruzi*, transmitted via the bite of the reduviid bug, is the blood-borne parasite responsible for Chagas' disease. After initial exposure of the host to the parasite, Chagas' disease manifests as a transient acute illness.<sup>146</sup> Over a number of years, the trypanosome mediates ongoing destruction of multiple organ systems, causing chronic cardiac, gastrointestinal, and neurologic disease resistant to treatment with current antimicrobial drugs.<sup>146</sup> Chagas' disease is endemic in Latin America, but thou-

sands of individuals in North America also carry the disease.<sup>146</sup> Transmission of *T. cruzi* via transfusion has been reported in several patients in the United States and Canada; most reported cases have occurred in severely immunocompromised oncology patients.<sup>147–150</sup> The seeming exclusivity of transmission to oncology patients is thought to be caused by underlying host immunosuppression.<sup>147</sup> As a result of the growing risk for trypanosome transmission in North America, US and Canadian blood centers have undertaken efforts to broaden laboratory and medical history screening measures to better assess donor risk factors for Chagas' disease.<sup>151,152</sup> As with other pathogens, increased vigilance should help to reduce the devastating effects of trypanosome transmission in oncology patients.

In addition to thorough donor history screening and a battery of serologic and nucleic acid tests, there have been several advancements in the field of pathogen inactivation that could be helpful to oncology patients undergoing transfusion.<sup>153</sup> For instance, there is growing interest in photochemical treatment of blood components involving the addition of the chemical amotosalen with subsequent long-wave ultraviolet irradiation.<sup>154,155</sup> This technique—which causes disruption of pathogen DNA, preventing microorganism activation and proliferation—has shown great efficacy in reducing the infectivity of a number of pathogens harmful to oncology patients including CMV, parvovirus B19, and *T. cruzi*.<sup>154,156,157</sup> If clinical trials and safety data continue to look promising, pathogen inactivation should likely further improve transfusion safety for the oncology patient. As of this writing, amotosalen-treated blood components are not FDA-licensed in the United States.

### Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) represents the development of noncardiogenic pulmonary edema in patients undergoing transfusion therapy. TRALI has been theorized to be caused by antibodies that activate neutrophils passing through pulmonary vasculature.<sup>158</sup> These antibodies are believed to be directed against HLA antigens and are more frequently found in donor blood than in recipient plasma.<sup>158</sup> Oncology patients, per se, are not at increased risk for TRALI as compared to other patient populations. However, particular blood components used in oncology populations, such as granulocytes, can be associated with increased risks for TRALI. Pulmonary problems associated with granulocyte infusion can be particularly severe for patients who previously have been alloimmunized to HLA antigens. There is also some evidence to suggest that concurrent administration of granulocytes and the antifungal agent amphotericin B can lead to higher rates of pulmonary complications.<sup>159</sup> Thus, it is recommended that granulocyte infusion and amphotericin B therapy be spaced out over time to avoid pulmonary decompensation.

### Acute Hemolytic Transfusion Reactions

Acute intravascular red cell hemolysis wherein red cells are destroyed can be a catastrophic complication of blood transfusion, leading to renal failure, shock, hypotension, and death. As

with TRALI, oncology patients are not necessarily at increased risk for hemolysis because of their underlying disease state. Nonetheless, a series of case reports has documented severe hemolysis occurring in oncology patients receiving ABO-incompatible apheresis platelet products with high-titer ABO agglutinins.<sup>57–60</sup> Thus, it is recommended that oncology patients, particularly children, receive ABO-compatible platelet pools whenever possible. If no other options exist and ABO-incompatible platelets must be provided, volume reduction with removal of incompatible plasma can greatly reduce the risk of hemolysis.<sup>83</sup>

### Febrile Nonhemolytic Transfusion Reactions

Most of the blood components provided to oncology patients can cause rigors, chills, and transient elevation in body temperature. Unfortunately, it is often difficult to distinguish between the signs and symptoms of a febrile nonhemolytic transfusion reaction (FNHTR) and new-onset fever caused by infection in an immunosuppressed patient. Some of the clinical characteristics of FNHTRs may be helpful in distinguishing between these entities. FNHTRs involve an increase in temperature of at least 1°C (1.8°F) during or within 2 hours of the completion of a transfusion.<sup>160</sup> Fevers that begin more than 2 hours after the completion of transfusion are most likely due to another cause. Symptoms of FNHTRs typically appear during the latter half of a transfusion as causative cytokines or agents accumulate in circulation.<sup>160</sup> Despite clues on presentation, FNHTR ultimately remains a diagnosis of exclusion. For the oncology patient who experiences fever during transfusion, a full evaluation by transfusion service personnel and the clinical team is necessary to rule out other causes for temperature elevation.

Another strategy to deal with FNHTRs in oncology populations is to prevent their occurrence. In patients who have had repeated febrile reactions to blood transfusion, an antipyretic agent (eg, acetaminophen) given 30 minutes before transfusion can decrease adverse febrile events.<sup>160</sup> Aspirin or aspirin-containing products should not be given to thrombocytopenic patients. Aspirin acetylates the platelet enzyme cyclooxygenase and this induces a thrombocytopeny, preventing the platelet release reaction. Prestorage leukocyte reduction of blood components has also been shown to reduce the incidence of FNHTRs.<sup>161</sup>

### Transfusion-Associated Immunomodulation

The administration of allogeneic blood components can have consequences for immune function in all patient populations; most notable among these are apparent decreases in cellular immunity. These deleterious immune effects have been reported in several non-oncologic populations wherein transfusion is noted to suppress the immune system.<sup>162,163</sup> The immunomodulatory effects of allogeneic transfusion for oncology patients are slowly being unraveled. Retrospective studies indicate that allogeneic transfusion in cancer patients could lead to immunosuppression, promoting solid tumor recurrence

and increased susceptibility to primary and reactivated viral infection.<sup>164-166</sup> Conversely, pediatric literature suggests that allogeneic transfusion has little negative effect on outcome for children with acute lymphoblastic leukemia; other groups of pediatric oncology patients have not been extensively studied.<sup>167</sup>

Several animal studies have recapitulated the tumor recurrence effects of allogeneic transfusion seen in adults.<sup>168-172</sup> These studies, and others performed *in vitro*, have identified several candidates that may be responsible for the immunosuppressive effects including ubiquitin, fas and fas-ligand, soluble HLA peptides, and other mediators derived from the mononuclear elements of blood.<sup>163,171,173</sup> Particular focus has been placed on the relationship between leukocyte reduction of blood components and their immunomodulatory effects. Prestorage leukocyte reduction appears to reduce the immunosuppressive effects of transfusion, perhaps by prophylactic removal of soluble immune mediators secreted by white cells that would otherwise accrue during storage.<sup>169</sup> Future models and randomized, controlled trials may help clinicians better classify this immunologic phenomenon and address its potential causes.

### Adverse Effects of Hematopoietic Progenitor Cell Infusion

The majority of allogeneic and autologous HPCs are cryopreserved using solutions containing 10% dimethylsulfoxide (DMSO).<sup>174</sup> DMSO is a unique chemical modifier that allows for the controlled freezing and thawing of mononuclear cells without development of membrane lysis.<sup>174</sup> Traditionally, the adverse events associated with HPC infusion have been associated with the DMSO content of the progenitor product. DMSO is a toxic substance and has been linked to fever, nausea, vomiting, and chills during or immediately after HPC infusion; patients receiving fresh, noncryopreserved cells generally experience these symptoms to a much less degree.<sup>175</sup> DMSO has also been linked to pulmonary and cardiovascular problems during HPC infusion including dyspnea, hypotension, bradycardia, and arrhythmia.<sup>174,175</sup> The number of HPC units being infused and the size of the individual receiving the infusion are believed to enhance DMSO toxicity. Small children and those patients receiving multiple HPC units are more susceptible to DMSO-related problems.<sup>174</sup>

As clinical experience and evidence have been compiled, researchers have begun to evaluate other components of the HPC product as they related to infusion toxicity. Several recent studies have correlated adverse events to the numbers of granulocytes present in HPC products.<sup>176,177</sup> These studies found that even after DMSO depletion in the cellular product, 50% to 60% of patients undergoing HPC infusion experienced an adverse event such as fever, rigors, or dyspnea. It is thus possible that the dyspnea associated with HPC infusion is not entirely caused by DMSO, but rather is mediated by granulocytes through TRALI-like mechanisms. These studies argue that a reduction in granulocyte content of the final HPC product leads to better tolerance of infusion. The challenge would be to remove the unwanted granulocytes while leaving behind the lifesaving CD34+ cells.

In addition to the adverse events associated with DMSO and granulocyte content, patients undergoing HPC infusion often experience symptoms similar to those seen after traditional blood component transfusion. TRALI and anaphylactic reactions during autologous and allogeneic HPC infusions have been reported.<sup>178,179</sup> These reactions are rare, but must be considered part of the differential diagnosis for a patient presenting with shortness of breath or cardiovascular complications following HPC infusion.

Bacterial contamination of HPC products, occurring during collection or processing phases, is also of concern.<sup>180</sup> HPCs are routinely cultured and, if bacterially contaminated, are provided to patients in conjunction with prophylactic broad-spectrum antibiotics before infusion. A recent study showed that of 13 patients who received bacterially contaminated HPCs, only one developed evidence of bacteremia.<sup>180</sup> Thus, with appropriate vigilance and antibiotic therapy, bacterial contamination of an HPC product need not be an absolute barrier to infusion.

Many efforts are under way to reduce the toxicity and side effects that are associated with HPC infusion. The largest target has been DMSO; many studies have shown that reducing the content of this additive from 10% to 5% of the final product volume does not negatively affect HPC viability during storage, thawing, or reinfusion.<sup>174</sup> There are also devices undergoing evaluation that can be used to “wash” HPC products, effectively reducing DMSO content before infusion.<sup>181</sup> With regard to DMSO-related symptoms, premedication with antipyretic and antihistamine as medications 30 minutes before infusion may help alleviate unpleasant side effects such as fever and rigors and chills. Adequate field sterilization practices during stem collection and the processing of HPC products in sterile areas with air-controlled fume hoods can also help to reduce risks of bacterial contamination.<sup>182</sup>

---

## Summary

Transfusion therapy plays a major role in the care of patients with hematologic or oncologic disorders; however, blood transfusion carries risks for these patients that are generally of less concern for other general hospital populations. For oncology patients, RBC transfusions are given for increased oxygen-carrying capacity, platelets for the cessation or prevention of bleeding due to thrombocytopenia, plasma for coagulopathies, and granulocytes for pervasive bacterial and fungal infections. All of these components can create special problems for oncology patients including TA-GVHD, transfusion-transmitted diseases, alloimmunization to blood cell antigens, pulmonary decompensation, and immunomodulation. Patients undergoing HPC transplantation are a unique group and present complex concerns related to transfusion, including major and minor ABO incompatibility and chimeric blood cells. Transfusion for patients undergoing treatment with cellular therapies requires careful blood component selection. The process of HPC infusion itself carries many risks including DMSO toxicity and hemolytic reactions. In all areas of transfusion therapy, new advances such as pathogen inactivation and synthetic alternatives

to whole blood should help to increase the safety and tolerance of blood component infusion within oncology populations.

**W. Conrad Liles<sup>1</sup> & David C. Dale<sup>2</sup>**<sup>1</sup> Professor and Vice-Chair of Medicine, Director, Division of Infectious Diseases, University of Toronto, Toronto, Ontario, Canada<sup>2</sup> Professor of Medicine, Department of Medicine, University of Washington, Seattle, Washington, USA

Hematopoietic growth factor (HGF) is an inclusive term for the family of glycoproteins that regulate proliferation and differentiation of hematopoietic cells.<sup>1-5</sup> Many of these factors also influence cell function. The term *cytokine*, a natural product of cells that influence other cells, is sometimes used as a synonym for *growth factor*. Some cytokines that function as HGFs are also called *interleukins* (ILs), regulatory factors produced by leukocytes that influence functions of other leukocytes. *Colony-stimulating factor* (CSF) is used in naming some cytokines that stimulate hematopoietic cells to grow in vitro in culture systems, such as granulocyte CSF (G-CSF), granulocyte-macrophage CSF (GM-CSF), and macrophage CSF (M-CSF). Another CSF, formerly called *multi-CSF*, is now most commonly called *IL-3*. The HGFs, their names, and principal functions are outlined in Table 32-1.

### Cell Biology and Physiology

The HGFs share some general structural features among themselves and with other cytokines, but each is the product of a different gene and has a distinctive amino acid sequence, secondary and tertiary structures, receptor-binding domain, and glycosylation sites.<sup>2,3</sup> Some HGFs, such as erythropoietin, are produced by relatively few cells at selected tissue sites (eg, the juxtaglomerular cells of the kidney). Others, such as G-CSF, are produced almost ubiquitously by endothelial cells, fibroblast cells, and many other cell types. The factors governing production and secretion also vary substantially. The feedback regulation of erythropoietin in relation to tissue oxygenation is well characterized. Although the relationships governing leukocyte production and deployment are less well understood, it is known that complete absence of G-CSF or its receptor leads to severe neutropenia.<sup>6-8</sup>

Improved immunoassay systems have greatly aided understanding of the pharmacokinetics and tissue binding of HGFs.

Neutrophilia occurs with many acute inflammatory conditions and in some malignant diseases, and is largely attributable to the increased production and levels of G-CSF.<sup>9-11</sup> Levels of G-CSF are elevated in patients with severe neutropenia who have fever and infection.<sup>10</sup> However, assay systems for G-CSF are not sensitive enough to determine whether there is a true direct feedback relationship between plasma levels of G-CSF and blood neutrophil counts. The presence of high-affinity receptors for the CSFs on both immature and mature neutrophils further confounds the study of these relationships. Levels of some other cytokines that influence neutrophil formation (eg, IL-1 and IL-6) also increase with inflammation.<sup>12</sup> In contrast, serum levels of GM-CSF, another factor that stimulates neutrophil formation, do not correlate with the presence of neutropenia or infection.<sup>10</sup> Levels of thrombopoietin (TPO), the platelet growth factor made primarily in the liver, vary inversely with platelet counts and are reduced with advanced liver disease.<sup>3,13</sup>

Proliferation, differentiation, and stimulation of hematopoietic cells occur through factor-specific cell surface receptors composed of dimers or trimers of transmembrane proteins.<sup>1-3</sup> There are general structural similarities in the extracellular and intracellular domains of receptors for many HGFs, and there are common components to the receptors for some factors (eg, a common  $\beta$  chain of the receptors for IL-3, IL-5, and GM-CSF). Specificity results from the unique, or private, components of the receptor for each factor. Receptor binding and cellular activation lead to conformational changes in the receptor, activation of intracellular kinases, and phosphorylation of specific proteins that are transferred to the cell nucleus.<sup>2</sup>

### Pharmacokinetics and Pharmacodynamics

The pharmacologic properties of HGFs depend on the dose, route of administration, affinity of binding to receptors, and complex circulatory and distribution factors, as with other drugs. There are extensive pharmacokinetic and pharmacodynamic data on erythropoietin, G-CSF, and GM-CSF (the growth factors

**Table 32-1.** Hematopoietic Growth Factors

| Factor                    | Other Name                                                                | Cell Source                                                           | Chromosome            |                                                                                                                           |

| M-CSF                     | Macrophage colony stimulating factor; colony-stimulating factor-1 (CSF-1) | Endothelial cells, macrophages, fibroblasts                           | 5q 33.1               | Stimulates monocyte formation and function                                                                                |
| IL-1 $\alpha$ and $\beta$ | Endogenous pyrogen<br>hemopoietin-1                                       | Monocytes, keratinocytes, endothelial cells                           | 2q 13                 | Proliferation of T, B, and other cells; induces fever and catabolism                                                      |
| IL-2                      | T-cell growth factor                                                      | T cells (CD4+, CD8+), large granular lymphocytes (NK cells)           | 4q                    | T-cell proliferation, antitumor and antimicrobial effects                                                                 |
| IL-3                      | Multicolony-stimulating factor; mast cell growth factor                   | Activated T cells; large granular lymphocytes (NK cells)              | 5q 23-31              | Proliferation of early hematopoietic cells                                                                                |
| IL-4                      | B-cell growth factor; T-cell growth factor II; mast cell growth factor II | T cells                                                               | 5q 23-31              | Proliferation of B and T cells; enhances cytotoxic activities                                                             |
| IL-5                      | Eosinophil differentiation factor; eosinophil colony-stimulating factor   | T cells                                                               | 5q 23.3-q32           | Stimulates eosinophil formation; stimulates T- and B-cell functions                                                       |
| IL-6                      | B-cell stimulatory factor 2; hepatocyte stimulatory factor                | Monocytes, tumor cells, B and T cells, fibroblasts, endothelial cells | 7p                    | Stimulates and inhibits cell growth; promotes B-cell differentiation                                                      |
| IL-7                      | Lymphopoietin 1; pro-B-cell growth factor                                 | Lymphoid tissues and cell lines                                       | 8q 12-13              | Growth factor for B and T cells                                                                                           |
| IL-11                     | Plasmacytoma stimulating activity                                         | Fibroblasts, trophoblasts, cancer cell lines                          | 19q 13.3-13.4         | Stimulates proliferation of early hematopoietic cells; induces acute phase protein synthesis                              |
| IL-12                     | Natural killer cell-stimulating factor                                    | Macrophages, B cells                                                  | 5q 31-33; 3p 12-q13.2 | Stimulates T-cell expansion and IFN- $\gamma$ production; synergistically promotes early hematopoietic cell proliferation |
| LIF                       | Leukemia inhibitory factor                                                | Monocytes and lymphocytes; stromal cells                              | 22q                   | Stimulates hematopoietic differentiation                                                                                  |
| SCF                       | Kit ligand; steel factor                                                  | Endothelial cells; hepatocytes                                        | 4q11-q20              | Stimulates proliferation of early hematopoietic cells and mast cells                                                      |

MGDF = megakaryocyte growth and development factor; IL = interleukin; NK = natural killer; SCF = stem cell factor.

approved for clinical use) but relatively little data on the other factors.

Intravenously administered recombinant erythropoietin has a circulating half-life of 4 to 13 hours in patients with chronic renal failure and approximately 20% less in healthy volunteers.<sup>14</sup> Therapeutically effective levels are maintained for at least 24 hours, after a single intravenous or subcutaneous injection. An increase in reticulocyte counts occurs within 10 days if erythropoietin is given daily. Exogenous erythropoietin accelerates erythropoiesis, but detectable increases in hematocrit and hemoglobin level usually take approximately 2 weeks to develop.<sup>14</sup> Increasing the degree of glycosylation or the attachment of polyethylene glycol to the erythropoietin molecule increases its size, delays its renal clearance, and extends the duration of its biological effects.<sup>15-16</sup> For most clinical applications, erythropoietin is administered weekly or biweekly.

Granulocyte colony-stimulating factor can be administered intravenously or subcutaneously. After intravenous administration, the elimination half-life is approximately 3.5 hours.<sup>17</sup> Blood levels are influenced by the neutrophil count, because neutrophils actively bind the injected drug.<sup>18</sup> G-CSF stimulates proliferation of neutrophil progenitors and rapidly mobilizes mature neutrophils from the marrow reserves. It increases blood neutrophils threefold to fourfold in hematologically healthy persons within 4 to 6 hours.<sup>19-20</sup> A sustained increase in blood neutrophils occurs if administration of G-CSF is continued on a daily basis.<sup>20</sup> Granulocyte colony-stimulating factor accelerates neutrophil formation, which leads to an increased percentage of circulating band neutrophils with more deeply staining primary granules. These changes are similar to those commonly seen with bacterial infection.

Granulocyte-macrophage colony-stimulating factor can be administered intravenously or subcutaneously, but intravenous administration has been associated with toxicity that includes fever, dyspnea, and acute respiratory distress syndrome.<sup>21,22</sup> These effects seem to be dose related and to occur less frequently with subcutaneous administration. Similar to G-CSF, GM-CSF stimulates neutrophil production and release of cells from the marrow. When given repeatedly for several days, GM-CSF increases total white cell count, including eosinophils and monocytes as well as neutrophils.<sup>23</sup> The leukocyte count returns to the baseline level when administration of G-CSF or GM-CSF is discontinued.

Results of in-vitro studies show that both G-CSF and GM-CSF influence the function of neutrophils.<sup>5,24,25</sup> Both types of CSF “prime” neutrophils to increase their responsiveness to other stimulators of the neutrophil oxidative (respiratory) burst, such as opsonized particles or bacteria. Neutrophils and other leukocytes produced in vivo in response to G-CSF or GM-CSF stimulation in general have normal or increased, but not decreased, responsiveness to exogenous stimulators of neutrophil function. The clinical significance of these findings is not clear. Substantial clinical data and numerous animal experiments indicate that neutrophils produced in vivo in response to these cytokines are

capable of killing bacteria and accelerating recovery from bacterial infection.<sup>5</sup> For some pathogens, in-vivo G-CSF treatment may enhance the microbicidal activity.<sup>26</sup>

The pharmacologic and physiologic properties of other HGFs are less well understood, but some generalizations are possible. The factors influencing the early phases of hematopoiesis tend to have multiple side effects, such as fever and flu-like symptoms, and a narrower range of tolerable doses than do factors that influence the later phases of hematopoiesis. Examples of early factors with substantial side effects include IL-1, IL-2, IL-3, IL-4, IL-6, and stem cell factor. The predominantly late-acting factors such as erythropoietin, G-CSF, GM-CSF, and M-CSF are much better tolerated.

---

## Clinically Approved Agents and Products in Development

Erythropoietin is approved for treatment of anemia in several clinical settings: to treat anemia of chronic renal failure, anemia in chronic zidovudine-treated human immunodeficiency virus (HIV)-infected patients, anemia in cancer patients on chemotherapy, and to reduce allogeneic blood transfusions in anemic surgery patients. Erythropoietin is available as a glycosylated recombinant protein from multiple manufacturers and as an identical 165-amino acid protein (darbepoetin) that differs from recombinant human erythropoietin in containing five *N*-linked oligosaccharide chains, whereas recombinant human erythropoietin contains three. Darbepoetin has delayed clearance and a longer biological effect permitting less frequent administration; it has been widely investigated as a stimulus to erythropoiesis.<sup>27,28</sup> A pegylated erythropoietin was shown to be effective in an open-label, parallel group, noninferiority trial involving 1115 patients with the anemia of chronic renal failure.<sup>16,29</sup> Currently, the long-term safety of all forms of erythropoietin is under review. An increase in the risk of venous thrombosis has been recognized from the earliest trials; recent questions also relate to an increased risk of malignancies observed as a secondary endpoint in some clinical studies.<sup>30-32</sup>

G-CSF and GM-CSF have been approved by the United States Food and Drug Administration (FDA) for the management of neutropenia in specific clinical situations. G-CSF is indicated for cancer patients receiving myelosuppressive chemotherapy, patients with acute myeloid leukemia receiving induction or consolidation chemotherapy, cancer patients receiving marrow or progenitor cell supportive therapy, and patients with various forms of severe chronic neutropenia. A pegylated form of G-CSF (PEG G-CSF) has a much longer blood half-life and longer biological effects and can be used once per chemotherapy cycle rather than on a daily basis. Chapter 15 describes the role of G-CSF in granulocyte collection and transfusion, a use similar to that for collection of hematopoietic progenitor cells (HPCs) but not yet approved by the FDA. GM-CSF is indicated following induction chemotherapy in acute myeloid leukemia,

for mobilization of marrow progenitor cells, and to accelerate marrow engraftment after hematopoietic transplantation.

Interleukin-11 is currently approved to prevent the need for platelet transfusions following myelosuppressive chemotherapy in adult patients with nonmyeloid malignancies at risk of severe thrombocytopenia. Adverse effects including fever, edema, atrial arrhythmias, and syncope have limited its use.

Several promising new agents are in development for treatment and prevention of thrombocytopenia, but none are currently approved by the FDA. The native (TPO) molecule was first identified and cloned in 1994 by several groups almost simultaneously.<sup>33-37</sup> Its receptor (TPO-R) is expressed on megakaryocytes, platelets, and primitive HPCs.<sup>3,13</sup> Soon after this discovery, preclinical data indicated that recombinant human TPO (rHuTPO) and a truncated version of TPO coupled to polyethylene glycol called megakaryocyte growth and development factor (PEG-rHuMGDF) stimulated a twofold to fivefold increase in platelet count with a peak occurring 10 to 14 days after beginning the stimulus.<sup>38</sup> Phase I and II clinical trials demonstrated the effectiveness of PEG-rHuMGDF to raise platelet counts, but the development of neutralizing antibodies and significant thrombocytopenia in some subjects led to discontinuation of clinical trials with these specific agents.<sup>39</sup>

A recombinant TPO-R protein with a carrier Fc domain to increase its size and reduce renal clearance (currently referred to as AMG531) has recently undergone Phase I, II, and III testing and appears to be safe and effective for treatment of chronic refractory idiopathic thrombocytopenic purpura (ITP) in trials for up to 96 weeks with weekly administration.<sup>40-42</sup> In a randomized, double-blind, placebo-controlled Phase III trial involving 63 patients with ITP who had previously had splenectomies, responses with either a durable or transient increase in platelet counts were observed in 33 of 42 treated patients and 0 of 21 patients receiving placebo.<sup>42</sup> The therapy was well tolerated; no neutralizing antibodies were observed. One subject had reversible evidence of increase marrow reticulins. A venous thrombosis occurred in one patient, but this did not prevent continuation of AMG531 treatment.<sup>42</sup> This drug has been licensed by the FDA for use in Chronic ITP.

Eltrombopag is an orally active TPO-R chrome agonist shown to increase platelet counts in healthy adults, and in patients with ITP<sup>43</sup> or thrombocytopenia caused by hepatitis C infection and cirrhosis of the liver.<sup>44</sup> Eltrombopag is a small-molecule, nonpeptide oral agonist to the TPO-R.<sup>45,46</sup> The clinical trial involving 118 ITP patients with platelet counts less than 30,000/ $\mu$ L showed that 80% of patients receiving 50 or 75 mg/day responded to this therapy.<sup>43</sup> The results in the hepatitis C trial were similar; headaches were the most common adverse event in both trials. Other oral agents (eg, AKR-501 and SB-559448) are under investigation.<sup>47</sup>

Despite several clinical trials, there are no approved uses for IL-3 or M-CSF.

### Use of Myeloid Growth Factors to Mobilize Peripheral Blood Stem Cells

For years it has been recognized that circulating HPCs are capable of forming hematopoietic colonies in vitro in culture systems

and of repopulating the marrow after total ablation. These cells appear to function normally to sustain hematopoiesis and to allow expansion in states of hematopoietic stress.

Before the availability of HGFs, several investigators reported that the number of circulating HPCs increases during the recovery period after hematotoxic chemotherapy. This occurs usually after about 10 to 16 days, when marrow recovery is in progress.<sup>48,49</sup> It was subsequently learned that a similar response occurs in hematologically intact persons given HGFs after about 5 to 7 days.<sup>50,51</sup> Numerous studies have shown that the number of these progenitor cells, also called *peripheral blood stem cells* (PBSCs) or *peripheral blood progenitor cells*, predictably increases in the blood as much as 100-fold during recovery from chemotherapy or 4 to 6 days after administration of HGF is begun.<sup>52-57</sup> The quantity and quality of cells are sufficient for PBSCs autologous reconstitution after myeloablative therapy and use of PBSCs is rapidly replacing marrow for that purpose.<sup>58</sup> Peripheral blood stem cells are preferred because of the relative ease of procurement, more rapid restoration of blood counts compared with marrow infusion, and the possible recovery of these cells from patients who previously received intensive chemotherapy or radiation therapy and from patients with tumors involving the marrow.<sup>58</sup>

An unexpected benefit of the development of PBSC support came with the recognition that transfusion of PBSCs accelerated recovery of platelet counts and thus obviated the need for many platelet transfusions.<sup>53</sup> This finding suggests that the persisting thrombocytopenia historically seen 3 to 6 weeks after conventional marrow transplantation was caused by the limited number or function of precursor cells infused rather than deficiencies in humoral or environmental factors.

The basic physiologic principles governing mobilization of PBSCs probably involve breakage of the molecular bonds between key adhesive marrow elements, ie, the receptor-ligand pairs, which hold the progenitor cells in the extravascular space of the marrow juxtaposed to the marrow stromal cells. In primates, antibodies to the adherence protein VLA-4 can induce more rapid PBSC mobilization.<sup>59</sup> The chemokine IL-8 has similar effects.<sup>60</sup>

Treatment with G-CSF is recognized to expand the total myeloid and progenitor mass, increase the number of circulating blood neutrophils, and also release neutrophil-associated proteases into the marrow and blood.<sup>61,62</sup> There is good evidence that the released proteases disrupt key adhesive bonds holding the progenitors in the marrow, including the receptor-ligand pair CXCR-4 on the progenitors and stromal-cell-derived factor 1 (SDF-1) on the marrow stromal cells. The CXCR-4 antagonist AMD 3100 has similar effects in that this molecule also disrupts these bonds and promotes release of progenitor cells into the peripheral blood.<sup>63-65</sup>

All mobilizing agents cause leukocytosis with an increase in blood neutrophils as well as increased numbers of circulating HPCs, but they do not proportionately increase the numbers of circulating promyelocytes, myelocytes, or metamyelocytes. With G-CSF the kinetics of the response (delay of a few days before

the increase in PBSCs occurs) suggests that early hematopoietic cells may need to expand in numbers before they “spill over” or are “released” into the blood. The increase in PBSCs in the recovery phase from chemotherapy generally occurs when the marrow is still relatively hypocellular, thus implying that marrow cell density is not the simple explanation for mobilization.<sup>65</sup>

In the initial development of support with PBSCs, many investigators questioned whether these cells are truly hematopoietic stem cells. Most of the cells collected and transfused after treatment with HGFs or chemotherapy undoubtedly are differentiated precursor cells. However, results of experiments with mice, dogs, and nonhuman primates as well as with humans support the contention that preparations of PBSCs do contain long-lived precursor cells along with many differentiated cells.

## Technical Considerations

### Quantitation

Peripheral blood stem cells are quantified according to the cell surface expression of cluster determinant 34 (CD34) or granulocyte-macrophage colony-forming unit (CFU-GM) as measured with an in-vitro colony-forming assay. Because the in-vitro bioassay requires approximately 2 weeks to complete and is highly dependent on the expertise of the tissue culture laboratory, it is used largely for quality control and for research studies. Flow cytometric analysis for CD34+ cells can be performed quickly and easily on the day of collection and is essential to determine the adequacy of PBSC collection. Total mononuclear cell numbers also are useful. Cell numbers that usually correlate with engraftment are  $4 \times 10^8$  or more mononuclear cells per kilogram,  $2 \times 10^6$  or more CD34+ cells per kilogram, and  $2 \times 10^5$  or more CFU-GMs per kilogram. Because this antigen is expressed on cells that have differentiated beyond the colony-forming stage, the number of CD34+ cells is 10-fold greater than the required number of CFU-GMs.<sup>66</sup>

### Cytokine Doses

Currently, G-CSF is the cytokine most frequently used to mobilize PBSCs. At doses of 5 µg/kg or less per day, the harvest of PBSCs usually is inadequate. Doses of approximately 10, 16, 24, and 32 µg/kg/day have been used in clinical trials. Although the yield may be slightly increased at higher doses, the usual dose is 10 to 16 µg/kg/day.<sup>58</sup> Granulocyte-macrophage colony-stimulating factor, IL-3, and stem cell factor (*c-kit* ligand) also mobilize PBSCs, but have greater side effects. The role of thrombopoietin in mobilization is still uncertain.<sup>67</sup> Combinations of G-CSF with each of these cytokines or with chemotherapy have been investigated at many centers. In general, it seems that a regimen of chemotherapy plus G-CSF (with or without a second cytokine) yields the greatest quantity of CD34+ cells and allows for the fewest leukapheresis procedures, but there is not yet a standard approach. The timing of the response to chemotherapy is quite variable, making this approach more difficult for patients and their families. Cyclophosphamide, carboplatin, paclitaxel, etoposide, and ifosfamide are the chemotherapeutic agents that

have been studied most extensively for mobilization and harvesting of PBSCs.

## Collection and Processing of Peripheral Blood Stem Cells

Currently, PBSCs are collected and used for both autologous and allogeneic hematopoietic stem cell transplantation.<sup>53,56</sup> Under these circumstances, the type and intensity of previous chemotherapy or radiotherapy affect collection of PBSCs. Extensive previous treatment may render adequate PBSC collection difficult, if not impossible. Most collections are performed using techniques and procedures evaluated by committees of the AABB, Foundation for the Accreditation of Cellular Therapy, International Society for Cellular Therapy, and American Society for Apheresis. When patients are treated with HGFs alone, collection usually is begun on treatment Day 4. Up to 20 liters of blood are usually processed to separate predominantly mononuclear cells, and the CD34+ cell collections from the first and succeeding days are counted to determine the total number of leukapheresis procedures to be performed.

### Tumor Cell Contamination

Both marrow aspirated for transplantation and apheresis-collected PBSCs may contain tumor cells. The number of contaminating cells seems to be determined according to marrow involvement, stage of disease, tumor type, and previous therapy. Previously untreated patients tend to have greater marrow reserves or mobilizable tumor cell burdens. Techniques for detecting tumor cells in these preparations are rapidly improving. It is unclear what the minimal tumor cell contamination must be to avoid the risk of tumor cell engraftment with PBSCs mobilized by administration of HGFs.<sup>68-70</sup>

## Selection for Peripheral Blood Stem Cells

Because CD34 is a useful marker of early hematopoietic cells, several methods have been devised in which antibodies to CD34 are used for selective collection of PBSCs. The goal is to select PBSCs and eliminate tumor cells from the materials to be transfused. At present, these technologies do not eliminate all tumor cells completely but reduce the numbers markedly. Studies are still in progress to determine the clinical advantage of these procedures.

### Cryopreservation

Peripheral blood stem cells collected after treatment with HGFs usually are preserved by means of controlled rate freezing with 10% dimethylsulfoxide (DMSO). Results of some studies suggest that HGFs may inhibit spontaneous apoptosis, but it is unclear whether this is clinically important for preservation of PBSCs.

## Clinical Trials of Growth-Factor-Mobilized

### Peripheral Blood Stem Cells

Numerous uncontrolled trials and a few randomized, controlled clinical trials have shown the efficacy of HGF-mobilized PBSCs to accelerate marrow recovery after intensive chemotherapy or

myeloablative chemoradiation therapy. The results of these studies have established that administration of more than  $4 \times 10^6$  CD34+ PBSCs per kilogram mobilized by G-CSF results in neutrophil recovery to more than 500/ $\mu$ L and platelets to 20,000/ $\mu$ L in approximately 10 to 12 days.<sup>62</sup> These recovery times probably can be achieved without treating the recipient with HGFs after infusion of PBSCs. These times for recovery with PBSCs are considerably shorter than those after autologous marrow transplantation, particularly for platelets. Platelet counts recover to 20,000/ $\mu$ L by approximately Day 12 after treatment with PBSCs without G-CSF or GM-CSF therapy and to 20,000/ $\mu$ L on approximately Day 20 or later after autologous marrow transplantation.

### Alternative Agents

Although the use of HGFs to mobilize PBSCs has greatly facilitated hematopoietic transplantation, there is a need to further improve this procedure. The discovery that SDF-1 and CXCR-4 play critical roles in hematopoietic cell homing was soon followed by identification of an antagonist to the binding of this receptor-ligand pair. AMD 3100 is a small organic chemical inhibitor of this interaction that was discovered in the process of screening for agents with anti-HIV properties.<sup>64</sup> AMD 3100 is administered subcutaneously and stimulates the semiselective release of CD34+ cells from the marrow to the blood in a dose-dependent fashion.<sup>71-73</sup> Clinical studies in human volunteers have established that AMD 3100 increases CD34+ cells at 6 to 10 hours after a single subcutaneous dose sufficient for collection of greater than  $5 \times 10^6$  cells/kg by standard leukapheresis. Clinical trials in normal volunteers and patients with multiple myeloma and non-Hodgkin lymphoma have demonstrated that AMD 3100 used in combination with G-CSF is more effective than either alone.<sup>73</sup> The additive effects of AMD 3100 to G-CSF are especially important for patients who are poor mobilizers because of their underlying disease or previous chemotherapy.<sup>74</sup> FDA approval of AMD 3100 is pending, as of this writing. Other similarly acting new agents are in development.

### Other Considerations

Many laboratories have intensively studied the expansion of marrow cells and PBSCs using in-vitro incubation of the cells with a mix of growth factors, including stem cell factor, IL-3, IL-6, GM-CSF, G-CSF, and erythropoietin. This approach is a promising way to expand the number of differentiated progenitor cells for supportive care. It also may prove useful for providing undifferentiated and stem cell support if, eventually, cells can be expanded without stimulating differentiation. Paralleling these efforts, many investigators are studying genetic alteration of PBSCs mobilized by HGF administration with the intent to introduce therapeutically important genes into PBSCs. This gene therapy strategy may prove useful for the management of genetic, infectious, and malignant diseases. This work is still at an investigational stage.

### Granulocyte Colony-Stimulating Factor and Granulocyte-Macrophage Colony-Stimulating Factor for Neutropenia Associated with Chemotherapy and Hematopoietic Stem Cell Transplantation

For many years, the myelosuppressive effect of chemotherapy has been the dominant factor determining treatment doses and schedules in therapy for hematologic and nonhematologic malignant diseases. It is generally believed that recovery of blood leukocyte and platelet counts is delayed because of the time required for cell proliferation and differentiation as well as for the generation of endogenous factors regulating cell recovery. The potency of G-CSF and GM-CSF to stimulate recovery, and the effectiveness of prophylactic administration of G-CSF to stimulate recovery were easily recognized in the first clinical trials.<sup>75,76</sup> In two randomized, controlled trials,<sup>77,78</sup> the effectiveness of prophylactic administration of G-CSF was definitively demonstrated in the care of patients with small-cell lung cancer. In these studies, patients treated with cyclophosphamide, doxorubicin, and etoposide received either placebo or G-CSF at a dose of 5  $\mu$ g/kg/day. The incidence of fever and documented infections was reduced in the G-CSF-treated group both in the first cycle and for the overall six cycles of treatment. Antibiotic use and days of hospitalization also decreased. The results of this trial have been replicated in a number of studies.<sup>79</sup> Meta-analyses and comprehensive reviews have confirmed the benefit to prevent febrile neutropenia and to prevent deaths from sepsis in adults treated with G-CSF.<sup>80,81</sup> Randomized clinical trials also have shown that marrow recovery after transplantation is accelerated by GM-CSF and G-CSF.<sup>82</sup>

The results of these trials have led to a number of conclusions and practice guidelines.<sup>83-85</sup> Granulocyte colony-stimulating factor effectively stimulates marrow recovery after chemotherapy for many malignant diseases, including myeloid and nonmyeloid leukemia. It has proven to be difficult to establish whether GM-CSF is equally effective. In healthy subjects and patients, GM-CSF is less potent as a stimulus to increase neutrophil production and thus to raise blood neutrophil counts.<sup>86</sup> In addition, GM-CSF may cause fever and inflammatory symptoms, making it difficult to use the occurrence of febrile neutropenia as the primary endpoint for clinical trials.

The greatest value of CSF treatment is in the care of patients with sustained neutropenia and a high likelihood of developing febrile neutropenia and severe infections. Conversely, it has been easier to show the clinical benefit of CSF treatment in trials of single-agent chemotherapy with a lower risk of febrile neutropenia.<sup>87</sup> This apparent paradox is attributable to effects of the chemotherapy on the hematopoietic tissues. More chemotherapy causes more severe and protracted neutropenia, but it also reduces the amount of target tissue for the CSF. The net effect is that the benefits of CSF treatment, particularly to accelerate hematopoietic recovery, are greater with milder chemotherapy treatments. For this and other reasons, the American Society of Clinical Oncology and other groups have revised their original guidelines to set a 20% risk of febrile neutropenia as the level for demonstrable benefit of prophylactic CSF.<sup>83,84</sup>

In any patient with documented febrile neutropenia after one course of chemotherapy, the use of these factors to avoid

infectious complications while maintaining dose intensity is generally indicated unless a dose-reduction strategy is more appropriate because of the disease, stage of the disease, comorbidities, or personal choice of the patient. The use of G-CSF and GM-CSF in the management of myeloid malignant disease has been studied extensively. It appears that these agents can be used safely to accelerate marrow recovery after chemotherapy, as in the management of nonmyeloid malignant disease.

The timing and dosing of G-CSF or GM-CSF are largely based on schedules used in randomized clinical trials, but many questions remain to be answered. Because of the potential for the CSF to increase hematotoxicity if given before or concomitant with chemotherapy, they are generally recommended to be given the day following chemotherapy. The duration of CSF treatment is also not well established. The best evidence of their effectiveness comes from the large randomized clinical trials that proved their benefits. In these trials the CSF was given until the blood counts were normal or above normal.<sup>77-80</sup> Conversely, the treatment period may have been longer than necessary in these trials. In general it would appear that treatment should be started without delay approximately 24 hours after completion of any course of chemotherapy and continued until there are clear signs of increasing blood neutrophils before stopping this supportive therapy. Uncertainty also exists about optimal dosing. For GM-CSF, dosing may be limited by side effects. For G-CSF, the acceptable dose range is much broader, but evidence suggests that doses greater than 5 µg/kg/day do not significantly accelerate marrow recovery. The G-CSF dose of 5 µg/kg/day is the current standard of practice.<sup>83-85</sup>

### Colony-Stimulating Factors for Idiosyncratic Drug-Induced Neutropenia

A wide array of drugs induce transient neutropenia, presumably on an immune or toxic basis. The penicillins, sulfonamides, and antithyroid and psychotropic drugs often are implicated. With respect to treatment, the offending (or presumably offending) agent should be discontinued, and patients with a fever should be treated with broad-spectrum antibiotics. Numerous case studies and small series have suggested that HGFs may accelerate marrow recovery in this setting. However, the evidence is largely anecdotal, and practices differ considerably. The sickest patients with documented infections and delayed marrow recovery are the ones most likely to benefit from CSF treatment.<sup>88</sup>

### Colony-Stimulating Factors in the Management of Chronic Neutropenia

The clinical benefit of long-term G-CSF therapy for patients with severe congenital neutropenia (including Kostmann syndrome), severe idiopathic neutropenia, or cyclic neutropenia, was established in a randomized clinical trial.<sup>89</sup> In a study of patients with severe chronic neutropenia, the occurrence of fever, oropharyngeal ulcers, infections, hospitalization, and antibiotic use were all significantly reduced with dose-adjusted, daily G-CSF treatment. The quality of life and activity profiles of these patients also improved. The principal side effect of G-CSF therapy was musculoskeletal pain early in

the course of treatment, which became less severe with long-term therapy. Data from the Severe Chronic Neutropenia International Registry have shown that the subgroup of patients with severe congenital neutropenia are at risk of developing myelodysplasia and acute myeloid leukemia.<sup>90,91</sup> The risk appears to be disease specific with a substantially lower, or no risk for patients with cyclic or idiopathic neutropenia. At present, hematopoietic transplantation is the only available alternative therapy, and it is limited largely by the availability of a suitable well-matched marrow donor. For these reasons, careful follow-up evaluation of patients receiving long-term G-CSF therapy, especially patients with severe congenital neutropenia, is indicated with regular blood counts and clinical observation and annual marrow examination.

### Colony-Stimulating Factors in the Management of Nonneutropenic Infectious Disease

Considerable research efforts have been devoted to the possible use of CSFs as adjunctive therapy for nonneutropenic infectious conditions. The rationale for these studies was to enhance the number and functional activities of neutrophils to promote recovery from, or prevention of, local or systemic infections. On the basis of results of Phase II studies, a set of large Phase III trials were conducted. In a double-blind, controlled, multicenter trial, 756 patients with community-acquired bacterial pneumonia were enrolled to receive intravenous antibiotics plus either G-CSF (300 µg/day for up to 10 days; *n* = 380) or placebo (*n* = 376).<sup>92</sup> Outcome measures included time to resolution of morbidity, 28-day mortality, length of hospital stay, and occurrence of adverse events. A microbial cause of pneumonia was identified for 56% of patients, and an independent review group judged use of antimicrobial agents appropriate in the care of 98% of the patients. Administration of G-CSF increased the peripheral blood neutrophil count threefold, but the primary endpoint—time to resolution of morbidity, mortality, and length of hospitalization—was not affected. Subgroup analysis showed that the time of resolution of infiltrates was significantly more rapid in the G-CSF-treated group. Administration of G-CSF was safe and well tolerated. Further studies of more severely ill patients with pneumonia also showed similar results, with no significant effect on the primary endpoint; however, there were intriguing findings with the secondary and subgroup analyses.<sup>93</sup>

Because of a lack of neutrophilia and impaired superoxide generation in neutrophils from patients with diabetes, G-CSF appears to be a reasonable candidate for adjunctive therapy in the management of severe infections in these patients. In a small randomized, double-blind, placebo-controlled trial, 40 patients with insulin-dependent diabetes and foot infections were assigned to receive either G-CSF (*n* = 20) or placebo (*n* = 20) for 7 days.<sup>94</sup> Both groups were treated with similar antibiotic and insulin regimens. After 7 days of G-CSF treatment, there was earlier eradication of pathogens, quicker resolution of cellulitis, shorter hospital stay, and shorter duration of antibiotic treatment. Other trials, however, have not confirmed these findings.<sup>95</sup> These results await corroboration in a multicenter trial before adoption of use of G-CSF for this purpose in routine clinical practice.<sup>96</sup>

Colony-stimulating factors may have therapeutic potential in the treatment of patients with HIV. Granulocyte-macrophage colony-stimulating factor has been shown to partially correct HIV-1-mediated impairment in the ability of monocyte-derived macrophages to phagocytose *Mycobacterium avium* complex in vitro.<sup>97</sup> In a study involving 258 patients with HIV-1 infection and moderate neutropenia, G-CSF treatment significantly reduced the incidence of severe neutropenia and bacterial infection.<sup>98</sup> Patients treated with G-CSF also had 54% fewer episodes of severe bacterial infection and needed 45% fewer days of hospitalization for management of bacterial infection than did the control group. The use of G-CSF to prevent or treat infections has been suggested in numerous other small trials, but randomized, controlled trials are necessary to establish the benefits of such practices.

### Granulocyte Colony-Stimulating Factor for Mobilization of Neutrophils in Granulocyte Transfusion Therapy

Granulocyte transfusion therapy would appear to be a rational approach to the management of severe bacterial and fungal infections in patients with prolonged neutropenia. Potential clinical efficacy, however, has long been limited by insufficient donor stimulation regimens and suboptimal leukapheresis techniques. Methodologic progress, in particular for mobilization of neutrophils in healthy donors by means of administration of G-CSF and dexamethasone, has greatly enhanced leukapheresis yields. Granulocyte transfusion therapy is discussed in detail in Chapter 20.

---

## Summary

The discovery and clinical development of HGFs have had great effect on the use of blood components in the supportive care of patients with many hematologic and malignant diseases. Hematopoietic growth factors are providing new opportunities for the provision of blood services, such as collection of PBSCs, autologous erythrocyte transfusion for elective surgical procedures, and G-CSF mobilization of neutrophils for granulocyte transfusion therapy.

# Hematopoietic Progenitor Cells: Biology and Processing

**Thomas Leemhuis<sup>1</sup> & Ronald A. Sacher<sup>2</sup>**

<sup>1</sup>Director, Cellular Therapies Division, Hoxworth Blood Center, University of Cincinnati Academic Health Center, Cincinnati, Ohio, USA

<sup>2</sup>Director, Hoxworth Blood Center, University of Cincinnati Academic Health Center, Cincinnati, Ohio, USA

Hematopoietic stem cells (HSCs) and hematopoietic progenitor cells (HPCs) used for hematopoietic reconstitution after myeloablative therapy were among the first cellular therapy products shown to have a real clinical benefit. The ability of the HSC to engraft and differentiate to produce all blood cell lineages, and the ethical issues surrounding the much publicized advances in embryonic stem cell research, have both prompted experimentation into additional therapeutic uses for HSCs and HPCs. A partial list of potential clinical uses of these hematopoietic cells is presented in Table 33-1. Many have not yet been proven safe or effective.

As the field of hematopoietic transplantation has progressed, much knowledge has been gained concerning the complex interactions between cell populations contained in the donor's marrow, mobilized peripheral blood progenitor cell (PBPCs), or umbilical cord blood (UCB) graft and the recipient's cells. As a result, much has been learned in the laboratory about how to selectively deplete or enrich for subpopulations of donor cells before infusion. These cells then can serve functions other than conventional marrow replacement or rescue. They can be used for adoptive immunotherapy,<sup>1,2</sup> as vehicles for gene therapy,<sup>3</sup> and perhaps even to induce tolerance of an organ transplant from the same donor.<sup>4</sup> There are several clinical situations where such in-vitro manipulations have been shown to provide significant clinical benefit.

Transfusion medicine and clinical laboratory technology have grown to include cell processing techniques that concentrate, separate, isolate, purify, enrich, deplete, cryopreserve, and quantitate cellular components contained within marrow, peripheral blood, and UCB. The more common, clinically relevant processing techniques used to prepare hematopoietic grafts for infusion are reviewed in this chapter. The focus is on the rationale and the basic principles behind the techniques, but select technical details and literature references are also provided to assist laboratory professionals with the task of preparing standard operating

procedures (SOPs). This chapter concludes with a discussion of the quality assurance and regulatory compliance principles that apply to any laboratory performing cell manipulations for therapeutic purposes.

## Sources of Hematopoietic Progenitor Cells

Human HSCs and HPCs reside primarily in the marrow, but can also be obtained in clinically relevant cell doses from cytokine-mobilized peripheral blood, and UCB. These cells can also be found in other locations, such as fetal liver, but their usefulness is limited by either the low cell numbers that can be obtained or by ethical issues. A partial list of the cellular characteristics of each of these source tissues is presented in Table 33-2.

Clinical-scale marrow collections often contain a significant amount of peripheral blood, thus they contain all hematopoietic cell types, from the most immature stem cells that enable long-term engraftment to the most mature granulocytes and erythrocytes with naturally short life spans. Marrow usually

**Table 33-2.** Cellular Characteristics of Various Stem Cell Sources

|                             | <b>Marrow</b> | <b>Mobilized<br/>Peripheral Blood</b> | <b>Umbilical<br/>Cord Blood</b> |
|-----------------------------|---------------|---------------------------------------|---------------------------------|
| Stem cell content           | Adequate      | Good                                  | Low                             |
| Progenitor cell content     | Adequate      | High                                  | Low                             |
| T-cell content              | Low           | High                                  | Very low                        |
| Risk of tumor contamination | High          | Low                                   | Not applicable                  |

contains between 0.5% and 1% CD34+ cells. Optimal post-transplant hematopoietic recovery requires 2 to  $5 \times 10^6$  CD34+ cells/kg.<sup>5</sup> Therefore a clinical-scale marrow harvest should contain 2 to  $5 \times 10^8$  total nucleated cells/kg. This generally requires a 1- to 1.5-liter collection for an adult recipient. Their large volume and complex cellular makeup make most selection procedures difficult. ABO compatibility is essential, unless a red cell or plasma depletion procedure is performed before infusion.

Mobilized PBPC products are routinely used as an alternative source of HSCs and HPCs for transplantation.<sup>6-8</sup> The CD34+ repopulating cells can be mobilized into the peripheral blood and then collected by apheresis following myelosuppressive chemotherapy and/or stimulation with 10 to 20 µg/kg granulocyte colony-stimulating factor (G-CSF).<sup>9,10</sup> Because an apheresis procedure is used to collect PBPC products, they contain very few erythrocytes or granulocytes, compared to marrow, and are primarily composed of mononuclear cells (MNCs). PBPC products also contain larger numbers of HPCs than either marrow or UCB, and therefore facilitate faster engraftment and shorter hospital stays. Patients who have been heavily pretreated with multiple rounds of chemotherapy or radiation therapy often mobilize poorly and require multiple collection episodes.<sup>11</sup>

PBPC products contain larger numbers of T cells than marrow collections, and thus present a greater risk of causing graft-versus-host disease (GVHD) in the allogeneic setting, although the rate of acute GVHD is less than originally feared.<sup>12-16</sup> Mobilized peripheral blood is easier to collect than marrow and, therefore, presents a lower risk to the volunteer donor. However, the long-term risks of G-CSF administration remain unclear.

The availability and relative ease of collection of cord blood stem cells, along with the reported decreased rate of GVHD, makes UCB transplantation an attractive option. Because of the limited number of HPCs that can be acquired from this source, however, most recipients have been children.<sup>17-19</sup> UCB contains a high proportion of HSCs and HPCs, but only approximately 10% of the cell dose of a typical marrow harvest; therefore, engraftment is often delayed with UCB transplants relative to marrow or PBPC transplants.<sup>20-22</sup> Some centers have begun to test whether infusing 2 UCB units would improve engraftment kinetics.<sup>23</sup> It appears that either the number or the alloreactivity of the T cells are reduced in UCB grafts, enabling the use of partially mismatched unrelated donors with relatively low rates of GVHD.<sup>24-26</sup> With its high proliferative

potential, UCB may be a good target for gene therapy,<sup>27</sup> and/or ex-vivo expansion.<sup>28</sup> However, results of studies of the ability of ex-vivo expanded portions of UCB grafts to shorten the time to engraftment have generally been disappointing.<sup>29-32</sup>

Even though each of these tissue sources contain HPCs capable of long-term engraftment, the products vary dramatically in terms of red cell content, granulocyte and platelet content, T-cell number, and CD34 number. Thus, they present different processing objectives and challenges to the processing laboratory. No two HPC products received for processing are the same, in terms of donor age, disease status, tumor cell infiltration, infectious disease status, or prior chemotherapy exposure. Therefore, processing results (purity, recovery, viability) will often vary for unknown reasons.

There are distinct advantages and disadvantages to using a particular HPC source tissue for transplantation. The decision regarding which source to use for a particular patient is best left to the patient's physician so that disease status and donor availability can also be factored into the decision. The preferred, sought-after donors of allogeneic HPCs have customarily been sibling donors who are HLA identical at the HLA-A, -B, and -DR loci. When such a match cannot be found, related donors mismatched at one or two HLA loci are used, as are HLA-matched unrelated volunteer donors from the international registries.

## Collection of Progenitor Cells

### Marrow Harvests

Marrow harvests are invasive surgical procedures performed in an operating room under general anesthesia. Approximately 1000 to 1500 mL of marrow is collected, 3 to 10 mL at a time, from multiple punctures of both posterior iliac crests, using specially designed stainless steel beveled needles and syringes. The marrow is collected into a disposable collection apparatus that contains a 500-micron filter and a 200-micron filter to remove most of the bone chips, clots, fat, and fibrin before the marrow is drained into a collection bag that contains an anticoagulant. Target cell doses often range between 2 and  $5 \times 10^8$  nucleated cells/kg and between 2 and  $5 \times 10^6$  CD34+ cells/kg. Collection protocols vary, but most often the syringes are heparinized in advance with 1 mL of a 100 U/mL heparin solution. The marrow is drained into a collection bag containing the same heparin solution, such that the heparin concentration is at least 10 U/mL in the final product. Additional heparin may be required if there is to be a long-distance transport or overnight hold of the marrow before processing. Although the marrow donor usually remains in the hospital overnight, it is possible to perform the marrow harvest as an outpatient procedure with local anesthesia. Complications from the general anesthesia or from infection at the anatomic site of the harvest can occur.

### Peripheral Blood Collections via Apheresis

With the development of recombinant colony stimulating factor (CSFs), it has become possible to mobilize large numbers of

**Table 33-3.** Instrument Settings for Peripheral Blood Progenitor Cell Collections

| Instrument | RBC Content (%) | Flow Rate (mL/min) | Anticoagulant to Whole Blood Ratio | Cycle Volume (mL) | Number of Cycles |
|------------|-----------------|--------------------|------------------------------------|-------------------|------------------|
| Spectra    | 1 to 3          | 60 to 150          | 1:12 to 1:15                       | Continuous        | N/A              |
| Amicus     | 6 to 8          | 40 to 75           | 1:12 to 1:15                       | 1000 to 1400      | 7 to 14          |
| COM.TEC    | 6 to 8          | 40 to 60           | 1:10 to 1:14                       | 300 to 500        | 25 to 40         |

progenitor cells into the peripheral circulation so that they can be collected by a much less invasive procedure. By stimulating the donor with either hematopoietic growth factors, or chemotherapy and growth factors, a sufficient number of circulating stem cells for marrow rescue can be collected in one to three apheresis procedures.<sup>10</sup> Although the peripheral blood of healthy individuals contains fewer than 0.1% HSCs, this number increases dramatically during recovery from cytotoxic therapy and even more so when recombinant CSFs such as G-CSF are administered. Peak counts usually are obtained 5 days after stimulation with G-CSF (10 to 20 µg/kg/day) or 10 to 14 days after chemotherapy and G-CSF. Daily monitoring of peripheral blood CD34 counts is useful for determining when to start leukapheresis after chemotherapy and G-CSF mobilization. Most centers begin leukapheresis when the peripheral CD34 count reaches or exceeds 10 CD34+ cells/µL. Stem cell factor, thrombopoietin, and flt-3 ligand have also been reported to successfully mobilize HPCs.<sup>33-35</sup>

Peripheral blood stem cells can be used as a source of stem cells for both autologous and allogeneic marrow transplants. A PBPC collection is performed with a cell separation device originally developed for therapeutic plasmapheresis, leukapheresis, and platelet donation procedures. This apheresis device uses a centrifuge to separate and collect MNCs, including peripheral HSCs, from the blood. In order to achieve a target cell dose of 2 to 5 × 10<sup>6</sup> CD34+ cells/kg, it is necessary to process 12 to 25 liters of blood or 2.5 to 6.0 times the patient's calculated blood volume. Investigators have reported that the yield of CD34+ cells increases continuously as more blood volumes are processed.<sup>36</sup> Although up to six times the donor's blood volume can be safely processed, some donors are not able to tolerate 4 or 6 hours being connected to an apheresis machine. Therefore, these donors require repeated collections on sequential days once the peripheral CD34 count has increased to acceptable levels (>10 CD34+ cells/µL) for collection.

There are currently three different commercially available apheresis instruments. In each case, instrument settings such as inlet flow rate, centrifuge speed, collect pump flow rate, and anticoagulant:whole blood ratio vary, depending on the target cell type to be collected. The three instruments operate differently. The Amicus (Baxter, Deerfield, IL) and the COM.TEC (Fresenius SE, Bad Homburg, Germany) are more automated, computer-controlled instruments; however, the Spectra (CaridianBCT, Lakewood, CO) is more widely used. Suggested settings for the collection of CD34+ progenitor cells using these instruments are presented in Table 33-3. Note that the red cell content setting for the Spectra is set with a colorgram. Targeting a colorgram of 1% to 3% results in a product with approximately 6% red cells,

whereas this parameter can be entered directly into the other two instruments. Also, because the final product is more concentrated when collected by the Amicus, adding 100 to 150 mL of autologous plasma is recommended to rinse the collection line and to improve viability during storage.

A high red cell content in PBPC collections can cause problems with patient/donor ABO incompatibility in allogeneic transplants, and cause processing issues when performing cell selection procedures. The CD34+ (MNC) layer is just below the platelet layer. Going deeper into the white cell layer (closer to the red cell layer) increases the collection of granulocytes (PMNs), which can cause increased clumping and clotting in the products. In order to achieve the desired product hematocrit, the collect valve may be closed until the desired interface is established.

Two donor-related issues require special consideration. First is the issue of priming of the apheresis machine. Even when devices to that minimize extracorporeal volume are used, priming of the apheresis machine with red cells is required for individuals in whom the volume of the tubing set exceeds 10% to 15% of the total blood volume. This step prevents unacceptable dilutional anemia during the procedure and prevents fluid overload associated with the return of red cells from the centrifuge chamber at the end of the procedure. Second is the use of acid-citrate-dextrose (ACD) anticoagulant. The citrate component of ACD poses a risk of symptomatic hypocalcemia, which can limit the rate of blood processing and/or the duration of the procedure. Calcium replacement should be strongly considered to prevent adverse events during the apheresis collection procedure.

The anticoagulant:whole blood ratio is important to both the product and the donor. Increasing the ratio can reduce the collection time, but it also reduces the amount of anticoagulant being mixed with the donor's whole blood and thus increases the potential for clotting inside the tubing set and/or the product bag. When making adjustments to this ratio, one must consider the donor's platelet count from the day of collection.

### Umbilical/Placental Cord Blood Collection

Harvesting of UCB is the least invasive of all HSC collection techniques. The cord is clamped, and a 16-gauge needle attached to a standard blood donor set containing a preservative, usually ACD formula A (ACD-A) or citrate-phosphate-dextrose-adenine (CPDA-1), is inserted into the umbilical vein. Cord blood collection can either be performed by the obstetrician with the placenta in situ, or immediately after delivery by a trained team that can process the placenta in a location in close proximity to the delivery room. If cells are collected after delivery, the placenta

can be suspended from a specially constructed frame to aid in drainage of the cord blood. The usual volume collected is less than 170 mL.<sup>37</sup> After collection by gravity, some additional blood remaining in the placenta can be expressed by means of physical massage of the organ. A device that applies pressure to the placenta in a funnel-like framework has been reported to provide increased yields in total volume and CD34+ content.<sup>38</sup>

## Processing Procedures

A few general principles must be followed to preserve product integrity and to protect the operator from harm. Collection of a good quality unit is the ultimate goal.

- *Practice universal precautions.* All products are potentially infectious and if handled carelessly, can spread disease to the operator, or to another product. Donors should be tested for transfusion-transmitted diseases in advance of the procedure.
- *Follow aseptic processing guidelines.* Closed systems are of course preferable, but if not available, adherence to strict aseptic processing guidelines, such as use of a biosafety cabinet, is essential to protect the product from environmental contaminants.
- *Prepare.* Time is a critical factor with these products; however, it is important to perform the procedure in a deliberate manner. Preparation, including taking time to prepare materials, reagents, workspace, worksheets, and labels in advance of product arrival frequently reveals problems that can be solved in advance, thereby improving product quality.
- *Follow the SOP.* The SOPs serve as a step-by-step guide during processing. These procedures need to be written clearly, kept in a convenient location, updated easily, version-controlled, and consulted frequently during processing to prevent errors—even if the procedure is being performed by experienced personnel. Assuming the procedures have been validated to result in the desired endpoint, they must be followed as written.
- *Observe.* Although it is important to follow the SOP as written, it is also important to be alert for product abnormalities or unexpected outcomes that might necessitate a procedural deviation.
- *Document.* The benefits of having detailed documentation on file for each procedure performed cannot be overstated. Such documentation is needed for accreditation by voluntary standard-setting organizations [AABB, Foundation for the Accreditation of Cellular Therapy (FACT), College of American Pathologists (CAP), The Joint Commission], regulatory review by federal agencies [Clinical Laboratory Improvement Act (CLIA) and Food and Drug Administration (FDA)], and for best practice analyses during any internal or external quality systems/outcome reviews.

As new techniques are developed, or existing procedures modified, the specific aims will of course vary. However, there are two common goals of all in-vitro manipulations of HPCs. First, there must be minimal loss of, or damage to, the progenitor cells. The operator needs to ensure that the cells are collected and processed in accordance with the existing standard of care, so

that an adequate number of viable cells will remain after processing to provide for robust engraftment in a reasonable amount of time. Second, the processing technique must not place the component at undue risk of contamination with microorganisms. All procedures must be performed under aseptic conditions, preferably in a closed system, with appropriate assays for detection and identification of infectious agents at critical steps. Several of the more commonly used cell processing procedures are listed in Table 33-4, and described below.

### Red Cell Depletion

When the donor and recipient have a major ABO incompatibility (patient has antibodies to donor red cells), infusing more than 20 mL of incompatible red cells can cause a serious hemolytic transfusion reaction. Often, red cells are removed from marrow and UCB products to debulk the product before cryopreservation or as a prerequisite to subsequent processing. In the latter case, the absolute residual red cell content is less important, so a simple buffy coat preparation may suffice. Red cell depletion of PBPC products is rarely necessary because the apheresis procedure results in relatively low level red cell content.

Red cells can be depleted from marrow or UCB products by use of several different techniques. Historically, red cell depletion strategies were either based on density differences between cell types,<sup>39</sup> or a differential sensitivity to hypotonic solutions. More recently, hetastarch has been used to cross-link red cells such that they rapidly settle out of solution. Exposure of red cells to a 1:5 v:v ratio of 6% hetastarch results in the formation of cross-links between multiple red cells, significantly increasing their weight and causing them to rapidly settle to the bottom of a V-bottom container (bag).<sup>40</sup> Within 45 to 60 minutes, the leukocyte-rich plasma layer can be expressed into a separate collection bag or the red cell pellet can be drained into a waste container. Some marrow contains an excessive number of red cells; thus normalizing the hematocrit before adding the hetastarch can be beneficial. In the authors' experience, this method results in a good leukocyte recovery (>90%) with approximately 95% reduction in red cell content, resulting in <20 mL residual red cells. This maneuver allows for safer product transfusion to an ABO-incompatible recipient. A somewhat less pure product results from centrifugation followed by removal of the leukocyte-rich buffy coat layer.

### Plasma Depletion

Plasma depletions are also commonly performed on allogeneic PBPC and marrow products to prevent donor antibodies to recipient ABO antigens from causing a transfusion reaction following product infusion or to simply reduce the volume of the product in order to prevent volume overload. The product is divided into multiple 300-mL or 600-mL transfer packs and centrifuged at approximately  $900 \times g$  for 10 minutes. The plasma is extracted, and the infranatant fluids are combined into one container. The addition of a heparinized isotonic buffer solution containing a small amount of protein (human serum albumin, HSA) helps preserve cell viability and improves the infusion flow rate.

**Table 33-4.** Commonly Used Cell Processing Procedures

| Aim                        | Rationale                                                                                                                                                                 | Methods                                                                                                                                                                                                                |

GVHD = graft-vs-host disease; GVL = graft-vs-leukemia; HPC = hematopoietic progenitor cell

One must be careful, however, that infusion volumes don't exceed approximately 20 mL/kg.

### Mononuclear Cell Enrichment

Marrow and UCB (and to a lesser extent PBPCs) are heterogeneous collections of cellular and noncellular components. The cells that lead to hematopoietic reconstitution are mononuclear; other cell populations in the graft may be superfluous, or cause harm. For example, most of the cells in a marrow or UCB product are mature red cells and granulocytes, which lyse and release potentially harmful enzymes during freezing and thawing. The CS3000 (Baxter) and the Spectra (CaridianBCT) use an automated differential centrifugation technique to remove approximately 95% of the red cells from a marrow product, while approximately 75% of the MNCs are recovered in a final product that contains more than 80% MNCs.<sup>41</sup>

### CD34 Selection

Immature progenitor cells possess a surface marker (CD34) that gradually disappears as the hematopoietic cells mature and

differentiate.<sup>42,43</sup> CD34 selection is used for the purpose of tumor purging, T-cell depletion, or to provide a starting population for gene therapy or stem cell expansion procedures. Two different CD34 selection devices are approved for clinical use in the United States or Europe. Both positively select antibody-coated CD34+ cells by immunomagnetic reactions that allow the CD34+ cells to be retained in the device while the antigen-negative cells are eluted. However, the details of the selection methods differ.

The Isolex 300i System (Baxter Oncology, Deerfield, IL) is the only CD34 selection device currently approved by the FDA for use in autologous PBPC transplantation. This system is almost fully automated and consists of four steps: 1) labeling cells with an anti-CD34 monoclonal antibody (MoAb); 2) mixing sensitized cells with paramagnetic beads coated with sheep anti-mouse IgG, whereby CD34+ cells form rosettes with the beads; 3) attaching the rosettes to a magnet and washing CD34- cells from the system; and 4) releasing the cells from the beads using a peptide mimotope (a synthetic polypeptide designed to mimic the CD34 antigen) that competes with the MoAb binding site of the CD34 molecule.<sup>44-46</sup> The magnetic field retains the beads and residual

antibody/peptide complexes in the separation chamber while the CD34+ cells are collected in a separate bag. All washes (including the initial wash to remove platelets) are performed within the closed system apparatus by using a unique spinning membrane technology. Reagent additions, incubations times, cell washing, and other steps in the selection are all software controlled. Depending on the protocol, the selected cells are then prepared either for immediate infusion, cryopreservation, or further manipulation.

The CliniMACS system is based on the immunomagnetic cell selection technology developed by Miltenyi Biotec.<sup>47,48</sup> This device is approved for clinical CD34+ cell selection in Europe, Canada, and some other countries and is currently undergoing clinical trials in the United States. In this partially automated system, the PBPC or red-cell-depleted marrow product is washed manually to remove platelets and plasma, and is then treated with a murine anti-CD34 that is conjugated to a stable colloidal suspension of super-paramagnetic particles composed of iron oxide and dextran. The cells are placed into the disposable tubing set in the selection device and the CD34+ cells are selected on a high-gradient magnetic separation column. The magnetically labeled cells are held in the column while unbound cells are washed through. The magnetic field is removed and the selected cells are collected. Buffer additions and flow rates are controlled via a computer-controlled system of peristaltic pumps, fluid sensors, and pinch valves. The retained antibody/particle complex does not affect the functional capacity of the selected cells. Other antibody-antigen systems can be employed for clinical application if performed under the appropriate FDA-approved investigational new drug (IND) protocol.

CD34 selection is considerably more efficient when starting with PBPC apheresis products than it is with either marrow or UCB, or frozen/thawed products. It is possible to routinely achieve greater than 90% CD34 purity and greater than 70% CD34 recovery when selecting CD34+ cells from PBPC, but recovery and purity both suffer when selecting CD34+ cells from either marrow or UCB. Preselection stem cell enrichment techniques such as density centrifugation or red cell depletion are helpful for achieving a better purity and recovery. Adding a small amount of a clinical grade DNase and magnesium chloride to older products delayed in transit or frozen/thawed products, greatly reduces clumping and improves postselection purity and recovery. Even with fresh PBPC, the starting product quality can affect selection performance. Products with low hematocrits and low granulocyte content are preferable, as are products with low to normal platelet counts.<sup>49</sup>

### T-Cell Depletion

The process of T-cell depletion (TCD) removes potentially host-reactive immunocompetent T cells from an allogeneic graft, resulting in a dramatic reduction in the incidence of GVHD. Unfortunately, if too many T cells are removed, this process may also increase the incidence of graft failure and leukemia relapse, suggesting that some residual T cells are beneficial in an allogeneic product. Rigorous depletion of 4 logs also significantly delays T-cell immune reconstitution, especially CD4+

T cells, after transplantation. Conversely, if not enough T cells are removed, GVHD may occur, particularly if the donor and recipient are not fully HLA-matched. Some centers prefer to use the most rigorous depletion procedure available (immunomagnetic, as discussed below), and then add back defined doses of T cells or T-cell subsets to combat graft failure or speed immune reconstitution. Other centers have chosen to do a less complete TCD and use additional posttransplant immune suppression to prevent GVHD. Thus, the choice of TCD procedure to employ should be based on the desired target dose for infusion. The critical number of T cells needed to support the graft-vs-leukemia effect has not yet been determined. However, transplantation with a T-cell dose of  $1 \times 10^5/\text{kg}$  body weight allows engraftment and minimizes the severity of GVHD. TCD may also be used to remove autoreactive T cells from autografts used to treat patients with various severe autoimmune diseases. This approach appears promising but is currently considered to be experimental.

Early T-cell depletion techniques were based on the phenomenon by which T cells form rosettes around sheep red cells.<sup>50</sup> After rosetting, the T cells can be removed from the suspension by means of density gradient centrifugation. This technique is tedious and labor intensive, but surprisingly effective. More recently, most centers that perform T-cell depletions utilize MoAbs to T-cell antigens to remove these cells from allogeneic grafts. Methods have been developed in which antibodies to antigens such as CD3, CD4, CD5, CD6, and CD8 are used in conjunction with complement, immunotoxins, or magnetic microspheres to remove T cells from allogeneic grafts.<sup>51-53</sup> Not all TCD methods target the total CD3+ T-cell population. Depleting only the CD8+ subset of CD3+ T cells may achieve similar outcomes to total TCD without as many of the negative side effects. Some centers even target only those donor T cells that respond to the recipient alloantigens.<sup>54</sup> Performing a CD34 selection also produces an infusion product with 4 log fewer T cells than were contained in the original product.<sup>55-57</sup>

### Donor Lymphocytes

Donor T cells that are reactive to recipient minor histocompatibility antigens can cause a graft-vs-leukemia response and thereby reduce relapse rates.<sup>58,59</sup> Donor leukocyte infusion (DLI), has been used to obtain complete remissions in relapsed acute myeloid leukemia, acute lymphocytic leukemia, multiple myeloma, non-Hodgkin lymphoma, myelodysplastic syndrome, and chronic myeloid leukemia.<sup>60-62</sup> It is most successful with chronic myelogenous leukemia. Approximately 65% of patients achieve complete remission in comparison with 25% of patients with acute myelogenous leukemia or myelodysplastic syndrome.<sup>63</sup> Donor lymphocyte infusions have been most effective when administered early in the relapse. The risks associated with DLI are GVHD and marrow suppression. The risk is minimized if treatment begins with a small dose that is increased if there is no response.

Allogeneic T lymphocytes are now commonly cryopreserved either before, or as part of, the HPC collection, especially in the unrelated donor setting. The donor CD3+ T cells contained in

marrow, mobilized PBPC products, nonmobilized PBPC products, or small-volume PBPC donations are enumerated and can be given to the recipient fresh, in specified doses, or else cryopreserved in CD3+ dose aliquots. Typically, the T-cell doses infused range from  $1 \times 10^6/\text{kg}$  to  $5 \times 10^7/\text{kg}$ . Physicians typically request that multiple doses be cryopreserved for later use, in case of relapse. The same cryopreservation procedure used for HPC products is most commonly used for these small-volume products.

### Cryopreservation

Transplantation of autologous marrow and PBPC and allogeneic UCB requires a means of efficient preservation of the progenitor cells, sometimes for months or even years before transplantation. As cryopreservation techniques have improved, more allogeneic products are being cryopreserved for donor convenience, or to reduce the risk of a collection failure or transport error while a patient is immunocompromised.

Cryopreservation is among the most critical manipulations performed in clinical cell processing laboratories. Techniques vary slightly among institutions; however, in all cases, the objective is to adjust the volume to the container of choice, add a cryoprotectant solution and then freeze the cells at a controlled rate, in a manner that preserves cell viability and proliferative potential after thawing. It is essential that the cryopreservation procedure prevent ice crystal formation, prevent the formation of toxic solute concentrations that can result from cell dehydration, and stabilize the cell membrane in order to prevent damage during the thawing process. Mononuclear cells tolerate freezing relatively well, so minor procedural deviations are not usually detrimental. Even so, process variables such as volume: surface area ratio and the rate that the cryoprotectant is added should be well controlled, and monitored regularly. Many centers prefer to perform a buffy-coat procedure to reduce the red cell content in UCB and marrow products before cryopreserving them.<sup>37</sup>

There are numerous cryoprotectant solutions being used with good results. All contain a colligative agent such as dimethylsulfoxide (DMSO); one or more polymeric agents such as HSA, autologous plasma, or hetastarch; an anticoagulant; and an isotonic diluent or culture media. The standard freezing mixture contains 20% DMSO (final concentration, 10%), ACD-A (final concentration 10%), an isotonic electrolyte solution, and a source of protein, usually autologous plasma or HSA, although several laboratories prefer a lower DMSO concentration.<sup>64-67</sup>

DMSO is toxic to cells if exposed for long periods at room temperature; thus, it is important to keep the cell suspension and all reagents chilled before and after the addition of the DMSO.<sup>68</sup> In addition, diluting DMSO in aqueous solutions is an exothermic reaction. Therefore, it is important to dilute the DMSO with an aqueous buffer and refrigerate the solution before adding it to the cells to minimize the DMSO toxicity. The addition of the DMSO solution to the cells needs to occur slowly for similar reasons. Product handling procedures that occur after DMSO addition need to be gentle and need to avoid exposing the cell membranes to excessive shear forces.

Stiff et al<sup>69</sup> were the first to incorporate hydroxyethyl starch (HES) as an additional cryoprotectant. The addition of HES to the cryopreservation media allows for the reduction of the DMSO concentration, thereby decreasing the unpleasant side effects and adverse events occasionally experienced during or after DMSO infusion.<sup>70,71</sup> However, it is important to be aware of possible complications, such as hypertension, that can result from infusing large volumes of HES. A 2.5% to 6% HES concentration in combination with 5% DMSO is an effective cryoprotectant for cryopreserving hematopoietic cells.<sup>72,73</sup>

Whichever cryoprotectant is used, the freezing rate is also important for viable cell recovery. A controlled freezing rate of  $-1^\circ\text{C}$  to  $-2^\circ\text{C}$  per minute is described as optimal in most reports. Thus, the most effective freezing profiles use a liquid nitrogen freezer that is programmed to maintain a constant freezing rate of between  $-1^\circ\text{C}$  and  $-2^\circ\text{C}$ , despite the heat of fusion that occurs as the solution begins to solidify.<sup>74</sup> Slightly different profiles are required for different container sizes. A typical freezing profile is shown in Fig 33-1. The program that the freezer used to generate this freezing profile is presented in Table 33-5. After the cells reach  $-90^\circ\text{C}$ , they are transferred to a liquid nitrogen storage freezer and are stored in the vapor phase, at  $\leq -160^\circ\text{C}$ .

Some centers do not use a programmable freezer, but instead place the products into a  $-80^\circ\text{C}$  mechanical freezer for 18 to 24 hours before transferring them to liquid nitrogen storage. There are several reports in the literature claiming equivalence to controlled-rate freezing if the packaging configuration is correct.<sup>66,75-79</sup> Although the storage of HSCs at  $-80^\circ\text{C}$  does not seem to cause obvious damage during short periods, there is evidence that complete cessation of enzymatic and metabolic activity does not occur until a temperature of at least  $-135^\circ\text{C}$  has been reached.<sup>69</sup>

Once a particular method has been validated to result in rapid engraftment and an acceptable postthaw viability (using 7-amino-actinomycin D), it is important to keep variables such as product volume, container size, and maximum cell concentration consistent so that the temperature distribution is uniform.<sup>80</sup> The optimal cell concentration is still not clear, so many laboratories choose to allow this parameter to vary, up to a maximum of between 1 and  $3 \times 10^8$  cells/mL, so that the product volume per bag can be consistent from patient to patient.<sup>81</sup>

### Storage

When the freezing program is completed, the bags can be removed from the chamber and placed in prechilled and labeled protective canisters for storage. The storage temperature should be low enough to slow the metabolism and block all the enzymatic pathways; thus, the lower the storage temperature the better. Mechanical freezers can achieve temperatures as low as  $-120^\circ\text{C}$ ; however, liquid nitrogen freezers are much more reliable and provide even lower temperatures. Vapor phase liquid nitrogen storage ( $-160^\circ\text{C}$ ) has the advantage of preventing product cross-contamination and minimizes occasional bag breakage during thawing. Vapor phase storage is most frequently

**Figure 33-1.** Typical freezing curve from the cryopreservation of a PBPC product in a controlled-rate freezer. This curve was generated using the freezing profile shown in Table 33-5.

**Table 33-5.** Typical Profile for Hematopoietic Cell Cryopreservation

| Profile   | Step No. | Rate<br>(degrees<br>per min.) | End Temp.<br>(degrees C) | Trigger      |
|-----------|----------|-------------------------------|--------------------------|--------------|
| 70-mL bag | 1        | Hold                          | 4                        | Chamber temp |
|           | 2        | -1                            | -8                       | Sample temp  |
|           | 3        | -25                           | -60                      | Chamber temp |
|           | 4        | +10                           | -30                      | Chamber temp |
|           | 5        | -1                            | -30                      | Sample temp  |
|           | 6        | -10                           | -90                      | Sample temp  |
|           | 7        | Hold                          | -90                      | Chamber temp |

used for short-term (<1 year) storage.<sup>82,83</sup> Liquid phase storage ( $-196^{\circ}\text{C}$ ) is less prone to occasional temperature fluctuations as freezers are accessed, and provides a larger safety margin if the liquid nitrogen source is depleted; thus, it is frequently used for long-term storage. In either case, continuous temperature monitoring, remote alarm notification, and automatic fill features are essential to maximize product safety during storage. Overwrap bags provide an extra layer of protection against product cross-contamination, and are advisable for high-risk products.

Short-term storage of products before or after processing is best accomplished by providing nutrients, buffering the pH, and augmenting the anticoagulant solution, if appropriate. Viability is best maintained if the cells are stored at a cool temperature in a gas-permeable bag. Because it is not clear how long HPC products remain effective when stored under these conditions, it is best to minimize storage times whenever possible.

## Transportation

Product transport is essentially short-term product storage under duress, yet it is a critical maneuver for those centers that process tissues from distant clinical sites. Even the best planned courier systems fail in bad weather, or when air travel is involved, requiring last-minute adjustments in staffing schedules. Such situations have the potential to compromise the product if delays are excessive. Diluting the cells with autologous plasma and a buffer solution at the collection site, adding extra heparin for long-distance transport, and shipping at a cool temperature in a well-insulated container help significantly to protect the product. Adding a source of DNase upon arrival in the laboratory for products more than 24 hours old can also improve processing results by eliminating the free DNA released from cells that have died during transport.

All product shipment procedures need to comply with current biohazard product packaging and labeling regulations. Fresh HPC products need to be packaged in sealed, puncture-proof containers. Transportation of frozen HPC products requires the use of a liquid nitrogen dry shipper that contains absorbent material in the wall of the device to absorb the liquid nitrogen and eliminate the risk of spillage. These devices are designed to hold temperatures below  $-160^{\circ}\text{C}$  for 8 to 10 days, but the liquid nitrogen evaporation rate needs to be checked before each use.

## Thawing/Infusion

Cryopreserved cells are less prone to injury when thawed rapidly. The bags of cell suspension are thawed just outside the patient's room in sterile overwrap bags in a  $37^{\circ}\text{C}$  waterbath. The bags are thawed one at a time and immediately, but slowly, infused through a central venous catheter or intravenous access, as soon as the product reaches approximately  $15^{\circ}\text{C}$ . It is generally best if

laboratory personnel perform the thawing procedure and clinical personnel perform the infusion.

The bag of cells may be hung and allowed to drip through an administration set, or the cell suspension can be withdrawn from the bag with a syringe and injected directly into the catheter port. A few centers wash the cell suspension to reduce the volume or to remove DMSO before infusion, particularly for pediatric patients or for patients with renal insufficiency. Because of the fragility of the cells after thawing, any procedure must treat the cells gently and not subject them to vigorous shaking or centrifugation, which can cause the suspension to clump, resulting in poor cell recovery. Slowly diluting the cell suspension with approximately 1:5 cold dextran and allowing the cell membranes to stabilize before centrifugation improves viability and recovery. If any postthaw processing is anticipated, it is advisable to consider the addition of DNase during either freezing or thawing to reduce the clumping caused by single-stranded DNA from the cells that did not survive the freeze-thaw process. Platelets and plasma proteins also can cause clumping of progenitor cells after thawing.

---

## Quality Control

Quality control testing plans need to be protocol-specific, and designed to demonstrate postprocessing product integrity and product safety. Product safety is the primary concern, especially for Phase I clinical trial products. However, demonstration of product integrity (potency) is also important for interpreting clinical findings.

## Safety

The tests most often performed in order to demonstrate safety are donor infectious disease testing, bacterial and fungal product sterility testing, endotoxin testing, and mycoplasma testing (for cultured products). Additional safety tests are often required by the FDA for complex products—for example, testing for the presence of replication-competent retrovirus in the final product is required when using a retroviral vector to genetically alter an HPC product.

Products need to be tested for sterility at receipt and at the end of processing. Final product testing is mandated; testing at receipt provides a way to determine whether any of the techniques or materials used have compromised the purity of the product. Even if every effort is made to maintain sterility during collection and processing of an HPC product, there is a risk of contamination with microorganisms, especially when multiple manipulations are performed. Contamination can result from microorganisms in the skin or bloodstream of the patient or donor, improperly sterilized equipment or materials, environmental contaminants, or faulty handling of the graft.<sup>84,85</sup>

Sterility testing should be performed with a validated method for detecting bacterial (aerobic and anaerobic cultures) and fungal contamination. Procedures need to be in place whereby the

patient's physician is promptly notified if a sterility test result is positive. For products released before even preliminary results of sterility testing, it is often difficult to obtain proof of product safety before infusion. It is still important to perform the cultures and to document product safety after the fact. Same-day procedures such as Gram's staining and endotoxin assays can also be helpful.

## Integrity

Integrity testing provides the patient's physician with important product purity and potency information and can be valuable for evaluating process improvements and deviations.

The most widely used potency assay for progenitor cell components is the number of viable CD34+ cells (or their subsets) present at the end of the procedure. Numerous reports in the literature have concluded that the time to hematopoietic recovery after transplantation is optimal with CD34 doses of at least  $5 \times 10^6$  per kg.<sup>86-88</sup> The total nucleated cell dose is obtained using an automated hematology analyzer. The percentage of MNCs can be determined by performing a differential count on a stained smear. Cell viability and phenotypic characterization (CD45, CD34, CD3) are best accomplished using flow cytometry.<sup>89-93</sup> Functional assays such as colony-forming ability, long-term culture-initiating ability, or animal model in-vivo hematopoietic reconstitution assays are essential for establishing the therapeutic potential of new products, but are impractical for everyday use.<sup>94</sup>

## Release Criteria

Minimal acceptance criteria for nucleated cell count, viability (FDA recommends >70%), target cell content, progenitor cell content, etc, should be established in advance. If a product does not meet release criteria, it must be further processed (to bring it into compliance), discarded, supplemented with additional product, or released with the approval of appropriate laboratory and clinical personnel.

In principle, product release criteria should have clinical relevance. With cell therapy products, however, the products are so extremely valuable to their intended recipients that physicians almost always want to infuse the cells even if they do not meet predefined acceptance criteria. Often, it is not possible to discard a contaminated product because the patient will not survive the myeloablative therapy without receiving the product. The patient's physician is notified when a product does not meet expectations and the procedures used to produce the product are thoroughly investigated.

Product release decisions should be based on objective criteria that are more encompassing than just the review of final product test results. Most release criteria are safety oriented; therefore, proper procedural documentation, raw material testing, and defined acceptance criteria for in-process test results all contribute to user confidence in product quality and should be incorporated into the quality assurance plan. The best way to design relevant release criteria is to determine under what circumstances the product should not be infused. What if the product wasn't properly labeled? What if it were known to contain human immunodeficiency virus? What if the purity was

so low that the chance of achieving the goal of the trial is too remote to justify the risks of proceeding? Such issues need to be addressed among the transplant team members.

## Quality Assurance

### Accreditation

Voluntary standards have been developed by two professional organizations in an effort to improve product quality. The AABB and FACT have published standards for the collection, processing, storage, and infusion of cell therapy products.<sup>95,96</sup> Both professional organizations offer on-site accreditation of laboratories acting in accordance with the published standards. Both systems emphasize the prevention of errors and an ongoing process of continuous quality improvement. FACT and AABB accreditation are theoretically voluntary, but are essentially mandatory because most clinical transplant programs are required to be accredited to obtain insurance contracts. Adherence to voluntary standards such as those promoted by these organizations is an excellent yardstick for predicting product performance. Accreditation should be mandated for every cell processing facility.

### Federal Regulations

All cell therapy products, including hematopoietic stem cells, are biologic products that are currently subject to regulation by the FDA via the *Code of Federal Regulations (CFR)* under 21 CFR part 1271 or 21 CFR part 211, depending on the product type. All cell processing groups must now be registered with the FDA and must be prepared for ad hoc FDA inspections. Minimally manipulated PBPC and marrow products for homologous use are regulated via FDA's current good tissue practice (cGTP) regulations that are contained in 21 CFR part 1271. The more complex biologic products, such as cord blood expansion products and gene therapy products, are regulated via FDA's current good manufacturing practice (cGMP) regulations that are contained in 21 CFR part 211.

### Quality Systems

The best way to meet all the various standards and regulations is to design and write a quality assurance plan that contains clear instructions for how to accomplish each of the universal quality assurance principles listed in Table 33-6.

Multiple resources are available for writing a quality management plan, including both FACT and AABB standards. In general, quality management plans that focus on error prevention (not error reporting) are the most effective. Many problems can be avoided by strict attention to process control. Control of the product collection, processing, transport, and storage procedures is critical. Standard operating procedures should be written clearly and concisely so that critical control points in the procedure can be monitored. Materials management procedures prevent problems by ensuring that all reagents and supplies are properly acquired, stored, and used. Validation programs are excellent tools for proving proper equipment operation and process performance. A good

**Table 33-6.** Quality Plan Essentials

|                                    |                                  |
|------------------------------------|----------------------------------|
| <b>Organization and Leadership</b> | <b>Monitoring and Assessment</b> |
| <b>Process Control</b>             | Audits                           |
| Standard operating procedures      | QC testing                       |
| <b>Materials Management</b>        | <b>Process Improvement</b>       |
| Supplier qualification             | Deviation management             |
| <b>Human Resources</b>             | Corrective and preventive action |
| Personnel training                 | <b>Equipment</b>                 |

| <b>Documents and Records</b>       | Calibration                      |
| Document control                   | Maintenance                      |
| Label control                      | <b>Information Management</b>    |
| Worksheets                         | <b>Nonconforming Events</b>      |
| <b>Facilities</b>                  | <b>Customer Focus</b>            |
| Environmental control              | Communication                    |
| Environmental monitoring           |                                  |
| Safety                             |                                  |

document control system ensures consistent SOP conformance and prevents most labeling errors. Environmental monitoring and control systems help prevent accidental contamination errors. Proper deviation reporting and corrective action tracking greatly facilitate continuous process improvement. Perhaps most important, a program of personnel training and ongoing competency assessment prevents the operator errors that are caused by miscommunication or misunderstanding. Once these systems are in place, it can be advantageous to file a type V drug master file with the FDA that can be referenced with each subsequent IND submission to speed the approval process.

## Hematopoietic Progenitor Cells: Autologous Transplantation

**Hooman H. Rashidi<sup>1</sup> & Scott D. Rowley<sup>2</sup>**

<sup>1</sup> Chief Resident, Department of Pathology and Laboratory Medicine, Yale University School of Medicine, New Haven, Connecticut, USA

<sup>2</sup> Chief, Adult Blood and Marrow Stem Cell Transplantation Program, Hackensack University Medical Center, Hackensack, New Jersey, USA

The number of patients undergoing hematopoietic stem cell (HSC) transplantation has grown rapidly as the efficacy of this treatment continues to be demonstrated in clinical trials. Transplant registries have collected data on over 65,000 transplant procedures, but this is believed to represent only a portion of all such procedures performed.<sup>1</sup> In Europe alone, over 12,000 marrow or peripheral blood stem cell (PBSC) transplant procedures are performed each year.<sup>2</sup> Much of this increase can be attributed to the adoption of PBSC products as the primary source of HSCs for transplantation, a change driven by the more rapid engraftment parameters of PBSCs, with resulting lower regimen-related risks of morbidity and mortality, and lower costs. Also, the use of high-dose chemo- and radiotherapy with stem cell rescue has increased because of success in randomized trials of dose-intensive therapy in achieving durable remissions in common dose-responsive malignancies such as multiple myeloma,<sup>3</sup> Hodgkin disease,<sup>4</sup> and non-Hodgkin lymphoma (NHL).<sup>5</sup> It has been 50 years since the discovery that cellular elements of the marrow protect against lethal irradiation.<sup>6</sup> Transplantation science during this interval is notable for the development of antineoplastic conditioning regimens achieving effective tumor cell kill, immunomodulation regimens allowing allogeneic transplantation without inevitable fatal graft-vs-host reactions, and simple HSC collection and cryopreservation techniques. An understanding of the hematopoietic and immunologic systems has continued to develop, so that enriched populations of HSCs or immunologic effector cells may be isolated and manipulated *ex vivo* to generate “somatic cell therapy” products that differ in function from native marrow cells.

Historically, HSC transplantation was developed as a technique to deliver high doses of chemotherapy with or without radiation therapy. The collection, storage, and infusion of autologous HSCs was intended to alleviate the iatrogenic marrow failure of the high-dose chemo- and radiotherapy regimen used

to treat the patient. The infusion of autologous HSCs, in contrast to allogeneic transplantation, conveys no direct immune antineoplastic benefit to the recipient given that there is no immunologic graft-vs-disease response. Autologous transplantation is, therefore, based on two considerations:

- The dose sensitivity of the disease being treated and the availability of dose-intensive regimens capable of ablating this disease.
- The ability to collect and successfully store adequate numbers of HSCs to allow rapid reconstitution of marrow function.

Although autologous HSC transplantation does not convey the immunologic graft-vs-disease effect achieved with allogeneic transplantation, the corresponding lack of graft-vs-host disease (GVHD) and the avoidance of toxic immunosuppressive medications required after allogeneic transplantation allows the use of dose-intensive therapy for older patients, including patients in their eighth or ninth decade of life, as well as for patients with comorbid conditions that might preclude allogeneic transplantation.

Both the dose and combination of agents used for chemotherapy are important in achieving cure of malignant diseases. Malignant diseases such as Hodgkin disease, intermediate-grade NHL, and acute leukemia are potentially curable if multiple chemotherapy agents are administered in a regimen that allows the use of an effective dose of each agent. The importance of combining multiple chemotherapy agents is illustrated by the increase in cure rates for Hodgkin disease treated with effective drugs in combination, in contrast to similar drugs used singly or in sequence. The importance of dose is illustrated by the lack of further increase in the proportion of patients cured by the inclusion of additional chemotherapeutic agents to a regimen, if such addition requires a reduction of dose to avoid regimen-related toxicities. Thus, the combination of mechlorethamine, vincristine, prednisone, and procarbazine (MOPP), and doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) in alternating schedules that doubles the number of drugs is no more effective than either regimen used alone in the treatment of Hodgkin disease. This is because in combining these regimens, the dose of the individual drugs is reduced by 50% because of

the alternate-cycle administration of each regimen. Frei et al<sup>7</sup> proposed that effectiveness of a chemotherapy regimen can be estimated by calculating the “summation dose intensity” that includes the amount of drug delivered over a period of time.

The curative treatment of dose-responsive malignancies such as breast cancer is limited by the lower activity of the chemotherapy agents available and because almost all of the agents are myelosuppressive, requiring dose reduction to accommodate combination chemotherapy. However, even for breast cancer, the importance of dose density (amount of chemotherapy administered over a unit of time) was demonstrated in 1981 by Bonadonna and Valagussa<sup>8</sup> in a retrospective analysis of two of their clinical trials with cyclophosphamide, methotrexate, and 5-fluorouracil (5-FU). They found that disease-free survival (DFS) was longer for those patients who received a higher percentage of the intended dose of chemotherapy. This could reflect either the larger amount of drug delivered or that women who tolerated the drugs were also more likely to live longer. Similarly, Kummel et al<sup>9</sup> reported a randomized trial of dose-dense therapy in the adjuvant treatment of patients with node-positive breast cancers and found improved disease-free survival and overall survival in the patient group receiving the dose-dense regimen. Wood et al<sup>10</sup> showed in a prospective randomized trial that the delivery of higher doses resulted in a significantly better survival of women being treated for early breast cancer. This larger amount of chemotherapy delivered was better regardless if it was delivered in higher doses with fewer cycles or if an equivalent amount of chemotherapy was delivered in lower doses but over a longer period. The authors conclude that these data are consistent with either a dose-response effect or a threshold level of the dose or dose intensity. The importance of dose in the treatment of lung cancer and NHL is also known.

The infusion of HSCs allows the administration of a dose-intense (higher doses of drugs over a short period) regimen without concern for the effects on hematopoiesis (myeloablative regimens). The importance of dose intensity instead of dose density for many diseases is demonstrated by randomized trials of autologous transplantation for diseases such as multiple myeloma,<sup>3</sup> Hodgkin disease,<sup>4</sup> and NHL.<sup>5</sup> These trials illustrate that dose-intense therapy is more effective than available non-transplant regimens delivered in multiple cycles over time. The delivery of even more chemotherapy using sequential (tandem) transplants has been explored in a small number of clinical trials,<sup>11</sup> but careful selection of regimens is required to avoid the nonmyeloid toxicities of the regimens used.

The infusion of HSCs has also been demonstrated to facilitate the administration of dose-dense nonmyeloablative regimens, potentially achieving a doubling of the amount of chemotherapy administered.<sup>12,13</sup> The potential of this approach was most clearly illustrated by Petengell et al,<sup>13</sup> who treated 25 patients with small-cell lung cancer with multiple cycles of ifosfamide, carboplatin, and etoposide (ICE) chemotherapy. Peripheral blood stem cells were collected after each cycle of chemotherapy and used for the support of the following cycle. The investigators

were able to double the dose-density, although only about 50% of the patients were able to complete the planned therapy. Five patients reverted to standard-dose therapy at a median of chemotherapy cycle four. Three patients died while on study (two of sepsis). Others reverted to standard-dose therapy because of prolonged cytopenias (two patients) and inability to collect cells or intolerance of dimethylsulfoxide (DMSO) (one patient each). One group treated 18 patients with sarcoma with high-dose ifosfamide and doxorubicin using a single PBSC collection split into multiple fractions and cryopreserved.<sup>12</sup> The group administered a median of  $0.9 \times 10^6$  CD34+ cells/kg with each cycle of therapy; the patients experienced a granulocyte count  $<500/\mu\text{L}$  for a median of 4 days and a platelet count  $<20,000/\mu\text{L}$  for a median of 2 days. The acceptance of cell support for these dose-dense regimens is limited by the logistics of delivering cryopreserved cells in hospitals and offices without easy access to this technology.

---

## Techniques of Autologous HSC Transplantation

### Patient Eligibility for Autologous HSC Transplantation

Careful patient selection and timing of treatment are critical to the success of dose-intense therapy. Patients with bulky tumor masses and patients with chemotherapy-resistant malignancies are much less likely to achieve durable control of malignancy even with the use of dose-intense regimens. The early introduction of dose-intense therapy in the treatment of a patient, before chemotherapy resistance and excessive chemotherapy-induced organ toxicity develop, is paramount. Therefore, treatment algorithms incorporating HSC salvage strategies must be part of the initial therapeutic decisions for each patient with a disease possibly treatable by high-dose therapy. Patients being prepared for autologous transplantation will frequently undergo several cycles of chemotherapy intended to:

- Demonstrate the sensitivity of the disease to chemotherapy.
- Reduce the bulk of the disease before autologous transplantation.
- Facilitate the collection of PBSCs.

Involved-field radiotherapy can be used to debulk large tumor masses but is, in general, reserved for administration after recovery from transplantation because of the deleterious effects of this treatment modality on the collection of PBSCs and the increase in organ toxicity within the treatment field with subsequent administration of chemotherapy. Radiotherapy used as consolidation therapy after autologous transplantation sometimes requires the infusion of additional HSCs to offset the marrow-suppressive effects of this therapy. This illustrates the need for comprehensive planning to ensure that reserve quantities of HSCs are available if needed.

Patients undergo a detailed evaluation to uncover any organ dysfunction that could preclude the safe administration of this therapy. Although HSC reinfusion rescues the patient from the hematologic toxicity of the conditioning regimen,

the nonhematologic (organ) toxicity of dose-intensive therapies remains. A retrospective review of 383 consecutive transplant procedures noted factors predictive of early transplant-related mortality including an FEV<sub>1</sub> (forced expiratory volume in 1 second) less than 78% of predicted, serum creatinine greater than 1.1 mg/dL, and serum bilirubin greater than 1.1 mg/dL.<sup>14</sup>

Current transplantation techniques using PBSCs minimize the period of neutropenia and the infection risk. Mortality rates reported after autologous HSC transplantation are frequently less than 5%, although this risk increases somewhat for older patients.<sup>15</sup> Because of this risk, patients undertaking dose-intensive therapy, if possible, should be free of infection and have other comorbid conditions such as diabetes mellitus under optimal medical control.

### Selection of Conditioning Regimen

Autologous HSC transplantation facilitates disease cure through the administration of dose-intensive regimens. Therefore, the conditioning regimen used should include drugs that are effective in the treatment of the particular malignancy and induce minimal nonhematopoietic organ damage at the myeloablative doses used for transplantation. Immunosuppression is not required for engraftment of autologous HSCs; therefore, agents such as antithymocyte globulin or total body irradiation (TBI) are not necessary. Some regimens, such as high-dose melphalan for the treatment of patients with multiple myeloma and carmustine (BCNU) based regimens for the treatment of lymphoma, are commonly used based on the results of multicenter Phase III studies showing the tolerability of these regimens. Relapse is the major cause of failure of autologous HSC transplantation. Therefore, some transplant programs are exploring novel techniques to deliver yet more intensive conditioning to the regimen. One example of this is the addition of radiolabeled

antibodies to a chemotherapy or TBI-based regimen to specifically target areas of tumor while sparing radiation-sensitive organs such as the liver, lung, and kidney.<sup>16</sup> In the study, 21 to 27 Gy of iodine-131-labeled anti-CD20 was added to a conditioning regimen of etoposide (20 mg/kg) and cyclophosphamide (100 mg/kg). This resulted in a 77% complete response rate and a 68% 2-year probability of progression-free survival (PFS) for patients with relapsed NHL. The 2-year PFS was almost double that previously experienced (36%) by similar patients treated with chemotherapy alone. This technique is currently being evaluated in a multicenter study sponsored by the National Heart, Lung, and Blood Institute, National Cancer Institute, and National Institute of Allergy and Infectious Diseases through the Bone Marrow Transplant/Clinical Trials Network.

### Selection of HSC Source

Peripheral blood stem cells have virtually replaced marrow as the HSC component for autologous transplantation and have shown benefit in Phase III studies in allogeneic transplantation.<sup>17</sup> Data published from a European transplant registry showed that the vast majority of autologous and all allogeneic HSC transplants were still marrow transplants in 1991.<sup>18</sup> By 2003, PBSCs were used in 97% of autologous HSC transplant procedures. The ease of collection and the rapid engraftment kinetics of PBSCs compared to marrow are widely recognized. With PBSCs, median times to achieve an absolute neutrophil count (ANC) >500/ $\mu$ L are typically about 10 to 12 days, and platelet recovery is even faster (Table 34-1).<sup>19-23</sup> In one Phase III study of 47 patients treated for germ cell tumor, rapid engraftment kinetics were achieved with PBSC transplantation. A small number of the PBSC recipients achieved a neutrophil count of >500/ $\mu$ L 1 day faster, and a sustained platelet count of >20,000/ $\mu$ L 7 days faster than the patients receiving marrow with all patients receiving

**Table 34-1.** Relationship Between Mobilization Scheme, Dose of CFU-GM or CD34+ Cells Infused, and Engraftment Kinetics After Autologous PBSC Transplantation\*

\* Shown are mean values for progenitor cell quantities infused and median values for time to achieve the particular endpoint of engraftment.

† CFU-GM cultures performed on thawed cells.

‡ Shown are median values.

CFU-GM = colony-forming unit-granulocyte-macrophage; PBSC = peripheral blood stem cell; ANC = absolute neutrophil count; ND = no data; G-CSF = granulocyte colony-stimulating factor.

granulocyte colony-stimulating factor (G-CSF).<sup>24</sup> A similar trial for patients with NHL or Hodgkin disease reported faster platelet recovery (time to a platelet count  $>20,000/\mu\text{L}$ ) of 16 vs 23 days, and faster granulocyte recovery (time to a neutrophil count  $>500/\mu\text{L}$ ) of 11 vs 14 days for recipients of PBSCs compared to recipients of marrow.<sup>25</sup> The PBSC recipients also spent fewer days in the hospital and required fewer red cell and platelet transfusions.

There are disadvantages to the use of PBSC components as a source of HSCs for autologous transplantation. These include the usual need for multiple days of collection, the current need for sophisticated flow cytometric analysis of the components to ensure adequacy of HSC content, the inability to collect adequate components from all patients, the (minimal) risks associated with administration of hematopoietic cytokines and the apheresis procedures, and the risks of infusion if the multiple components are cryopreserved. Marrow collection and infusion is available to patients for whom adequate PBSC component(s), defined by the number of CD34+ cells collected, cannot be harvested and stored.

The dose of CD34+ cells in the PBSC component(s) required for infusion depends upon the intended treatment regimen. Lower doses of CD34+ cells appear satisfactory for nonablative regimens.<sup>12,13</sup> For example, one group infused  $0.9 \times 10^6$  CD34+ cells per cycle for patients treated with high-dose ifosfamide and doxorubicin.<sup>12</sup> Despite an overall doubling of the ifosfamide dose in this Phase I study, the median times between cycles did not progressively increase, indicating that adequate marrow stores were maintained. For myeloablative regimens, increasingly higher CD34+ doses result in greater likelihood of rapid recovery of PBSC counts.

Patients who receive a dose of CD34+ cells above an ill-defined threshold experience engraftment. At lower doses of CD34+ cells there is considerable heterogeneity in engraftment speed, especially for platelet recovery, with some patients experiencing quick engraftment despite low doses of PBSCs. It is not known why this heterogeneity exists but it may reflect host marrow stromal cell damage from previous disease infiltration or chemotherapy, a weakness in the correlation between CD34+ cells and the cells responsible for hematologic recovery or, more simply, a greater degree of error in the measurement of CD34+ cells at the lower cell concentrations found for “poor mobilizers.” As the dose of CD34+ cells increases, the engraftment speed becomes more consistent for the population studied, although the median days of cytopenia and the minimum number of days is not affected.<sup>19,23</sup> Several investigators showed more consistently rapid granulocyte and platelet engraftment for recipients of products containing a quantity of CD34+ cells above a dose of about  $2$  to  $3 \times 10^6/\text{kg}$  of recipient weight.<sup>26-28</sup>

Many of the randomized studies showing an advantage of autologous HSC transplantation over other (nontransplant) therapies used marrow as the source of HSCs. The duration of aplasia predicts the incidence of peritransplant mortality after autologous transplantation.<sup>29</sup> Although this may reflect patient

characteristics rather than graft characteristics, it is possible that use of PBSCs will result in yet a greater difference in the outcome of these therapies.

### Expansion of Inadequate HSC Components

Hematopoietic stem cells are characterized by the ability to self-renew and to differentiate to mature blood cells. Collections of HSCs from the marrow or peripheral blood are termed “stem cells” despite the fact that they contain distinct populations of true HSCs and more differentiated progenitor cells with limited proliferative capacity. In-vitro techniques to increase (expand) the numbers of HSCs in components that contain limited or inadequate numbers of HSCs are being developed with the hope that expansion of HSCs will allow simpler collection techniques or the administration of dose-intense therapy to patients from whom adequate marrow or PBSC components cannot be collected. These techniques have been used in Phase I studies involving marrow, PBSCs, or umbilical cord blood.<sup>30</sup> The results of these studies are encouraging, but clinical utility has not been conclusively demonstrated and requires further study.

### Tumor Cell Purging

Hematopoietic stem cell components are a complex mixture of cells, and many of these cell populations affect the outcome of allogeneic or autologous transplantation. The preponderance of evidence demonstrates that malignant cells contained in an HSC graft are capable of causing disease after transplantation. The transmission of malignant cells in an organ graft has been demonstrated in both HSC and solid organ (eg, orthotopic heart, liver, or kidney) transplantation from living or cadaveric donors suffering from occult disease at the time the graft was harvested.<sup>31,32</sup> These reports conclusively demonstrate that even very small quantities of malignant cells can engraft when infused into a properly conditioned host. It is not surprising, therefore, that relapse of disease occurs after autologous HSC transplantation for diseases involving or likely to involve the blood or marrow.

Tumor cell contamination or minimal residual disease (MRD) of the component contributing to relapse after autologous HSC transplantation was demonstrated in studies involving the transplantation of genetically marked marrow cells from patients with acute or chronic leukemia or neuroblastoma.<sup>33-35</sup> The level of marked cells detected after relapse was very low, and these studies cannot conclude that the cell inoculum was the sole source of malignant cells causing the disease relapse. Nor do these studies demonstrate that purging of tumor cells is necessary or effective. However, the implication of these studies, as with the solid organ transplant experience, is that the infusion of tumor-contaminated HSCs may be detrimental to the recipient and purging, if without undue toxicity and of proven efficacy, may be beneficial to the subset of patients whose HSC components are contaminated by tumor cells. The unanswered question, therefore, is not whether the cell inoculum can be a source of posttransplant relapse but, rather, whether manipulation of the HSC component can affect this outcome.

It is generally accepted that collections of hematopoietic progenitor cells from the peripheral blood likely contain fewer malignant cells than marrow collections. However, circulating malignant cells have been found for patients with neuroblastoma, breast cancer, and lymphoma.<sup>36</sup> Despite the evidence cited above about the potential contribution of MRD to poor transplant outcome, no study to date in any malignant disease demonstrates a benefit from purging of HSC components intended for autologous transplantation. The hypothesis that purging is beneficial for patients with B-cell malignancies such as chronic lymphocytic leukemia (CLL) or NHL is supported by clinical reports. The University of Nebraska program reported that 10 of 11 patients who received marrow from which lymphoma cells could be cultured relapsed after transplantation compared with 2 of 13 patients who received “culture-negative” grafts.<sup>37</sup> This group subsequently reported a fourfold greater PFS of 57% vs 17%, for recipients of grafts with no detectable MRD.<sup>38</sup> Only the presence of a positive culture from the HSC inoculum predicting for a lower event-free survival (EFS) was confirmed in a subsequent randomized study conducted by this group comparing PBSCs and marrow as sources of HSCs.<sup>39</sup>

The Dana-Farber transplant program reported similar differences in DFS based on the presence or absence of detectable MRD in trials involving antibody-mediated purging.<sup>40-42</sup> These studies used sensitive polymerase chain reaction (PCR) techniques to monitor the presence of tumor cells before and after purging with monoclonal antibodies and complement. Patients who had documented persistence of tumor cells had a significantly lower probability of DFS than patients who received components that were PCR negative after purging. The difference in DFS remains highly significant even after 10 years of follow-up (Kaplan-Meier estimate of DFS probability of 80% vs 10%).<sup>43</sup> These publications provide the strongest evidence to date that complete tumor cell purging (based on the most sensitive tumor cell detection assays available) is both necessary and beneficial. This group reported much less success in achieving PCR negativity in the purging of components from patients with mantle cell NHL and a concomitant high relapse rate after transplantation for that disease.<sup>44</sup> Although the number of patients transplanted for CLL was too small for definitive conclusions, the Dana-Farber group likewise suggested a higher probability of DFS for those patients who received PCR-negative HSC components.<sup>45</sup>

These MRD detection techniques are surrogate markers for transplant outcome. It is, therefore, not surprising that other transplant programs have published contradictory reports. For example, one group reported relapses for three of four patients treated for follicular NHL whose marrow components became PCR negative after purging with one antibody and complement but for only 11 of 25 patients who received PCR-positive marrow.<sup>46</sup> A multivariate analysis by other investigators to determine the risk of relapse for 24 patients with poor-prognosis NHL who received unpurged PBSCs did not demonstrate any effect from tumor cell contamination on the risk of relapse after transplantation.<sup>47</sup> Yet, these investigators did report that the

persistence or return of tumor cells detected by molecular analysis into the blood or marrow after transplantation was predictive of relapse in 81% of the patients, and that patients with detectable disease after transplantation experienced a 24-fold higher risk of relapse compared with patients who became and remained PCR negative.

An alternative explanation for the Nebraska and Dana-Farber reports is that the detection of tumor in the graft with or without purging reflects the quantity of tumor cells in the component which, in turn, is proportional to the amount or the aggressiveness of the disease in the patient. Patients with higher body burdens of tumor are less likely to achieve a durable remission after HSC transplantation. Sharp et al,<sup>38</sup> however, assigned patients with marrow involvement to PBSC transplantation, so the better PFS observed by them after PBSC transplantation does not support the contention that marrow contamination reflects only overall body burden of tumor. Although many patients relapse at sites of previous disease, this could reflect preferential trafficking into previous sites of disease of malignant lymphocytes reintroduced with the HSC inoculum.<sup>48</sup> Recurrence at previous sites of disease is not conclusive evidence that residual disease in the patient is the only source of relapse after autologous HSC transplantation. The discrepancy between the experiences of these various centers could reflect the importance of adequate purging, differences in patient selection, or the efficacy of the conditioning regimen. This discrepancy also illustrates the need for properly designed studies to directly address the benefit and toxicity of purging. A variety of purging agents have been tested in Phase I and II studies. The numbers of patients and financial resources estimated to be required for definitive Phase III tests of purging efficacy have discouraged the conduct of these studies.

### Cryopreservation of HSC Components

The primary difficulty in using HSC components to reduce the hematologic toxicity of dose-intense regimens is the necessity for cryopreservation. Three considerations apply. First, current cryopreservation techniques for PBSC components require cryopreservation of both the HSCs that account for about 1% of the nucleated cell population of the component and the mature blood cells that do not contribute to the recovery of marrow function after infusion. These mature cells both increase the volume of the component (thereby increasing the amount of cryoprotectant solution added) and appear to contribute to the postinfusion morbidity experienced by the recipient.<sup>49</sup> Second, the recipient of cryopreserved HSC components may experience considerable toxicity from the DMSO used in the cryoprotectant solution. Third, the cryopreservation of HSCs is technically difficult. Long-term cryopreservation of cells using DMSO requires storage and shipping of cells at a temperature below  $-135^{\circ}\text{C}$ , generally using liquid nitrogen containers. The thawing of large numbers of bags of cells is usually performed by a skilled laboratory technologist at the patient's bedside.

A high incidence of generally mild, infusion-related morbidity with the reinfusion of cryopreserved cells has been reported by

several centers.<sup>50-52</sup> Dimethylsulfoxide has a variety of pharmacologic effects.<sup>53</sup> The LD<sub>50</sub> values (amount of DMSO required to kill 50% of test animals) reported for intravenous infusion of DMSO are 3.1 to 9.2 g/kg for mice and 2.5 g/kg for dogs.<sup>54</sup> The acute toxic dose of DMSO for humans has not been determined. If a large amount of cryopreserved material is to be infused (eg, >1 g DMSO/kg of patient weight), the infusion can be separated over 2 days to avoid complications from infusion of excessive amounts of DMSO. Because the osmolality of thawed marrow (with 10% DMSO) is about 1800 mOsm/kg, central venous catheters are the preferred route of administration. The incidence of the more common reactions appears to be related to the volume of the product infused.

The most dramatic toxicity is the rare anaphylactic reaction occurring during the initial administration of thawed cells. This appears to be an allergic reaction to DMSO or other components of the solution used for cryopreservation and, after resuscitation of the recipient, the remainder of the cells should be administered cautiously. Nonallergic, profound hypotension can result from the intravenous infusion of DMSO, presumably from histamine-induced vasodilation, especially for patients who were not adequately premedicated with appropriate antihistaminic medications such as diphenhydramine. Skin flushing, dyspnea, abdominal cramping, nausea, and diarrhea, reported to varying degrees after HSC infusion, can also be attributed to DMSO-induced histamine release. These complaints resolve over a few hours and should be treated symptomatically.

Dimethylsulfoxide affects the cardiovascular system in a variety of ways. In a series of 82 patients premedicated with diphenhydramine, both increased blood pressure and decreased heart rate, which became maximal about 1 hour after the completion of the marrow infusion, were observed.<sup>50</sup> Cardiac arrest or high-degree heart block occurring during or immediately after the infusion of cryopreserved marrow or PBSCs has been described.<sup>55,56</sup> In these two series, the incidence of bradycardia (heart rate <60 beats/minute) was 48.8% and 65%, second-degree heart block was 9.7% and 24%, and complete (third-degree) heart block was 4.8% and 5.9%. In both reports, the median time of onset was about 3 hours after the completion of the infusion. In one series, the authors noted that the heart block was often episodic, occurring with episodes of emesis.<sup>55</sup> In both series, the cardiac rhythm abnormalities resolved spontaneously within 24 hours after infusion. In contrast, another group found no cardiac rhythm changes in a prospective series of 29 patients.<sup>57</sup> A slower overall infusion rate may have accounted for the lack of rhythm changes.

Headache has been reported in up to 70% of recipients of cryopreserved cells,<sup>52</sup> but other central nervous system complications are rare and generally related to the amount of DMSO infused. Two recipients who received HSC components containing a total of 225 mL and 120 mL, respectively, of DMSO developed reversible encephalopathy.<sup>58</sup> The first patient underwent plasmapheresis with prompt improvement in mental status; the second patient recovered over 5 days without specific treatment.

The weights of the patients were not cited in this report, but both patients probably received more than 2 g DMSO per kilogram of body weight. The infusion of large quantities of poorly cryopreserved mature blood cells can cause renal failure.<sup>59</sup> Seizures have been associated with the infusion of highly concentrated PBSC products, suggesting that freezing at very high cell concentrations is not an acceptable strategy to avoid large volumes of DMSO.<sup>49</sup>

### Posttransplant Support

Hematopoietic growth factors are administered to speed neutrophil recovery after allogeneic or autologous transplantation. Randomized studies of granulocyte-macrophage colony-stimulating factor (GM-CSF) or G-CSF administration after autologous HSC transplantation demonstrated that these hematopoietic cytokines speed granulocyte recovery, decrease the morbidity caused by the transplant procedure, and are associated with a smaller probability of relapse.<sup>60-62</sup> But this has not consistently translated into earlier hospital discharge or reduced transplant cost. Administration of cytokines that primarily stimulate the proliferation of mature hematopoietic progenitor cells may not greatly affect the time to initial hematopoietic recovery after transplantation, although the subsequent rate of rise in peripheral blood counts is notably enhanced, suggesting that adequate numbers of cells at the appropriate maturational stage must be present before growth-regulatory effect from these cytokines can be obtained.<sup>63</sup> Late administration of cytokine support (starting several days after HSC infusion) may be as effective as early administration while being less costly to the patient.<sup>64</sup>

### Complications of High-Dose Therapy

The patient undergoing dose-intensive therapy with autologous HSC transplantation experiences a period of marrow hypoplasia that can persist for days or (rarely, with PBSCs) weeks. During this time, the patient requires antibiotic and blood component support, but death from infection or hemorrhage is uncommon.

Common nonhematopoietic toxicity that is not life-threatening includes alopecia, sterility, and varying degrees of mucositis with concomitant mouth pain, inanition, and diarrhea. Rarely, mucositis compromises airway patency, and intubation of the patient is temporarily required for airway protection. Serious organ toxicity includes hepatic veno-occlusive disease (from high-dose regimens in general), interstitial pneumonitis (eg, BCNU-induced), cardiomyopathy (eg, cyclophosphamide-induced), and hemorrhagic cystitis (eg, cyclophosphamide-induced). The risk of nonhematopoietic toxicity increases for older patients and for patients who previously received intensive chemotherapy regimens. For these patients, reduction of dose of the transplant conditioning regimen reduces toxicity but possibly increases the risk of relapse of disease.

Patients may experience long-term marrow hypoplasia after HSC transplantation despite the infusion of large quantities of HSC, possibly as a result of poor cryopreservation techniques, marrow stromal cell damage, or posttransplant events, and this complication may preclude the subsequent administration of

chemotherapy or radiotherapy for patients who experience relapse of disease. The development of myelodysplasia or secondary leukemia is being increasingly reported for patients previously treated with autologous HSC transplantation, particularly for patients with the diagnosis of NHL treated with radiation-containing conditioning regimens.<sup>65</sup> The incidence of this complication appears to be small in patients treated for leukemia,<sup>66</sup> but has been reported above 10% for patients treated for lymphoid malignancies.

Recipients of autologous or allogeneic HSC transplantation are at risk of long-term complications of their treatment including hypothyroidism, hypogonadism, organ toxicity (eg, drug-induced pneumonitis), and secondary malignancies. Patients treated with HSC transplantation should be enrolled in a program of long-term supportive care.<sup>67</sup>

### Adjuvant Therapy with Autologous HSC Transplantation

The incidence of relapse after high-dose therapy leads to the conclusion that high-dose therapy with autologous HSC transplantation, although well tolerated and likely to prolong life, should be viewed as a platform for other approaches that may be effective in eliminating the MRD of patients destined to relapse after the dose-intense therapy is administered. Additional or yet higher-dose chemotherapy or radiotherapy, unless directly targeted to the tumor target, increases the risks of nonhematopoietic toxicity and loss of patients from causes other than relapse. Immunologically based therapies are of interest in this regard and include administration of posttransplant cytokines,<sup>68</sup> the addition of tumor-specific antibodies used before or after transplantation or both as an in-vivo-purge,<sup>69</sup> and the development of tumor-specific vaccines such as with tumor-antigen-pulsed dendritic cells (DCs).<sup>70</sup>

## Diseases

### Acute Myelogenous Leukemia

Induction chemotherapy yields complete remission for most patients with acute myelogenous leukemia (AML), but these patients will rapidly relapse without postinduction consolidation therapy. Randomized studies of consolidation regimens of varying intensity demonstrate that intensity is correlated with probability of durable remissions.<sup>71</sup> The role of autologous or allogeneic HSC transplantation as intensive consolidation therapy for patients entering first remission has been explored in several randomized studies that assigned patients with available sibling donors to allogeneic transplantation and randomly assigned other patients to autologous transplantation or nontransplant consolidation therapy.<sup>72-76</sup> In general, autologous marrow transplantation has not proven to be more effective than nontransplant intensive consolidation chemotherapy (Table 34-2). In a study sponsored by the Eastern Cooperative Oncology Group (ECOG), patients assigned to allogeneic transplantation achieved a 43% DFS compared with 35% for patients assigned to chemotherapy and 35% for patients assigned to autologous transplantation

using marrow cells purged ex vivo with a cyclophosphamide derivative that caused a delay in hematologic recovery.<sup>72</sup> Overall survival (OS) was slightly but significantly higher for chemotherapy-treated patients because of the ability to rescue patients who relapsed, with subsequent autologous transplantation administered in second remission. However, only 54% of patients assigned to autologous transplantation in the ECOG-sponsored study received this treatment, and analysis of outcomes was by intent of treatment, raising the question of whether a difference could have been found with better compliance. Furthermore, transplant-related mortality was 14% for patients assigned to the autologous marrow transplant group, which is higher than would be expected for PBSC transplantation using nonpurged HSC products. A subsequent analysis of treatment outcome for patients stratified by cytogenetic risk group revealed a particularly poor outcome for patients with adverse risk cytogenetics who underwent either autologous HSC transplantation or nontransplant therapy.<sup>77</sup> In contrast, in one study the DFS at 7 years was 54% for recipients of autologous transplantation compared to 40% for recipients of chemotherapy ( $p = 0.04$ ).<sup>73</sup> Another study demonstrated a significantly better DFS for recipients of allogeneic transplantation (48% vs 30%,  $p = 0.04$ ) compared to recipients of chemotherapy. The probability of DFS for recipients of autologous marrow was intermediate, but not significantly different from either of the two other study arms.<sup>76</sup> Therefore, the role for autologous transplantation in the treatment of patients in first remission is not obvious, and questions remain about the selection of HSC source, value of ex-vivo purging, and timing of transplantation relative to other options for postinduction consolidation.

Several Phase II studies of autologous transplantation for the treatment of patients with AML in second or later remission have been published.<sup>78,79</sup> Many of these studies reported survival probabilities of 35% or better, which is higher than what would be expected with standard chemotherapy regimens. A review of British registry data described 154 patients who underwent autologous marrow and/or PBSC transplantation in second remission.<sup>80</sup> At 10 years, the actuarial probability of OS was 32%

**Table 34-2.** Multicenter Randomized Studies Comparing Autologous Marrow Transplantation to Intensive Consolidation Chemotherapy

| Study                      | Probability of Event-Free Survival (%) |            |                           |

| Ravindranath <sup>75</sup> | ND <sup>†</sup>                        | 38         | 36 (3 year)               |

\* Significantly different compared to chemotherapy treatment arm.

<sup>†</sup> Allogeneic transplantation was not performed as part of this trial.

<sup>‡</sup> Shown is the median duration of follow-up at time of analysis.

with PFS. Overall survival was better for patients who experienced a longer duration of first remission and had a younger age at time of transplantation (which may reflect a difference in the biology of this disease for different age groups). Most patients for whom this information was available in this registry had favorable or intermediate risk cytogenetics; only 1% had adverse risk cytogenetics. Autologous HSC transplantation appears to be effective therapy for the patient with AML in second complete remission (CR) who do not have adverse-risk features.

Purging of tumor cells from the HSC inoculum may be beneficial, but remains unproven. In nonrandomized studies, patients who received marrow cells treated with chemotherapy agents were less likely to relapse after transplantation.<sup>81</sup> Similarly, indirect laboratory assessments of purging efficacy suggest a benefit for patients who are treated with an aggressive purging technique.<sup>82,83</sup> The role of purging has not been proven in randomized studies, nor has it been shown to be of benefit for recipients of PBSC.

### Acute Lymphoblastic Leukemia

Few adults with acute lymphoblastic leukemia (ALL) are currently cured with induction and consolidation regimens.<sup>84</sup> Results have improved modestly with more intensive postremission chemotherapy and with tailoring of protocols in individuals with specific subsets of ALL. There are few data, however, supporting the effectiveness of autologous HSC transplantation as currently performed in ALL despite the theoretic potential of dose-intensive therapy. Two published reports comparing autologous to allogeneic marrow transplantation reported DFS after autologous transplantation similar to that reported for patients undergoing less intense induction and maintenance chemotherapy (approximately 20% to 30%).<sup>85,86</sup> A third study comparing autologous to allogeneic transplantation reported significantly improved probability of long-term survival for patients undergoing allogeneic transplantation.<sup>87</sup> Weisdorf et al<sup>88</sup> described transplant outcomes after autologous or unrelated donor transplantation for 712 younger (median age <18 years) patients with ALL (517 unrelated donor, 195 autologous) in first or second CR with data in two registries. They reported much higher treatment-related mortality for recipients of unrelated donor transplants, but more frequent relapses after autologous transplantation in first (49% vs 14%) and second remission (64% vs 25%) leading to similar outcomes for these two transplantation choices. Transplantation in CR1 yielded similar 3-year survival rates for recipients of unrelated donor (51%) and autologous (44%) transplants, as did transplantation in CR2 (40% vs 32%, respectively). As with AML, adverse risk features appears to favor allogeneic transplantation in first remission. A large Phase III study involving 1500 patients with a new diagnosis of ALL comparing specific outcomes for autologous or related-donor allogeneic HSC transplantation or nontransplant consolidation/maintenance therapy has not yet been reported in final analysis, although the study confirmed previously reported risk groups for patients with this diagnosis.<sup>89</sup>

Phase II reports from investigators from the University of Minnesota and Dana-Farber transplant programs reported 56

recipients of 214 adults alive and without disease at a median of 25 months after autologous transplantation.<sup>90</sup> The randomized addition of posttransplant interleukin-2 therapy after autologous transplantation did not improve the DFS. A similar matched-pair study involving children transplanted in second remission reported a 9-year probability of DFS of 26% for patients undergoing autologous transplantation compared to 32% for similar patients treated with chemotherapy alone.<sup>91</sup> In contrast, others reported a 1-year DFS of 50% for adult patients transplanted in first remission and 27% for patients in second or later remission using marrow with or without ex-vivo purging.<sup>92</sup> As with AML, autologous HSC transplantation appears effective for a subpopulation of patients with ALL, particularly those without adverse risk cytogenetic features and (for patients in second remission) who experienced longer durations of first remission.

### Chronic Myelogenous Leukemia

Limited numbers of patients with chronic myelogenous leukemia (CML) in chronic phase or with more advanced disease have been treated with autologous HSC transplantation.<sup>93</sup> In a large, single-center study of 73 patients, the survival of patients with chronic-phase disease who underwent transplantation did not differ from that of patients treated with interferon. Of patients with more advanced disease, 58% achieved a complete hematologic remission but only 10% achieved a complete cytogenetic response, and the median survival for this group of patients was only 5 months. However, other studies have reported longer durations of survival and remission for patients who receive Philadelphia-negative grafts,<sup>94</sup> leading to the hypothesis that products collected from patients in molecular remissions after treatment with imatinib may be useful in dose-intensive therapy for patients with subsequent progression of disease.<sup>95</sup> A meta-analysis of a number of incomplete clinical trials comparing autologous transplantation to nontransplant therapy (principally, interferon-alpha) found no evidence of a difference in survival or statistically significant differences between treatment groups in best hematologic or cytogenetic response achieved in the first year.<sup>96</sup> Furthermore, this analysis was unable to determine whether autologous HSC transplantation with predominantly Philadelphia-negative cells early on in the disease resulted in a better outcome. Autologous HSC transplantation for this disease is, in general, limited to clinical research protocols.

### Chronic Lymphocytic Leukemia

Aggressive treatment is less likely to be used in CLL because of its long natural history, indolent nature, and the advanced age of most patients. Although the disease responds to chemotherapy and radiotherapy initially, relapse is inevitable. The extensive infiltration of marrow by malignant lymphocytes has served to focus transplantation trials on allogeneic transplantation or autologous transplantation with HSC products collected in remission or purged ex vivo. Few clinical studies have been reported. Investigators from the M.D. Anderson Cancer Center reported 6 of 11 patients treated with autologous marrow cells (seven purged

ex vivo) surviving in remission up to 29 months after transplantation.<sup>97</sup> Investigators at the Dana-Farber Cancer Institute reported a high CR response rate for 12 patients who received autologous marrow that had been purged with multiple monoclonal antibodies,<sup>98</sup> but a subsequent report of a total of 137 patients found no plateau in the survival probability, indicating that late relapses continue to occur.<sup>99</sup> Currently, autologous HSC transplantation in the treatment of CLL is limited to clinical research protocols.

Multiple Myeloma

Multiple myeloma, a malignancy of plasma cells, is now the most common indication for autologous stem cell transplantation in North America (Fig 34-1). Autologous stem cell transplantation with dose-intense melphalan is now considered a standard component of the initial therapy of newly diagnosed patients based

on Phase III studies that demonstrated improved response rates and better survival for recipients of this treatment (Table 34-3).

Dose-intense melphalan therapy was first noted to have a dramatic response in nine patients with refractory myeloma in 1983, including five patients who achieved a complete biochemical and marrow remission.<sup>101</sup> Hematopoietic toxicity was initially dose-limiting for dose-intense melphalan, but this could be ameliorated by infusion of previously collected HSCs. The ability to administer high doses of melphalan with or without other drugs or TBI was confirmed in a series of Phase I and II studies. A matched-pair analysis by the University of Arkansas group and Southwest Oncology Group comparing dose-intense with standard-dose therapy demonstrated the benefit of autologous HSC transplantation for the treatment of multiple myeloma with a marked improvement in CR rate (22%) when compared

Figure 34-1. Indications for hematopoietic stem cell transplantation in North America in 2005.

Table 34-3. Risk Factors for Survival After Autologous Transplantation for Multiple Myeloma

| Event-Free Survival*       |     |         | Overall Survival           |      |         |

to currently available low-dose regimens (5%).<sup>102</sup> Event-free (49 vs 27 months) and overall survivals (62+ vs 48 months) were also improved for patients treated with dose-intense therapy as part of their initial treatments.

Several randomized studies comparing dose-intense therapy with autologous stem cell support to standard therapy regimens have been conducted (Table 34-4).<sup>103</sup> The French Myeloma Intergroup reported a large-scale randomized trial (IFM 90) that randomly assigned 200 patients to either conventional dose VMCP/VBAP polychemotherapy regimen or autologous marrow transplantation with melphalan and TBI after four cycles of induction treatment.<sup>3</sup> The findings were strikingly in favor of the dose-intense approach with improvements in complete response rates (22% vs 5%) and median probabilities of EFS (27 months vs 18 months) and OS (60+ months vs 37 months). The British Medical Research Council (MRC) Myeloma VII trial of 407 patients reported similar results for a comparison of six cycles of BCNU, doxorubicin, cyclophosphamide, and melphalan to at least three cycles of doxorubicin, vincristine, methylprednisolone, and cyclophosphamide followed by melphalan at 200 mg/m<sup>2</sup> and autologous stem cell transplant.<sup>104</sup> The French group Myelome Autogreffe (MAG) achieved results comparable to the IFM 90 trial; however, there was no significant difference in OS as a result of unexpected prolonged survivals in the chemotherapy arm.<sup>105</sup> The Spanish PETHEMA group did not find a statistically significant difference in EFS and OS between chemotherapy and dose-intensive therapy.<sup>106</sup> However, only patients who responded (CR: 15%; partial response: 68%; minor response: 17%) to conventional dose chemotherapy were randomly assigned to treatment groups and patients in the chemotherapy arm were allowed to cross over into the dose-intensive therapy group. The Italian Multiple Myeloma Study Group compared melphalan-prednisone to two courses of melphalan at 100 mg/m<sup>2</sup> with autologous stem cell support.<sup>107</sup> They found significant improvement in CR and EFS in the transplant study arm. The MRC trial comparing high-dose therapy to conventional therapy deserves special consideration.<sup>104</sup> It is the most recent of the randomized trials and was carried out in the era of more advanced

supportive care and the availability of newer therapeutic agents. It still showed a statistically significant advantage for high-dose therapy in terms of CR, EFS, and OS. Moreover, it did not show any increase in treatment-related mortality relative to conventional therapy. These randomized trials all showed a trend to significantly improved results for patients treated with dose-intense therapy. Adding the support of numerous Phase II trials, the data clearly indicate that dose-intense therapy with autologous HSC transplantation should be offered to appropriate patients as part of their initial treatment. The median EFS is remarkably constant (25-31 months). It is more difficult to analyze OS results because that depends partly on salvage therapy. However, median OS was significantly longer in the three studies where differences in EFS were more marked. In all studies, procedure-related death rate was <5% and not greater than that observed with conventional chemotherapy.

With HSC support, mucositis becomes the dose-limiting effect of dose-intense melphalan. In an attempt to increase the total amount of melphalan administered, the Arkansas transplant program explored the feasibility of two consecutive autologous transplants given at intervals of only a few months, doubling the total dose of melphalan administered.<sup>108</sup> The investigators described 42 patients who received two consecutive autologous PBSC transplants using melphalan 200 mg/m<sup>2</sup>. In patients who were capable of receiving two transplants, the CR rate increased from 24% after the first transplant to 43% after receipt of the second transplant. This experience has now been extended in over 1000 patients with overall CR rates of 40% and projected 5-year EFS and OS of 25% and 40%, respectively.<sup>100</sup> The French Intergroup randomly assigned 399 newly diagnosed myeloma patients under age 60 to single vs tandem transplants.<sup>109</sup> They found similar CR rates between the two groups (42% single transplant vs 50% tandem transplant), but superior 7-year EFS (10% vs 20%,  $p = 0.03$ ) and OS (21% vs 42%,  $p = 0.01$ ) for the tandem transplant group. For patients who did not achieve a very good partial response (less than 90% reduction in serum or urine paraprotein) after one transplant, the improvement in 7-year OS was more dramatic (11% vs 43%,  $p < 0.01$ ). These

results support tandem autologous transplants for patients with a diagnosis of multiple myeloma who do not show disease progression after the first transplant.

The success of autologous transplantation led to several analyses of the risk factors predictive for the survival of patients after initial transplantation. A retrospective study of 344 patients with multiple myeloma treated with high-dose chemotherapy and autologous stem cell transplantation showed a 5-year OS of 72% for patients who achieved a complete response, which is defined as absent monoclonal protein by both serum protein electrophoresis (SPEP) and immunofixation (IFE). This is compared to 48% for patients who achieved a near complete remission (monoclonal protein absent on SPEP but still detectable by IFE). The EFS was also superior in the CR group (35%) in comparison to the non-CR group of patients (21%).<sup>110</sup> Investigators from the Arkansas transplant program reported the long-term outcomes for 515 consecutive patients intended to receive melphalan-based tandem transplants with follow-up of at least 5 years.<sup>111</sup> One quarter of the patients had EFS of  $\geq 5$  years with no further relapses seen after 7 years (46 patients on the plateau). Factors associated with long-term EFS included initial transplantation within 1 year of diagnosis, absence of chromosome 11 or 13 abnormalities, and a lower  $\beta_2$ -microglobulin at initial diagnosis. This group subsequently reported that of 135 patients enrolled in a study of tandem autologous HSC transplantation, patients with normal cytogenetics had median EPS and OS of 43 and 50 months or more, respectively.<sup>112</sup> The EFS and OS for patients with abnormalities of chromosome 13 were 21 and 29 months; for patients with abnormalities involving 11q, 20 and 21 months; and for patients with abnormalities of both 13 and 11q, 11 and 12 months. The absence of chromosomal abnormalities was the single strongest prognostic factor associated with prolonged survival in this study. Other factors that are considered poor prognosticators are fluorescence in situ hybridization (FISH)-defined chromosome 13 deletions<sup>113</sup>; hyperdiploidy<sup>114</sup>; the detection of abnormal metaphases<sup>100</sup>; elevations in C-reactive protein, lactate dehydrogenase,  $\beta_2$ -microglobulin, and creatinine; and low levels of hemoglobin, albumin, and platelets.<sup>115</sup>

The role of maintenance therapy after transplantation remains open to question. A recently published study assigned 597 patients to three arms of (A) no maintenance therapy, (B) pamidronate therapy given monthly, or (C) pamidronate with thalidomide starting 2 months after a second autologous HSC transplantation.<sup>116</sup> Those who received pamidronate and thalidomide (Arm C) had the best CR or very good partial response when compared to the Arm A and Arm B patients (67% vs 55% and 57%, respectively). The 3-year probability of relapse-free survival was also higher in Arm C vs Arm A and B (51% vs 38% and 39%, respectively); 87% compared to 77% and 74%, respectively. Of note, the thalidomide therapy showed no benefit in patients with chromosome 13 deletion or those who achieved least a very good partial response to the dose-intense therapy. Additional studies of this question are in progress.

## Amyloidosis

Primary amyloidosis is a plasma cell dyscrasia in which clonal plasma cells in the marrow produce a monoclonal immunoglobulin protein. These M-protein light chains or light-chain fragments form insoluble fibrils that are deposited into the extracellular matrix of a variety of tissues, resulting in severe multi-organ dysfunction and poor patient survival. Randomized studies have shown that melphalan-based therapy can prolong the life of patients with primary amyloidosis.<sup>117</sup> Dose-intense therapy with melphalan and autologous PBSC transplantation can induce a complete hematologic remission, defined as the absence of detectable plasma-free light-chain protein.<sup>118</sup> Responders who achieve a complete disappearance of light-chain secretion are more likely to achieve reversal of underlying organ dysfunction.<sup>119</sup>

Patients frequently present with extensive systemic disease, rendering this disease difficult to treat. Regimen-related mortality is close to 20% of patients in some studies.<sup>120</sup> Multi-organ disease (particularly cardiac dysfunction) predicts a poor transplant outcome. In one study, the EFS was only 60% for patients with cardiac involvement but 100% for patients with renal involvement and no evidence of cardiac dysfunction.<sup>118</sup> Single center studies, particularly with adjustment of melphalan dose for patients with higher risk of toxicity, report a much lower mortality incidence. This suggests that the use of dose-intense therapy should be limited to centers with greater experience in the treatment of this disease.<sup>121</sup> A randomized study conducted in Europe did not find improved survival for patients treated with PBSC transplantation, but the transplant arm was characterized by a high mortality rate that could obscure the benefit of dose-intense therapy for selected patients.<sup>122</sup> As with the treatment of multiple myeloma, one group found that tandem cycles of dose-intense melphalan with autologous PBSC support improved the response rate for patients with systemic amyloidosis.<sup>123</sup> Thalidomide and lenolidamide are also effective therapies in the treatment of amyloidosis with a small proportion of patients achieving a complete hematologic response. These agents may be useful in the pre- or posttransplant management of patients with amyloidosis.<sup>124,125</sup>

## Lymphoma

The lymphomas represent a diverse group of hematologic malignancies arising from lymphoid tissues. They vary from the slowest to some of the fastest growing tumors. They also range from highly curable to essentially incurable. The lymphomas are highly responsive to chemotherapy and radiation in most cases. These tumors exhibit a strong dose-response relationship, and the benefit of high-dose treatment with autologous stem cell rescue is well established for some categories of this disease.

Several high-dose chemotherapy regimens have been developed for the treatment of the lymphomas. Radiation-based regimens including cyclophosphamide with TBI and etoposide plus TBI have significant activity but frequently are difficult to administer in patients already exposed to radiotherapy. Popular

chemotherapy regimens include cyclophosphamide, BCNU, and etoposide (CBV) and BCNU, etoposide, cytarabine, and melphalan (BEAM). However, no single chemotherapeutic regimen has emerged as a superior treatment.

### Hodgkin Disease

Many patients with Hodgkin disease will achieve durable remissions with nontransplant chemotherapy with or without radiation therapy, and algorithms for staging and treatment of this disease are well defined. Dose-intense therapy with autologous transplantation should be considered for those patients who do not achieve a remission or who relapse after initial therapy and will succumb without aggressive therapy.<sup>4,126</sup> The inclusion of dose-intense therapy as part of the initial therapy of patients with adverse-risk features is not supported in clinical studies.<sup>127</sup>

For patients who suffer a relapse after achieving CR, the prognosis with conventional salvage therapy is directly related to the duration of the initial remission. The outcome for patients whose remissions lasted less than 1 year is dismal with standard-dose second-line treatments, and most experts concur that these patients are best treated with high-dose chemotherapy with stem cell rescue. Approximately 40% to 50% of patients with Hodgkin disease who suffer a relapse within 1 year will achieve durable remissions after autologous HSC transplantation.<sup>128-130</sup> For patients whose first remission lasts more than 1 year, both conventional-dose chemotherapy and high-dose autologous stem cell therapy provide the possibility of overall survival, although HSC transplantation favors PFS.<sup>131</sup> Two randomized trials comparing high-dose chemotherapy with conventional salvage treatment have been performed.<sup>132,133</sup> These studies suggest similar overall long-term survival rates but possibly a better DFS rate for the transplant arms. The British national lymphoma trial compared high-dose BEAM-with-transplant with mini-BEAM salvage therapy. Accrual was terminated prematurely because patients refused randomization and requested the high-dose therapy. Patients who underwent autologous transplantation had statistically greater EFS and PFS rates. Overall survival rates, however, were the same in both groups in this very small trial. A second European Group for Blood and Marrow Transplantation (EBMT) trial comparing standard-dose with high-dose treatment revealed improved time to treatment failure with the autologous arm but, again, overall survival in this slightly larger trial was not yet improved. Numerous risk factors are now identified that predict lower rates if disease control after HSC transplantation is achieved in the treatment of Hodgkin disease. These risk factors include chemotherapy-resistant disease, more than minimal residual disease at the time of transplant, B symptoms at relapse, poor performance status, relapse within a prior radiation field, and high International Prognostic Factor Project score.<sup>134,135</sup>

Patients with refractory Hodgkin disease may achieve durable complete remissions with high-dose chemotherapy and stem cell rescue. Numerous series, including that from the Autologous Blood and Marrow Transplant Registry [ABMTR—now the Center for International Blood and Marrow Transplant Research

(CIBMTR)] demonstrate that high-dose treatment can overcome drug resistance in Hodgkin disease. In the ABMTR analysis, patients were considered to have primary refractory Hodgkin disease if they never achieved CR. Following transplantation, the probability of 3-year PFS was 38% with an OS rate of 50%.<sup>136</sup> Results from an EBMT Registry analysis were similar to that in the American series. The European group reported an actuarial 5-year DFS rate of 32% and an OS rate of 36% for patients with refractory Hodgkin disease.<sup>126</sup>

### Low-Grade Non-Hodgkin Lymphoma

Low-grade NHLs, in general, exhibit variable and prolonged natural courses, with many patients not requiring treatment until symptoms or organ toxicity appear. Therefore, most of the experience with HSC transplantation has been in patients after initial relapse rather than at the time of initial diagnosis, avoiding the potential for morbidity and mortality of dose-intense therapy. Multiple studies have demonstrated a greater response after dose-intense chemotherapy with autologous HSC transplantation compared to combination chemotherapy rescue regimens in the treatment of advanced or relapsed follicular lymphoma. Patients enrolled in a European Phase III randomized trial received dose-intense therapy and marrow transplantation (with or without ex-vivo purging). They benefited from a longer PFS compared to patients who were randomly assigned to the more standard-dose chemotherapy arm (55-58% vs 26%) and a significantly longer OS at 4 years (71-77% vs 46%).<sup>137</sup> The benefit of dose-intense therapy for newly diagnosed patients is less obvious. A German study enrolled 240 newly diagnosed patients with advanced follicular lymphoma in a Phase III randomized trial comparing myeloablative therapy followed by autologous HSC transplantation to combination chemotherapy with interferon.<sup>138</sup> At a median follow-up of 4.2 years, the myeloablative therapy arm was found to have a much longer 5-year PFS (65% vs 33%). However, this treatment arm also had higher acute toxicity associated with it and a higher 5-year risk of developing other hematologic malignancies such as treatment-related myelodysplasia (3.8% vs 0%). In contrast, 401 newly diagnosed patients with advanced follicular lymphoma were also studied in the GELA randomized study that compared dose-intense chemotherapy and TBI with autologous HSC transplantation to combination chemotherapy with interferon and found no significant difference in EFS or OS between the two arms after a median follow-up of 7.5 years.<sup>139</sup>

Although response rates are high, a continuing pattern of relapse has been observed with autologous transplant. One group reported a 68% CR rate for a single-center series of 100 patients with relapsed disease but, at a median of 4 years, a probability of failure-free survival of 44% with no plateau to the curve depicting probability of relapse.<sup>140</sup> The Dana-Farber transplant program reported a series of 86 patients with advanced follicular lymphoma who underwent autologous marrow transplantation as part of initial therapy. Their publication raised the question about the necessity for and efficacy of tumor cell purging.<sup>141</sup>

Patients who received marrow products that were free of disease (based on a sensitive PCR detection technique for the t14;18 abnormality commonly found in follicular non-Hodgkin lymphoma) experienced a much lower rate of relapse than similar patients whose products contained detectable tumor after purging. However, no plateau to the curve depicting probability of relapse was reported. Patients who undergo allogeneic transplantation will experience a higher probability of transplant-related mortality but a lower risk of relapse after transplantation.<sup>142</sup> The difference in relapse rates could result either from reintroduction of lymphoma cells in the HSC product or, more likely, from the lack of the powerful and beneficial graft-vs-disease effect of allogeneic HSC transplantation.

Small numbers of patients have undergone autologous HSC transplantation for aggressive non-Hodgkin lymphoma after transformation from indolent non-Hodgkin lymphoma,<sup>143,144</sup> with several reports describing improved survival for patients treated with dose-intense therapy compared to standard combination chemotherapy regimens. In patients under the age of 60 with chemotherapy-sensitive disease, the 4- to 5-year DFS and OS were reasonable (30%-52% and 37%-63%, respectively),<sup>144</sup> suggesting that this therapy should be considered for this group of patients.

### Aggressive Non-Hodgkin Lymphoma

The standard of care for patients with B-cell non-Hodgkin lymphoma in first "chemotherapy-sensitive" relapse is HSC transplantation.<sup>5,145-147</sup> The success of this therapy reflects the extent and the responsiveness of the disease to chemotherapy at the time of transplantation.<sup>148,149</sup> Relapse is the major cause of failure of autologous transplantation.

The role of high-dose chemotherapy with stem cell rescue in patients with chemotherapy-sensitive aggressive (intermediate or high-grade) lymphomas in relapse has become well established. The Parma trial randomly assigned 109 patients in first chemotherapy-sensitive relapse after two cycles of salvage chemotherapy to either high-dose therapy or four additional cycles of conventional-dose treatment.<sup>5</sup> The EFS at 5 years was superior for the group undergoing high-dose therapy compared with the group receiving standard-dose treatment (46% vs 12%,  $p = 0.001$ ). The same superiority for transplant was true of 5-year OS (53% vs 32%,  $p = 0.038$ ). Furthermore, it is notable that in the Parma trial no patients assigned to the conventional-dose salvage therapy could be rescued at the time of second relapse with a delayed transplant. Therefore, excessive pretransplant "debulking" therapy with or without delays in transplant timing should be avoided. This randomized trial confirmed previous Phase II studies and conclusively demonstrated that transplantation therapy represents the treatment of choice for most patients with chemotherapy-sensitive first-relapsed aggressive non-Hodgkin lymphoma.

Hematopoietic stem cell transplant may also be indicated for patients who respond slowly to initial therapy, have high-risk disease, are resistant to initial therapy, and are in relapse with chemotherapy-insensitive disease. The appropriate approach

for patients who achieve less than a complete response or who exhibit a slow response to conventional induction therapy is not yet clear. In one small trial of 69 slow responders to CHOP chemotherapy (cyclophosphamide, doxorubicin, and vincristine along with prednisone), the use of early transplant compared to five additional cycles of CHOP was not associated with an overall improvement in survival or EFS ( $p < 0.10$ ).<sup>150</sup>

The International Prognostic Index (IPI) identifies patients with aggressive non-Hodgkin lymphoma who have a high likelihood of relapse and poor overall survival with conventional first-line therapy.<sup>151</sup> The French LNH-87 trial examined the role of consolidation transplantation for patients in CR1 after standard-dose treatment.<sup>146,152</sup> The initial analysis of this trial demonstrated no advantage gained by the addition of intensive consolidation. However, subsequent analysis that included only those patients with intermediate or high risk by the more restrictive criteria of the IPI, revealed a superior DFS for those patients undergoing high-dose transplantation. Similarly, the Italian Non-Hodgkin Lymphoma Study Group showed no benefit from high-dose therapy with stem cell rescue in patients judged to be at high risk by virtue of tumor bulk or advanced-stage disease.<sup>153</sup> However, a striking advantage in DFS was noted when the 70 patients who qualified as high-intermediate or high risk based on the IPI were analyzed. In this subgroup, transplantation yielded a superior 6-year DFS rate (87% vs 48%,  $p = 0.008$ ). Autologous transplantation therapy is likely to be beneficial in patients with high-risk disease as measured by IPI.

Analysis of ABMTR data showed that among 184 patients who had never achieved a complete remission with conventional therapy (primarily induction failures), 44% could achieve one after autologous marrow or PBSC transplantation.<sup>154</sup> The probability of PFS 5 years after transplantation was 31%. Chemotherapy resistance, administration of multiple cycles of chemotherapy before transplantation, poor performance status at time of transplantation, older age, and the lack of use of consolidative radiotherapy before or after transplantation predicted poor outcome.

Patients with disease that is unresponsive to chemotherapy at the time of relapse have a low (about 15% to 20%) chance of achieving a long-term remission with high-dose therapy and stem cell rescue.

Mantle cell lymphoma is known for its unremitting clinical course when treated conventionally and has proven relatively resistant to high-dose treatment with autologous HSC support, especially when used as a salvage therapy.<sup>155</sup> Incorporating high-dose therapy into the initial treatment plan, however, may be more likely to provide durable remissions. At M.D. Anderson Cancer Center the results of using an intensive induction regimen followed by autologous transplantation have been encouraging.<sup>156</sup> Among previously untreated patients, the EFS rate at 3 years was 72%. Mantle cell NHL is very responsive to the graft-vs-disease effect of allogeneic transplantation, and this treatment approach should be given priority over autologous HSC transplantation.

Burkitt lymphoma, Burkitt-like lymphomas, and lymphoblastic lymphomas are eminently curable in most children. However, these high-grade non-Hodgkin lymphomas are associated with relatively poor long-term survival rates in adults. Data from the EBMT Registry suggests that disease status at the time of transplant is the most important predictor of outcome in patients with high-grade disease.<sup>149</sup> For Burkitt and Burkitt-like lymphoma, the 3-year actuarial OS rate was 72% for patients who received a transplant during CR1, compared with 37% in those with chemotherapy-sensitive relapse, and 7% in patients with disease that is unresponsive to chemotherapy. For patients with lymphoblastic lymphoma, the 6-year actuarial survival rate ranged from 63% in patients who were in first CR1 to 15% in those who had resistant disease. Patients in CR2 had an intermediate survival rate of 31% at 6 years. These results with transplantation are superior to conventional-dose salvage therapy.

### Waldenström Macroglobulinemia

Waldenström macroglobulinemia is a rare lymphoproliferative disorder characterized by the production of IgM paraprotein. Waldenström macroglobulinemia, despite the paraprotein production, is distinct in its natural history and response compared to multiple myeloma, with alkylating agents, nucleoside analogues, and rituximab all being effective in the initial treatment of this disease. Only limited numbers of patients who have undergone autologous (or allogeneic) transplantation are described in single center or registry reports but, despite this limitation, a recent workshop on the treatment of patients with this disease recommended collection of autologous HSC before extensive therapy that would limit the ability to collect adequate products.<sup>157</sup> In a Phase I/II study of autologous transplantation, seven patients (untreated or after first-line therapy) with symptomatic disease underwent two or three cycles of cytoreductive chemotherapy with collection and purging of PBSC followed by autologous transplantation after conditioning with TBI and high-dose cyclophosphamide.<sup>158</sup> Engraftment was prompt, without any procedure-related deaths. A strong reduction or normalization of the marrow infiltration and serum IgM levels occurred in all evaluable patients, but immunofixation electrophoresis revealed persistent paraproteinemia in five. A registry report of 10 patients who underwent autologous transplantation reported a PFS at 3 years of 65% with an OS of 70%.<sup>159</sup>

### Solid Tumors

Autologous transplantation for the treatment of solid tumors is less established, primarily because most malignancies do not exhibit the strong dose-response to myelosuppressive chemotherapeutic agents. Exceptions are germ cell tumors and some pediatric malignancies such as neuroblastoma.

### Breast Cancer

Breast cancer was at one point the most frequent indication for autologous HSC transplantation.<sup>160</sup> However, this treatment approach is no longer considered appropriate. The experience of

Bonadonna and others showing a dose response for this malignancy led investigators in the early 1990s to explore the use of dose-intense chemotherapy regimens for women with micrometastases involving 10 or more axillary lymph nodes and for women with inflammatory breast cancer. Peters et al<sup>161</sup> treated 102 women with high-risk ( $\geq 10$  axillary lymph nodes positive for disease) Stage IIA, IIB, IIIA, or IIIB cancer with four cycles of standard-dose CAF (cyclophosphamide, doxorubicin, fluorouracil) chemotherapy followed by high-dose STAMP-1 (cyclophosphamide, BCNU, and cisplatin) chemotherapy with autologous stem cell rescue. The actuarial EFS for the study population at 2.5 years was 72%. Comparison to three historic or concurrent Cancer and Leukemia Group B adjuvant chemotherapy trials selected for similar patients showed an EFS at 2.5 years to be between 38% and 52%. However, several randomized studies did not demonstrate a survival advantage for patients treated with dose-intense therapy compared to those treated with more standard-dose treatments.<sup>162-165</sup> Dose-intense therapy with HSC transplantation also does not appear to provide a survival advantage for women with metastatic disease.<sup>166</sup>

### Germ Cell Tumors

Germ cell cancers are relatively uncommon diseases accounting for about 1% of all malignancies in primarily adolescent and young men. Germ cell tumors, highly curable with nontransplant therapies, are classified as seminomatous or nonseminomatous tumors. Despite a propensity for metastatic spread, germ cell cancers are one of the most highly curable human malignancies. Over 60% of patients with high-risk disseminated disease will achieve durable responses after treatment with four cycles of cisplatin, etoposide, and bleomycin. Patients with refractory disease or who relapse after initial treatment can be effectively rescued with one or two cycles of dose-intense therapy.

Forty cisplatin-refractory patients were entered into a large multi-center Phase II (ECOG-sponsored) trial of carboplatin and etoposide, of whom 22 (58%) were able to proceed to a second cycle.<sup>167</sup> Five patients (13%) died of treatment-related causes including infection, hemorrhage, and hepatic veno-occlusive disease. All treatment-related deaths occurred during the first course of therapy. Nine patients (24%) achieved a complete response (including two patients after surgical resection of residual disease). Another eight patients achieved a partial response for an overall response rate of 45%. Three of the complete responses occurred after the first marrow transplant, and for four patients the partial response converted to complete response after the second marrow transplant. Five of the nine patients were alive and free of disease at a minimum follow-up of 18 months. A striking finding of this study was the poor outcome in patients with nonseminomatous primary mediastinal germ cell tumors. Eleven patients with this diagnosis were enrolled in this study and none obtained a durable complete remission.

The initial ECOG experience with multiple cycles of high-dose therapy has been replicated at single centers. The Memorial Sloan Kettering group treated 58 patients with refractory germ

cell tumors with two cycles of high-dose carboplatin, etoposide, and cisplatin. Forty percent achieved a complete response, with a 2-year survival rate of 31%. Patients with pretreatment beta human chorionic gonadotropin ( $\beta$ -hCG) values below 100 and those without retroperitoneal masses fared better.<sup>168</sup> In contrast, this same group reported that the inclusion of dose-intense therapy did not improve survival for newly diagnosed patients with poor-risk features, although there was a trend for better survival for patients not showing a rapid response to initial treatment who then received dose-intensification with HSC support.<sup>169</sup>

The Indiana University group reported 184 patients with seminomatous and nonseminomatous germ cell tumors who had progressed following cisplatin-based regimens.<sup>170</sup> Patients received one or two cycles of conventional-dose salvage, followed by one ( $n=11$ ) or two ( $n=173$ ) cycles of high-dose carboplatin and etoposide with stem cell support. At a median of 48 months of follow-up, 116 patients remain progression free, including patients with cancer refractory to standard doses of cisplatin. This very aggressive schedule resulted in one of the highest response rates noted to date.

### Ovarian Carcinoma

Autologous transplantation for the treatment of epithelial (non-germ-cell) ovarian carcinoma remains under active investigation, and promising results have been reported for some groups of women. A review of registry data for 421 patients undergoing transplantation identified a better outcome for patients with platinum-sensitive, low-bulk disease with the authors recommending prospective clinical studies.<sup>171</sup> However, one reported Phase III study that enrolled 149 previously untreated women with epithelial ovarian cancer found no differences in EFS or OS, indicating that further studies are needed.<sup>172</sup>

### Other Diseases

The improved safety of autologous PBSC transplantation encourages studies of dose-intense therapy in the treatment of nonmalignant diseases, including autoimmune disorders such as multiple sclerosis, scleroderma, systemic lupus erythematosus (SLE), Crohn disease, and refractory rheumatoid arthritis.<sup>173</sup> The hypothesis of currently ongoing studies is that dose-intense lymphoablative conditioning regimens will achieve prolonged remission or cure of these diseases by destruction of the clone of cells responsible for the disease. This hypothesis is supported by reports of remission of autoimmune diseases (eg, rheumatoid arthritis, SLE) that existed as a comorbid condition for patients undergoing autologous or allogeneic transplantation,<sup>174,175</sup> although this has not been a universal finding.<sup>176</sup> The use of intensive chemoradiotherapy with HSC rescue offers an opportunity to deliver maximally tolerated immunosuppression. Factors that may influence the relative efficacy of this approach include the number and relative resistance to ablation of the responsible lymphoid effector populations and the nature and persistence of the relevant antigen against which the immune response is raised. Although lymphoid effectors are not well defined for

these diseases, evidence points to the involvement of T and B lymphocytes. High-dose therapy followed by autologous HSC transplantation may allow the immune system to “reset” with control of the autoreactive lymphocytes. As with the treatment of malignant diseases, depletion of the unwanted lymphoid cell population from the HSC inoculum (purging) might be necessary for optimal clinical outcome. These nonmalignant diseases are debilitating, and appropriate patient selection is necessary so that the risks (morbidity and mortality) are appropriately balanced against the benefits (possibly, lack of progression instead of reversal of damage already incurred) of this therapy.

Multiple centers have now published their experiences in the treatment of small numbers of patients indicating that this treatment may be effective in controlling autoimmune diseases in certain patient populations. Burt et al<sup>177</sup> recently reported 50 patients who received a nonmyeloablative conditioning regimen of high-dose cyclophosphamide and equine antithymocyte globulin with autologous PBSC support in the treatment of SLE. The treatment-related mortality was 4% (2/50; one death occurring after mobilization of PBSC and one after transplantation), but the probability of 5-year OS was 84%, and the probability of DFS was 50%. These patients also demonstrated stabilization of renal and pulmonary functions and significant improvement or stabilization in markers of disease activity. Similarly, 73 patients were identified from registry data as having received autologous HSC transplantation for the treatment of rheumatoid arthritis, with 49 patients (67%) achieving at least a 50% response at some point after transplantation. There was a significant reduction in the level of disability. Most patients restarted other therapies within 6 months for persistent or recurrent disease activity. This provided disease control in about half the cases, suggesting that the transplant may have ameliorated the disease.<sup>178</sup> These publications set the stage for larger Phase II and III clinical studies to determine proper patient selection and choice of treatment strategies.

---

## Summary

Autologous HSC transplantation with dose-intense therapy is now a standard treatment for many diseases. Improved safety of this therapy has increased acceptance by patients and allowed its extension to older patients and those with comorbid diseases. The major failing is the difficulty in curing patients with advanced or refractory diseases. Older patients face a higher risk of relapse that appears to be a result of differing sensitivity of their diseases to dose-intense therapy. This suggests the need for a different approach based on age. Posttransplant immunologic approaches now being studied may, however, be able to convert the minimal disease remaining after transplantation into a cure. Continued effort will determine if modifications of pretransplant conditioning regimens, choice of HSC source, ex-vivo processing, or supplementation of the cell inoculum with other myeloid or lymphoid cells affects engraftment kinetics or immunologic

reconstitution, and thereby enhances the therapeutic value of autologous transplantation for patients with malignant and non-malignant diseases.

# Hematopoietic Progenitor Cells: Allogeneic Transplantation

**Amin M. Alousi<sup>1</sup> & Sergio A. Giral<sup>2</sup>**

<sup>1</sup>Assistant Professor, Stem Cell Transplantation, The University of Texas M.D. Anderson Cancer Center, Houston, Texas, USA

<sup>2</sup>Professor, Stem Cell Transplantation and Lymphoma/Myeloma, The University of Texas M.D. Anderson Cancer Center, Houston, Texas, USA

In 1957 Thomas and colleagues published the first reported attempts at marrow transplantation in six patients with advanced malignancies who were given marrow after receiving limited doses of chemo- or radiotherapy.<sup>1</sup> For the next decade this therapy was limited to patients with terminal leukemia or severe marrow failure resulting from radiation exposure or disease. Although these first efforts provided groundwork for later animal and human studies, success was minimal with almost all of these early patients dying from complications of graft failure, graft-vs-host disease (GVHD), infections, or their primary disease. It was not until 1968 that the first successful allogeneic marrow transplant was reported, in a patient with severe combined immunodeficiency.<sup>2</sup> As a result of the pioneering work of Thomas and colleagues, the number of allogeneic transplants began to increase dramatically over the next decades into the established specialty it is today.<sup>3,4</sup> This chapter provides a brief overview of hematopoietic stem cell transplantation (HSCT) including the types of transplants, key procedural elements, donor sources, disease indications, and potential complications.

## Hematopoietic Stem Cell Transplantation

HSCT can be divided into three main types: 1) autologous transplantation, in which a patient serves as a self-donor, 2) syngeneic transplantation wherein the donor is a genetically identical twin, and 3) allogeneic transplantation wherein the donor is genetically different from the recipient. Marrow transplantation was initially conceived as a means for allowing hematopoietic recovery following the administration of dose-intensive chemo- and radiotherapy for treatment of malignancies. For autologous and syngeneic transplants, the therapeutic role remains hematopoietic cellular rescue following high-dose therapies. In comparison, for allogeneic

transplants, the infused cells result in an additional therapeutic potential arising from a powerful donor immune-mediated response against the host malignancy, a phenomenon referred to as graft-vs-tumor (GVT) effect. Numerous lines of evidence support the therapeutic potential in the GVT effect and are detailed in Table 35-1.<sup>5-10</sup> Although a GVT benefit does not occur with autologous transplants, these types of grafts are associated with less risk because the infused cells will not be immunologically rejected or mediate an immunologic reaction. In comparison, allogeneic transplants have a greater rate of complications because of the potential for graft rejection, or more commonly, GVHD.

### Procedure Fundamentals: Autologous Transplantation

Autologous transplantation is a strategy in which high-dose therapy is administered to patients with a malignancy known to be dose-responsive. In order to receive an autologous HSCT, the patient must first undergo stem cell collection, followed by cryopreservation and storage of the marrow or peripheral blood progenitor cells (PBPCs). Once marrow or PBPCs are successfully collected, the patient can receive intensive myeloablative chemo- or radiotherapy (or both), followed by infusion of the previously

**Table 35-1.** Evidence Substantiating a Graft-vs-Tumor Effect

1. Relapse is lower in allogeneic transplants when compared to autologous or syngeneic transplants.
2. T-lymphocyte-depleted transplants have a higher incidence of relapse when compared to T-lymphocyte-replete transplants.
3. Relapse rates are inversely associated with acute graft-vs-host disease (GVHD) incidence and severity.
4. Relapse rates inversely associated with incidence of chronic GVHD.
5. Delayed clearance of minimal residual disease following allogeneic transplantation (beyond the timeframe in which it could be attributed to cytotoxic therapy administered with the conditioning regimen).
6. Induction of remission following withdrawal of immunosuppression after transplantation in a minority of cases.
7. Induction of remission following infusion of donor lymphocytes.

cryopreserved cells to restore hematopoiesis. Autologous HSCT is discussed thoroughly in Chapter 34. Its brief description here is for ease of comparison with allogeneic transplantation.

### Progenitor Cell Collection

Ideally, the collection process should occur at a time when the marrow has normal cellularity and a limited number of malignant cells. The resting marrow contains both hematopoietic stem cells (HSCs) and hematopoietic progenitor cells (HPCs). HSCs are defined as clonal precursor cells that are capable of self-renewal as well as giving rise to a defined set of differentiated progeny. HPCs lack the ability for self-renewal but, similar to HSCs, have the ability to differentiate and proliferate.<sup>11,12</sup> The ability of the stored product to engraft depends on the presence of both types of cells. This chapter collectively refers to these cells as HPCs, which can be identified by the cell expression of CD34 and Thy-1 and the absence of Lin and CD38 cell markers.<sup>11,13</sup>

Historically, HPCs capable of reconstituting hematopoiesis were collected through harvesting the marrow via multiple aspirations from sites such as the ilium. More commonly today, HPCs are collected from the peripheral blood by leukapheresis. In this procedure, the normally low levels of circulating HPCs are increased through the use of hematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) alone or in combination with mobilizing doses of cytoreductive chemotherapy (termed chemomobilization).<sup>14,15</sup> Chemomobilization strategies generally result in a higher yield of HPCs when compared to strategies using hematopoietic growth factors alone.<sup>16</sup> PBPC collections have now largely replaced marrow harvesting procedures because of the ease and safety (sparing the need for general anesthesia) of the procedure. In addition, PBPC transplantation results in quicker recovery of granulocytes and platelets than does marrow transplantation.<sup>17</sup> Quantification of CD34-expressing cells in the PBPCs is often performed to assess the probability of successful reconstitution of hematopoiesis upon infusion.<sup>18</sup> Threshold levels resulting in timely neutrophil and platelet recovery range from 3 to  $5 \times 10^6$  CD34+ cells/kg body weight.<sup>19</sup>

### Preparative Regimens

The combination of chemo-, radio-, and biologic therapies in preparation for HSCT is referred to as a preparative (or conditioning) regimen. The sole role of the preparative regimen in the autologous transplant setting is eradication of any residual cancer. High-dose therapy is employed to overcome tumor resistance. In addition, the combination of chemotherapies may provide a way to act on different targets within cancer cells.<sup>20</sup> Creation of regimens is generally based on the principles of minimizing overlapping toxicity and mechanisms of resistance. Dose escalation achievable with the combination regimens is usually less than with each drug alone. Candidate drugs for incorporation into preparative regimens are those agents with a steep dose-response curve and myelosuppression as their dose-limiting toxicity. However, dose escalation is not feasible when

extramedullary toxicity occurs at lower doses or at the same dose levels as myelosuppression. For this reason, alkylating agents are commonly employed. For instance, the dose of thiopeta can be escalated significantly with stem cell support.<sup>21,22</sup> Conversely, adriamycin is seldom used because the mucositis and cardiac toxicity associated with dose escalation of this drug cannot be overcome by the use of HPCs.

Numerous conditioning regimens have been evaluated for various diseases with choice of regimens often based on the preference and experience of the clinician. High-dose chemoradiation therapy for multiple myeloma and lymphoma, two of the most common indications for autologous transplantation, is reviewed later in this chapter. Recently, the addition of newer “targeted” therapies to conditioning regimens has been explored as a way of increasing efficacy and minimizing toxicity. Monoclonal antibodies and radioconjugates for B-cell lymphomas and certain leukemias are examples of newer therapies that have been added safely to conditioning regimens and may offer additional therapeutic benefit with little or no increase in toxicity.<sup>23,24</sup>

Autologous transplantation is a relatively safe procedure with minimal treatment-related mortality. There is no specific age cut-off for the procedure, and patients well into their seventh and eighth decades of life safely undergo the therapy.<sup>25,26</sup> Specific disease indications and complications are discussed later in the chapter.

---

## Allogeneic Transplantation

The most obvious difference between autologous and allogeneic HSCT is the need for a donor in the latter. Historically, most allografts used marrow cells obtained from an HLA-matched sibling. However, many potential candidates for this therapy lack a matched sibling donor and transplant procedures using cells obtained from volunteer unrelated donors, mismatched family members, and cord blood are becoming more common. HLA compatibility is the strongest predictor for the occurrence of severe GVHD and is the single most important factor to consider in selecting an allogeneic donor.<sup>27</sup>

The major histocompatibility complex (MHC) is located at p21.3 on the short arm of chromosome 6, where several closely linked genes referred to as the HLA system are located.<sup>28</sup> These genes have been subdivided into Class I loci, which includes HLA-A, -B, and -C, and Class II loci, which includes HLA-DR, -DQ, and -DP. For HSCT, HLA-A, HLA-B, and HLA-DR are routinely evaluated.<sup>29,30</sup> Matching at HLA-C has been confirmed to have an impact on outcome.<sup>27</sup> In its strictest sense, HLA identity means that the donor and recipient are matched for the amino acid sequence encoded by all HLA loci. It is important to note that conventional typing techniques detect a limited number of HLA polymorphic sequences. Therefore, “HLA matched” may not be “HLA identical.” HLA genotypically identical siblings inherit the same MHC haplotypes and, therefore,

are also identical for other non-HLA genes and polymorphisms that are carried on those haplotypes. This is unlike the case for unrelated donors and patients who, although matched for Class I and II alleles, may not necessarily be identical for non-HLA polymorphisms. However, to date studies have not been able to substantiate an effect on outcome for mismatching at any of the known microsatellite polymorphic regions tested.<sup>31</sup>

Conventional serologic typing is based on the complement-dependent microlymphocytotoxicity test and uses selected HLA-specific alloantisera or monoclonal antibodies to identify HLA antigens.<sup>32</sup> Mismatching between cross-reactive antigens is considered a minor mismatch, whereas mismatching between non-cross-reactive antigens is considered a major mismatch. For related patient-donor pairs, a single minor mismatch may be of little biological significance. Molecular typing relies on polymerase chain reaction (PCR) amplification of specific gene segments and can be performed 1) at a level corresponding to the specificities identified by serology (low resolution), 2) at a level where a limited number of alleles are possible (intermediate resolution), or 3) at a level where the specific allele is identified (high resolution). Sequence-based HLA typing is the most precise technique available. Improvement in typing techniques through high-resolution molecular typing has had a profound impact in reducing the risks of immunologic complications with unrelated allogeneic transplantation.<sup>33</sup> This is highlighted by studies finding that just over 50% of donor-patient pairs typed by conventional serologic typing are found to be matched at the allele level when retrospectively typed using high-resolution techniques. This translated into higher probabilities of severe acute GVHD and transplant-related mortality, as well as lower survival in those retrospectively identified allele-mismatched patients.<sup>34</sup> The fact that immunologic complications (GVHD) often develop even among HLA genotypically identical siblings suggests that this system is not the only mediator of immunologic complications following allogeneic transplantation. In HLA-matched transplants, GVHD is felt to result from mismatching of poorly defined minor histocompatibility antigens. The only easily identified minor histocompatibility antigen is the HY antigen.<sup>35</sup> The chance of mismatching for these minor antigens should increase with increasing distance in the relationship between donor and recipient.<sup>36</sup>

### Donor Factors

Efforts to identify a donor is a lengthy process and must be carried out as soon as a patient has been referred, often before a definitive decision related to transplantation has been made. Usually all potential sibling donors are typed first and if no compatible donors are identified, an unrelated donor search is performed. Because of the shrinking size of households, the frequency of unrelated donor transplant is becoming more common and is currently estimated to account for one third of all allogeneic transplants.<sup>37</sup> To help facilitate this process, registries containing HLA-typed potential adult donors were created. The largest of these registries is the National Marrow Donor

Program (NMDP), which was established in 1986 to facilitate donor enrollment as well as the donor search process. There are more than 7.5 million individuals listed on these registries with approximately 800,000 new volunteers added annually.<sup>38</sup>

Since the early 1990s the use of PBPCs has become increasingly common and now constitutes the most common HPC source. The rationale for using PBPCs is derived from studies in the autologous setting that demonstrated accelerated recovery of hematopoiesis when compared to traditional marrow transplantation.<sup>39-40</sup> For donors, this has eliminated the risks and morbidity associated with general anesthesia and marrow harvest. Recombinant growth factors such as G-CSF are used to mobilize HPCs into the peripheral blood where they may be collected through one or more leukapheresis procedures. In addition to the benefits to the donor, PBPC transplantation offers a number of advantages to the recipient. G-CSF-mobilized PBPCs contain more HPCs than marrow grafts.<sup>41</sup> This has shortened the duration of absolute neutropenia and thrombocytopenia in recipients by approximately 4 to 8 days.<sup>41,42</sup> Donor T cells are found in much higher concentration in PBPC grafts and help to facilitate engraftment especially after less dose-intensive preparative regimens. The presence of higher numbers of T cells initially raised the concern for greater frequency and severity of GVHD; however, many large studies have shown that the risk of severe acute GVHD using PBPC grafts does not exceed the risk seen in traditional marrow grafts.<sup>43,44</sup> The incidence of chronic GVHD in patients receiving PBPC grafts has tended to be higher than those receiving marrow grafts. Thus, longer follow-up will be needed before it is safe to conclude that these two sources are comparable.<sup>45,46</sup>

Only a fraction of patients will have a fully matched unrelated donor identified despite the growing number of typed volunteers on worldwide registries. Populations of European ancestry have an approximately 50% chance of identifying a matched unrelated donor, whereas ethnic or mixed communities have as low as a 10% chance.<sup>47</sup> This disparity is largely the result of the increased polymorphisms with respect to HLA seen in certain minority groups.<sup>48</sup> For this reason, alternative donor transplants are an area of active research.

Umbilical cord blood (UCB) offers another source of hematopoietic stem cells for use in allogeneic transplantation. UCB transplants have increased the available donor pool because of the reduced need for HLA compatibility between the donor and recipient. In addition, UCB has shortened the time it takes to secure a donor, because the cells are readily available and do not require delays in the collection process. One review found that 19% of patients who did not have a potential HLA-matched unrelated donor were able to find a UCB unit matched at four of six HLA antigens. This same analysis found that the median time from search to clearance of an unrelated donor was 49 days; securing UCB units took just 13.5 days.<sup>49</sup> Because the number of cells required for successful engraftment is dependent on recipient size, a limiting factor for this form of transplant is the low number of HPCs in a unit of cord blood. Recent registry

analysis<sup>50</sup> evaluating outcomes for UCB transplantation in pediatric patients with leukemia found similar leukemia-free survival for one- or two-antigen mismatch UCB transplants when compared to HLA-matched unrelated transplants. This study found similar rates for acute GVHD between the mismatched UCB transplant and unrelated donor transplant recipients. Treatment-related mortality was higher in two-antigen mismatch UCB when compared to one-antigen UCB or matched unrelated donor recipients. In addition, patients who had a low-cell dose, one- or two-antigen mismatch UCB transplant had higher transplant-related mortality than those receiving a matched, unrelated donor transplant. Median time to neutrophil and platelet engraftment were higher following one- to two-antigen mismatched UCB transplants when compared to unrelated marrow recipients.<sup>50</sup>

Retrospective studies in adults have confirmed a low rate of acute GVHD when comparing one-antigen and two-antigen mismatch UCB transplants to one-antigen mismatch unrelated marrow recipients but most have demonstrated inferior outcomes when compared with matched unrelated donor recipients. These studies also confirmed a higher graft failure rate and treatment-related mortality for UCB transplants in adults when compared to matched unrelated donor transplants and lower leukemia-free survival.<sup>51</sup> Nonetheless, UCB transplants are a feasible option for adults who do not have a related or unrelated, matched donor and strategies for improving engraftment are an active area of research.

Haploidentical transplants offer another option when a matched sibling or unrelated donor cannot be identified. The advantage of these transplants is that parents, children, or half-matched siblings can serve as a donor. These forms of transplants call for highly selecting the collected product for CD34+ HPCs in an effort to minimize the amount of T cells in the final infusion. In this way, the risk for GVHD (which would otherwise be universal with transplants from haploidentical donors) is reduced. In addition, the conditioning regimen often includes antibodies directing against T cells. While these efforts reduce the risk for GHVD, delayed immune reconstitution occurs, resulting in a high risk for infectious complications.<sup>47,52</sup>

### Recipient Factors

It is estimated that over 20,000 allogeneic transplant procedures have been performed worldwide for a variety of malignant and nonmalignant disorders.<sup>53</sup> The International Bone Marrow Transplant Registry (IBMTR), an invaluable resource that collects data from more than 400 centers worldwide, allows transplant physicians to see current transplant trends, compare outcomes of different transplant strategies, and conduct retrospective and prospective studies in HSCT. According to data submitted to the IBMTR, the following trends have been noted: Currently the most common diagnoses for which allogeneic progenitor cell transplantation is being performed are acute myelogenous leukemia (AML), acute lymphocytic leukemia (ALL), chronic myelogenous leukemia (CML), and

**Figure 35-1.** The proportion of older recipients of allogeneic transplants for AML, ALL, CML [as reported to the Center for International Blood and Marrow Transplant Research ([www.cibmtr.org](http://www.cibmtr.org))] is increasing.

**Figure 35-2.** The proportion of allogeneic transplants performed using reduced-intensity conditioning is increasing [data incomplete for 2004; provided by the Center for International Blood and Marrow Transplant Research ([www.cibmtr.org](http://www.cibmtr.org))].

myelodysplastic syndromes (MDS) (in decreasing order). The indications for transplantation have changed over time; eg, CML is no longer the most commonly transplanted hematologic malignancy because of the advent of imatinib. Likewise, the average age of transplant recipients has increased over time. The proportion of patients receiving allografts over the age of 50 years is approaching 15%. Paralleling the increasing age of recipients has been the use of less-intense conditioning regimens (Figs 35-1 and 35-2).<sup>37</sup>

Numerous recipient factors determine the outcome following transplantation and include the disease stage at transplantation, recipient age, performance status, and presence of comorbidities. Apart from poor performance status, there is no one factor that precludes allografting in an individual patient. Instead, the decision to undertake transplantation depends on a careful assessment and discussion of the risks and benefits of the procedure when contrasted with the natural history of the disease. All potential transplant recipients undergo an extensive pretransplant evaluation that usually includes a complete history and physical examination in addition to evaluation of cardiac, pulmonary, hepatic, and renal function.

## Preparative Regimens

In allogeneic transplantation, the preparative regimen serves two main purposes: eradicating the underlying malignancy and inducing a state of immune tolerance to allow for the donor cells to engraft and expand. Generally speaking, efforts to decrease relapse through intensification of the preparative regimen have come at the expense of increased treatment-related mortality. As in autologous transplantation, there is no one standard preparative regimen in the setting of allogeneic transplantation. Allogeneic transplant conditioning regimens can generally be divided into chemotherapy-based protocols or total body irradiation (TBI)-based protocols.

TBI provides both immunosuppressive and myeloablative effects. The use of fractionated regimens and organ-shielding has lowered the toxicity.<sup>54-57</sup> Most modern regimens deliver a total dose of 1000 cGy to 1500 cGy using a variety of fractionation schedules. Although there is some evidence that further escalation of the total dose of TBI is more effective at preventing relapse, these benefits have been offset by increased nonrelapse mortality.<sup>58,59</sup> TBI is most often combined with high-dose cyclophosphamide (Cy), a potent immunosuppressive agent.<sup>60</sup> Other chemotherapy regimens with demonstrated efficacy in conjunction with TBI included etoposide either alone or together with Cy. Efficacy appears similar between these regimens with the combination of etoposide and Cy showing increased toxicity in patients with advanced disease.<sup>61,62</sup> TBI-based regimens are still commonly used in all disease states; however, it remains the most favored transplant regimen for patients with ALL (often combined with etoposide).<sup>63</sup> Although efficacious, TBI is associated with a number of short- and long-term complications including secondary malignancies, cataracts, and endocrine dysfunction.<sup>64</sup>

The creation of non-TBI-containing regimens developed out of a wish to decrease the above-mentioned long-term toxicities as well as expand this therapy to centers without dedicated radiotherapists. The most extensively studied regimen was one created by Santos in the early 1980s<sup>65</sup> and later modified by Tutschka.<sup>66</sup> Santos' original regimen replaced TBI with busulfan (Bu) at a dose of 16 mg/kg divided orally every 6 hours over 4 days combined with Cy 200 mg/kg divided in four daily doses (BuCy4). This regimen was found to be too toxic with a high rate of early transplant-related mortality and was later modified to the BuCy2 regimen with a decrease in the dose of Cy to 60 mg/kg for 2 days. This regimen remains in wide use today for various malignancies in both allogeneic and autologous transplantation. The safety and efficacy of the BuCy2 regimen when compared to TBI-Cy has been extensively evaluated in multiple, randomized studies.<sup>67-71</sup> Most of these studies showed comparable outcomes for these two regimens; however, a few demonstrated superiority of the TBI-containing regimens especially for those AML and ALL patients with advanced disease. With these exceptions there currently are no data that confirm the superiority of one specific regimen over another. Recent modifications to the BuCy2 regimen with pharmacokinetic (PK)-guided dosing of Bu and/or an intravenous (IV) formulation probably eliminate any small

advantage in the TBI-Cy regimen that has thus far been inconsistently demonstrated.

The dose-limiting side effect of oral Bu is hepatotoxicity with veno-occlusive disease (VOD) of the liver a major limitation of the BuCy2 regimen. It has been well documented that oral dosing of Bu results in frequent variability in inter- and inpatient steady-state drug concentrations.<sup>72-76</sup> Elevated levels of Bu in the blood have been shown to result in higher incidences of VOD of the liver,<sup>77</sup> while low doses may be associated with relapse (in CML)<sup>78</sup> and nonengraftment.<sup>79-82</sup> It has been hypothesized that by reducing this variability, results with Bu-containing regimens might be improved. PK-guided oral dosing followed by administration of an IV formulation of the drug has been evaluated.

The need for PK-guided Bu dosing is strongest in pediatric transplantation where the variability of oral dosing is most pronounced. This is especially true for patients less than 4 years of age who have increased clearance of the drug when administered orally because of a higher conjugation rate with glutathione in the hepatocyte.<sup>83</sup> Bolinger et al<sup>84</sup> performed one of the earliest trials evaluating targeted-dosed Bu in pediatric patients undergoing allogeneic transplantation. In this study, adjustment from standard dosing was required in a majority of the patients to achieve the target steady-state concentration. By so doing, 30 of 32 (94%) patients successfully achieved the target concentration. This strategy improved the rate of engraftment when compared to a historical group of patients who received standard-dosed Bu. Similar results were shown by Bleyzac et al<sup>85</sup> who were also able to document lower incidences of VOD of the liver when compared to historical controls. PK-guided strategies have also been shown to be feasible and result in low treatment-related mortality in adult patients receiving oral Bu regimens.<sup>86,87</sup>

In 1996, a patent was filed for an IV formulation of Bu. In 2000, researchers at M.D. Anderson Cancer Center performed a safety and feasibility study of the IV formulation and determined the bioequivalent dose.<sup>88</sup> Phase II studies performed with the IV formulation have determined a lower incidence of VOD of the liver, death from VOD, and treatment-related mortality when retrospectively compared to patients treated during the same period who received the standard oral BuCy2 regimen.<sup>89-93</sup> However, questions related to whether IV Bu is superior to oral Bu, whether PK-guided dosing of the IV formulation is needed, and whether oral PK-guided doses are equivalent to the IV formulation remain unanswered in the absence of randomized studies.

Additional modifications to the BuCy regimen have stemmed from reports determining that Cy and its metabolites contribute not only to the development of hemorrhagic cystitis after transplantation but also to the liver toxicity of the preparative regimen.<sup>94</sup> Therefore, fludarabine has replaced Cy in many modern myeloablative regimens. Initial studies with the combination of fludarabine and Bu have produced high engraftment rates with low levels of toxicity.<sup>95,96</sup>

## Reduced-Intensity Conditioning Regimens

Traditionally, allogeneic transplantation has been limited to younger patients because of toxicity related to the intensive

**Table 35-2.** Examples of Reduced-Intensity Conditioning Regimens

1. Total body irradiation at doses  $\leq 500$  cGy
2. Total busulfan dose  $\leq 9$  mg/kg
3. Total melphalan dose  $\leq 140$  mg/m<sup>2</sup>
4. Regimen includes a purine analog—fludarabine, cladribine, or pentostatin

**Table 35-3.** Most Commonly Used Reduced-Intensity Conditioning Regimens

1. Low-dose total body irradiation (200 cGy)  $\pm$  fludarabine
2. Busulfan + fludarabine  $\pm$  others
3. Fludarabine + cyclophosphamide  $\pm$  others
4. Fludarabine + melphalan  $\pm$  others
5. Fludarabine  $\pm$  others

conditioning regimens. Unfortunately, the cancers for which this therapy is most commonly prescribed occur in older adults. Reduced-intensity conditioning regimens employ lower doses of chemo- or radiotherapy to allow for engraftment and rely on the GVT effect to prevent relapse. As a result, patients who traditionally were felt to be too old for allogeneic transplant or who suffer comorbidities that previously would have precluded them can now safely undergo this therapy. There is no one standard reduced-intensity regimen, with commonly used regimens differing in the degree of intensity administered. Some regimens employ the same agents used in full-intensity regimens, but at reduced doses. On the other end of the spectrum are regimens that provide minimal cytotoxic agents and instead rely on immunosuppressive treatments to allow donor engraftment. Agreed-upon definitions of reduced-intensity regimens as well as commonly employed agents used are listed in Tables 35-2<sup>97</sup> and 35-3.<sup>98</sup>

### Potential Complications of Dose-Intensive Therapy Followed by HSCT

The potential risks resulting from high-dose chemoradiotherapy and blood and marrow transplantation are numerous and include toxicity from the preparative regimen, infections resulting from granulocytopenia or posttransplant immunodeficiency, hemorrhage caused by thrombocytopenia and tissue toxicity, and, in the case of allogeneic transplants, transplant rejection and GVHD.

The creation of better supportive medications has minimized many of the acute toxicities associated with high-dose chemoradiotherapy regimens. This includes the incorporation of selective type three 5-hydroxytryptamine (5-HT<sub>3</sub>) receptor antagonists, which has decreased the incidence of severe treatment-related nausea.<sup>99</sup> The addition of palifermin (recombinant human keratinocyte growth factor) and mesna (2-mercaptoethane sodium sulfonate) have been shown to reduce the incidence of severe radiation-induced mucositis<sup>100</sup>

and chemotherapy-induced cystitis,<sup>101</sup> respectively. The risk for serious organ toxicities and infections are detailed below. Generally accepted mortality rates associated with autologous transplants are approximately 5%, whereas allogeneic transplant recipients have a 10% to 50% risk for transplant-related death depending on host factors, including age, comorbidities, disease stage, baseline toxicities, and donor factors (namely, matching).

### Myelosuppression

Shortly after infusion, HPCs migrate to sites in the lungs, liver, spleen, and marrow. For most patients, some degree of marrow cellularity can be demonstrated within 14 days of transplantation. Neutrophil and platelet engraftment is defined as being the first of three consecutive days in which the absolute neutrophil count is  $>500/\mu\text{L}$  and the platelet count is  $>20,000/\mu\text{L}$  (without transfusion support), respectively. This generally occurs 14 to 24 days after stem cell infusion, with longer time to engraftment in cord blood transplants. Before engraftment, patients require aggressive hematologic support with transfusion of platelets and red cells. Blood components must be irradiated to minimize the possibility of graft-vs-host reactions mediated by blood donor T cells.<sup>102</sup> For patients experiencing prolonged cytopenias, growth factors may be used to shorten the duration of aplasia without increasing the risk of GVHD or relapse.<sup>103,104</sup> In the allogeneic setting, engraftment of donor cells can be documented by use of molecular tests such as DNA restriction fragment length polymorphisms, or by PCR of microsatellite regions demonstrating a donor pattern. Following successful transplantation, cells of the recipient's reconstituted hematologic and immunologic systems are derived primarily from the donor's blood or marrow, although in some cases mixed chimerism occurs in which both donor- and recipient-derived cells are present in the recipient's circulation and marrow.<sup>105</sup>

### Graft Failure

The failure to recover hematologic function or the loss of marrow function after initial reconstitution constitutes graft failure. Graft failure is an unusual event for autologous transplant recipients but can occur in 5% to 11% of HLA-identical allogeneic recipients.<sup>106</sup> Graft failure generally takes place within 60 days of transplantation although late graft failure has been known to occur.<sup>107</sup> Several factors are known to increase the risk of graft failure in allogeneic transplantation, including a low nucleated cell count infused, increasing HLA disparity between donor and host, T-cell depleted grafts, and inadequate immunosuppression of the host. Historical graft failure rates were as high as 35% in patients undergoing transplantation for aplastic anemia, which was felt to be caused in large part by alloimmunization from prior transfusions. This has now been reduced to  $<10\%$  for patients with aplastic anemia through the minimizing of pre-transplant transfusions and administration of leukocyte-reduced, irradiated blood components.<sup>108</sup> Evidence now exists implicating host T cells as the mediators of an active host immune response against minor alloantigens expressed by the donor cells. On the

basis of this understanding, several strategies to further eliminate or inactivate host T cells have evolved, including the use of additional or increased intensity immunosuppressive agents such as fludarabine or the elimination of host T cells through the use of antithymocyte globulin (ATG) or anti-CD52.<sup>109-111</sup> Treatment of graft failure depends on whether donor cells can be detected in the patient's marrow. If present, a repeat infusion of donor cells can be attempted with or without further conditioning. When no donor hematopoietic cells are detected, a second conditioning regimen may be administered followed by donor stem cells; however, outcomes in this setting are extremely poor.<sup>112</sup>

Graft-vs-Host Disease

GVHD represents one of the most frequent complications of allogeneic transplantation and has been the major barrier to wide-scale application of this therapy. GVHD results from the recognition of host tissues as foreign by donor immunocompetent cells. The incidence increases with greater HLA disparity between the donor and host. A fundamental problem for allogeneic transplantation is the close association between this complication and the derived benefit resulting from a GVT effect. Both GVHD and GVT effect are mediated by donor T cells with both being reduced when T cells are depleted from the infused graft (referred to as T-cell-depleted transplants). Identifying and separating the target antigens resulting in GVHD and GVT effect are active areas of research that may one day result in maximizing the therapeutic potential of this modality while eliminating this frequent obstacle.<sup>113</sup>

Two forms of GVHD are commonly distinguished: acute and chronic. Historically, acute GVHD was defined as occurring within the first 100 days of transplant and chronic GVHD was defined as occurring after the 100-day mark. It is now clear that this time point was an artificial one and clinical manifestation and histologic findings are now the sole factors used in defining these distinct entities.<sup>114</sup>

The incidence of acute GVHD varies from 20% to 70%, depending upon the intensity of the conditioning regimen, the extent of histocompatibility differences with the donor, the age of the recipient, and the stage of primary disease.<sup>115-120</sup> Acute GVHD is graded clinically using a standardized system that takes into account clinical changes in the primarily affected organs: skin, liver, and gastrointestinal tract. This grading system allows for quantitative estimates of disease severity and response to therapy with scoring consisting of Grades I to IV (Table 35-4).<sup>121</sup> These clinical findings are usually confirmed by pathologic changes in the affected organs, although the pathologic findings do not change the grading or staging of the disease. Corticosteroids remain the standard initial treatment, but even with prompt initiation of such therapy, the treatment is suboptimal. Fewer than 50% of patients with acute GVHD have a durable response after initial therapy; most patients require secondary treatment.<sup>122,123</sup> Attempts to improve the complete response rate by adding additional therapies to corticosteroids or by using higher doses have been unsuccessful.<sup>124,125</sup> Moreover, the outcome for patients with steroid-refractory GVHD is poor, with a mortality rate of 70%; at this time, no therapy has been shown to affect survival.<sup>126</sup> The causes of death among patients with advanced GVHD include organ failure and infections related to poor immune reconstitution. For these reasons, improving prophylaxis has been the preferred strategy.

The prophylactic use of cyclosporine (CSA) and methotrexate (MTX) are effective prophylaxis for acute GVHD and have been shown to improve survival.<sup>115</sup> Corticosteroids have also been successfully used in combination with CSA for GVHD prophylaxis; however, the addition of prednisone to CSA and MTX has been shown not to add additional benefit.<sup>127</sup>

CSA is a cyclic polypeptide that prevents T-cell activation by inhibiting interleukin-2 production and expression. Although effective as GVHD prophylaxis, CSA has significant toxicities including hypertension, nephrotoxicity, hypomagnesemia, risks

Table 35-4. Organ Stages of Acute GVHD

| Organ Stage | Organ                                                            |                           |                                                                                      |
|-------------|------------------------------------------------------------------|---------------------------|--------------------------------------------------------------------------------------|
|             | Skin (body surface area)                                         | Liver (mg/dL bilirubin)   | Gastrointestinal Tract (24-hour stool output)                                        |
| 0           | No rash                                                          | <2.0                      | <500 mL or <280 mL/m <sup>2</sup>                                                    |
| I           | Rash <25% or 25% to <50%                                         | <2.0                      | <500 mL or <280 mL/m <sup>2</sup>                                                    |
| II          | ≥50% or generalized erythroderma                                 | 2.1 to 3.0                | 501 to 1000 mL or 280 to 555 mL/m <sup>2</sup> or persistent nausea and/or vomiting  |
| III         |                                                                  | 3.1 to 6.0 or 6.1 to 15.0 | 1001 to 1500 mL or 556 to 833 mL/m <sup>2</sup> or >1501 mL or 833 mL/m <sup>2</sup> |
| IV          | Generalized erythroderma with bullous formation and desquamation | >15.1                     | >1501 mL or 833 mL/m <sup>2</sup> with severe abdominal pain and ileus               |

for seizures, hypertrichosis, gingival hyperplasia, tremors, and anorexia.<sup>128</sup> Typically CSA is initiated intravenously 1 to 2 days before stem cell infusion and converted to oral dosing when possible. The risk of acute GVHD increases when cyclosporine concentrations in blood drop below a target level.<sup>129</sup>

Tacrolimus is a macrolide lactone that closely resembles CSA in mechanism of action, spectrum of toxicities, and pharmacologic interactions. In a randomized study,<sup>119</sup> the prophylactic regimen of tacrolimus and MTX was demonstrated to reduce Grade II-IV acute GVHD when compared to CSA and MTX. However, there was a higher regimen-related death rate in patients with advanced disease who received tacrolimus in this study, possibly related to the use of tacrolimus at levels beyond those currently recommended. The implications of this finding are unclear and generally CSA and tacrolimus are viewed as equivalent. The addition of MTX has the potential for increased severity of regimen-related mucositis and delays in engraftment. At M.D. Anderson Cancer Center, a modification of the tacrolimus-MTX regimen using “mini-dose MTX” was found to be as effective as full dose therapy with less toxicity (Fig 35-3).<sup>130</sup>

ATG has also been used effectively in the prophylactic setting.<sup>131</sup> In patients with aplastic anemia who underwent transplantation using a Cy and ATG conditioning regimen, low rates of acute GVHD (15%) and chronic GVHD (34%) were reported and a significant survival benefit at 3 years was identified for patients receiving this regimen when compared with historical controls who received Cy alone (92% vs 72%).<sup>109</sup>

In addition to the immunosuppressive agents above, T-cell depletion before marrow infusion has been shown to effectively reduce the incidence and severity of GVHD; however, it also results in increased graft rejection, infectious complications, and relapse rates in a disease-specific manner.<sup>8</sup> Selective T-cell subset depletion or “add-back” of allo-depleted T cells are future strategies that may be effective for reducing the risk of acute GVHD while preserving the GVT effect.<sup>52,132</sup>

Chronic GVHD shares many features with various autoimmune disorders, including autoantibodies and disease

manifestations that are similar to such disorders as the sicca syndrome and scleroderma. The manifestations of chronic GVHD are extensive with nearly every organ potentially affected.<sup>114</sup> The consequences for affected patients can be profound, with its presence or absence being the most significant determinant of long-term outcome and quality of life following allogeneic HSCT.<sup>133</sup> Approximately 60% to 70% of patients who receive an allogeneic transplant are affected to some degree by chronic GVHD.<sup>134</sup> Despite progress in other areas of this field, our understanding of this entity is limited; therefore, advancements in the prevention and treatment of chronic GVHD have been sparse.

## Organ Toxicity

### Veno-Occlusive Disease of the Liver

VOD, also referred to as sinusoidal obstruction syndrome, is a complication of both allogeneic and autologous transplant as well as occasionally chemotherapy regimens in the nontransplant setting. The process occurs as a result of direct injury to the hepatic venous endothelium. The syndrome is characterized by the constellation of signs and symptoms consisting of tender hepatomegaly, jaundice, weight gain, and ascites. The incidence of this syndrome has varied among reports and has ranged from 5% to 50% of all allogeneic and autologous transplants.<sup>135,136</sup> These studies suggest VOD is life-threatening in roughly one-quarter of cases. Risk factors include preexisting liver disease, high-intensity conditioning regimens, prior chemotherapy regimens, and mismatched or unrelated donor transplants.<sup>136</sup> Preliminary reports have found defibrotide (a polydeoxyribonucleotide) to be a promising treatment for patients suffering from severe VOD.<sup>137</sup>

### Lung

Myriad pulmonary complications can occur in patients following autologous and allogeneic transplantation. Most of these complications are a result of acute or delayed complications of the conditioning regimen and previous treatments. It is important to distinguish these entities from an infectious etiology. Direct toxicity can result from the conditioning regimen including carmustine-induced

**Figure 35-3.** Standard GVHD prophylaxis at M.D. Anderson Cancer Center. CSA = cyclosporin A; ATG = antithymocyte globulin; GVHD = graft-vs-host disease.

pulmonary toxicity and radiation-induced lung injury. Diffuse alveolar hemorrhage (DAH) may occur in the immediate post-transplant period during pancytopenia. One study found a strong association between DAH and previous thoracic irradiation, whereas no association was found between the presence of thrombocytopenia, coagulopathy, or neutropenia.<sup>138</sup> Idiopathic pneumonia syndrome may occur following allogeneic transplant. It is described as a diffuse, non-infectious pneumonia that in animal models appears to be an immune-mediated process in part induced by the toxicity of the conditioning regimen.<sup>139,140</sup> Bronchiolitis obliterans is a pulmonary manifestation of chronic GVHD.<sup>114</sup>

## Infections

Patients undergoing autologous and allogeneic transplants are at risk for a variety of infections as a result of the myelosuppression induced by the chemo- and radiotherapies employed during conditioning, delayed immune reconstitution following myeloablative therapy, and, in the case of allogeneic transplantation, immunosuppression used to prevent and treat GVHD as well as GVHD itself. Risk for infection is generally divided into three phases: Phase I, the period following preparative regimen while awaiting engraftment; Phase II, following engraftment and up to Day 100; and Phase III, from Day 100 to months and year(s) following transplantation. Infectious risks for each of the three periods varies, respectively, depending on the degree of tissue toxicity and length of neutropenia following the preparative period, the presence of acute GVHD, and the presence of chronic GVHD. Based on the high risk and associated morbidity resulting from bacterial, fungal, and viral pathogens, several prophylactic and surveillance strategies have been developed for patients undergoing transplantation.

Bacterial, candidal, and herpes simplex virus (HSV) infections pose the greatest risk for patients during the preengraftment period. In addition to conditioning-induced myelosuppression, patients often have impaired primary immunity as a result of indwelling catheters and tissue toxicity (mucositis, gastroenteritis, etc). Bacterial prophylaxis with a quinolone antibiotic is often employed in an effort to suppress intestinal flora and prevent serious gram-negative infections<sup>141,142</sup>; however, this is controversial and currently not recommended in guidelines from the Infectious Disease Society of America (IDSA)/Centers for Disease Control and Prevention (CDC).<sup>143</sup> The prompt administration of broad-spectrum antibiotics following a neutropenic febrile event is of paramount importance in preventing morbidity of bacterial infections.

In a randomized study,<sup>144</sup> the prophylactic use of fluconazole has been shown to reduce the incidence of systemic and superficial fungal infections. Fluconazole has not, however, been shown to affect the incidence of infections with resistant organisms such as *Candida krusei* or *C. glabrata* and invasive mold infections. Prophylaxis against other invasive fungal infections such as *Aspergillus* species is an area of debate with some studies supporting the use of newer azole agents<sup>145</sup> or echinocandins.<sup>146</sup>

Herpes simplex virus reactivation is seen commonly in seropositive patients during the first 6 weeks after transplantation unless prophylaxis is administered. Acyclovir prophylaxis has been

shown to prevent reactivation, reduce morbidity, and lower the incidence of antibiotic resistance and is routinely administered.<sup>147</sup> Patients in whom HSV reactivation occurs should be treated with acyclovir or valacyclovir. For patients who develop resistance after multiple episodes of HSV reactivation, foscarnet may be required.<sup>148</sup>

Prophylaxis against *Pneumocystis carinii* (PCP) is recommended following engraftment and continued for a minimum of 6 months following transplantation or while taking immunosuppressive drugs. Trimethoprim-sulfamethoxazole is the agent of choice for PCP prophylaxis given that it has the lowest breakthrough rate. Various other agents have been used including dapsone and aerosolized pentamidine.<sup>149</sup>

Cytomegalovirus (CMV) infections were once a common and fatal occurrence in the first 3 months following marrow transplantation. The routine prophylactic use of ganciclovir has largely eliminated CMV disease after transplantation. Randomized studies have clearly demonstrated efficacy in reducing the incidence of CMV disease by the prophylactic treatment of all CMV-seropositive patients.<sup>150</sup> However, this strategy is problematic in that many patients will require discontinuation of therapy because of the development of neutropenia, which places the patients at increased risk for other infections. The creation of highly sensitive tests capable of detecting CMV reactivation before overt CMV disease has allowed for an alternative strategy to routine prophylaxis. These tests include direct detection of CMV pp65 antigen in peripheral blood leukocytes<sup>151</sup> and detection of CMV DNA in leukocytes, plasma, or serum.<sup>152</sup> Preemptive therapy when reactivation is first detected has been shown to result in similar rates of CMV-related death and survival when compared with universal ganciclovir prophylaxis starting at the time of engraftment. Patients receiving routine prophylaxis experienced less CMV disease in the first 100 days after transplantation; however, this benefit was offset by a higher rate of invasive fungal infections and late CMV disease.<sup>151</sup> Thus, current recommendations support either approach for patients at risk for CMV disease (ie, all CMV-seropositive recipients and seronegative recipients with seropositive donors). For CMV-seronegative patients with CMV-seronegative donors, the use of CMV-seronegative or leukocyte-reduced blood components are effective in preventing primary infections.<sup>153</sup>

Viral infections continue to pose significant challenges to clinicians managing posttransplant patients. In addition to community respiratory viruses, intestinal viruses are easily transmitted through person-to-person contact and have been associated with increased morbidity and mortality. Because of a lack of specific therapies for these agents, the focus must be on appropriate isolation of patients and the prevention of person-to-person transmission.

## Long-Term Complications of High-Dose Therapies

Several long-term complications occur following HSCT, requiring patients to maintain regular office visits and practitioners familiar with posttransplant follow-up guidelines to monitor patient progress. Regular eye screening for cataracts is required especially for those who received a TBI-containing regimen or steroids for

the treatment of GVHD.<sup>154</sup> Several endocrine complications occur including hypothyroidism, stunted growth and development (in pediatric patients), and premature gonad failure/sterility.<sup>155</sup> Patients who have undergone autologous HSCT are at increased risk for treatment-related MDS and AML, especially if they were subject to prior radiation (especially to the pelvis), were heavily pretreated, were slow PBPC mobilizers, or were subject to TBI-containing conditioning regimens.<sup>156</sup> Both autologous and allograft recipients are at higher risk for additional secondary cancers especially bone, head, neck, and connective tissue malignancies.<sup>157</sup>

## Disease Indications

### Acute Myelogenous Leukemia and Myelodysplastic Syndromes

AML and MDS currently constitute the most common indication for allogeneic transplantation. Treatment decisions pertaining to postinduction therapy are centered on disease risk for relapse as determined by cytogenetic abnormalities.<sup>158</sup> Most would agree that suitable candidates with intermediate risk and all poor-risk candidates who have a suitable donor should undergo allogeneic transplantation while in first complete remission (CR).<sup>159</sup> Patients who are in first relapse/second remission should be offered an allogeneic transplant regardless of their original cytogenetics provided that they have a suitable donor. Although the likelihood of success with allogeneic transplantation is substantially less for this group of patients when compared to those in first CR, no other therapy is known to offer long-term cures.<sup>160</sup> Reduced-intensity conditioning regimens have allowed for allogeneic transplantation to be offered to older adults with AML and MDS with acceptable treatment-related mortality.<sup>161</sup> This is extremely pertinent for disease that has an average age of onset in the seventh decade of life.

### Acute Lymphocytic Leukemia

Conventional chemotherapy offers prolonged remission and even a cure for most children and many adults. Accordingly, transplantation is not usually undertaken until after relapse.<sup>162</sup> First remission transplantation has been reserved for adults with high-risk disease such as patients with t(4:15) or t(9:22) cytogenetics.<sup>163</sup> Successful results of marrow transplants in first remission for these patients range from 30% to 60%, depending on patient age and donor type. The GVL effect may be less in ALL than is observed in CML or more indolent malignancies.<sup>164</sup> The rarity of allogeneic donor lymphocyte infusion inducing remission for relapses after allogeneic transplantation supports this observation. Patients with active leptomeningeal leukemia should have this complication treated before transplantation, because few marrow transplant preparative regimens have agents that cross the blood-brain barrier.

### Chronic Myelogenous Leukemia

Before the advent of tyrosine kinase inhibitors such as imatinib, CML represented the most common disease group treated with

allogeneic transplantation. A meta-analysis of four randomized trials of allogeneic transplantation in patients with CML in chronic phase found 10-year survival estimate of more than 60%.<sup>69</sup> Patients with favorable prognostic factors (young age, favorable donor characteristics, and newly diagnosed disease) have a demonstrated overall survival of over 70%, albeit with a significant risk for acute and chronic GVHD.<sup>165</sup> These results need to be viewed in the context of the promising Phase II trials with imatinib demonstrating a complete hematologic response in 95% and a major cytogenetic response in 65% of patients treated in chronic phase with a median follow-up of 4 years with minimal toxicity.<sup>166</sup> For this reason, expert consensus opinion has recommended allogeneic transplantation be limited to patients who have not achieved a prompt complete hematologic response with initiation of imatinib or have evidence of persistent cytogenetic abnormalities. There is not enough evidence to determine whether newer, more potent tyrosine inhibitors will change these recommendations.<sup>167</sup>

### Multiple Myeloma

Multiple myeloma currently represents the most common indication for autologous HSCT. This is based upon multiple randomized studies demonstrating higher complete remission rates, event-free survival, and overall survival in patients undergoing high-dose therapy followed by autologous HSCT when compared to chemotherapy alone. A French study<sup>168</sup> reported a CR and 5-year survival rates of 22% and 52% in the high-dose group vs 5% and 12% in the standard-dose study arm. Randomized studies have established melphalan 200 mg/m<sup>2</sup> as the “standard” regimen for patients under the age of 65.<sup>169</sup> The role of double autologous transplants was investigated in a protocol of the Intergroupe Francophone du Myelome. Attal et al<sup>170</sup> randomly assigned 399 untreated patients younger than 60 years to receive melphalan 140 mg/m<sup>2</sup> with TBI 8 Gy (single transplant) or melphalan 140 mg/m<sup>2</sup> followed by a second transplant using the TBI/melphalan regimen.<sup>170</sup> Response rate was similar, but overall and event-free survival was significantly improved in the double autologous transplant study arm. The subset of patients who did not achieve at least a partial remission with the first procedure appeared to benefit the most with this strategy. It should be noted, however, that all studies that determined the key role of autologous transplantation in this disease were conducted before the development of new “target” therapies, which may change radically the way multiple myeloma is treated in the future. To date, no therapy is felt to be curative for this disease. Recently, autologous stem cell transplant followed by reduced-intensity conditioning allogeneic transplantation in patients with a sibling donor has been explored with some randomized studies suggesting improvement in survival over tandem autologous transplant.<sup>171</sup>

### Lymphoma and Chronic Lymphocytic Leukemia

High-dose therapy followed by autologous HSCT is considered standard treatment for patients with diffuse large-cell lymphoma and Hodgkin disease who fail to achieve remission

following initial therapy, or subsequently relapse after an initial remission with chemo-sensitive disease. The Parma study was a randomized trial comparing standard salvage chemotherapy in first relapse for large-cell lymphoma to standard chemotherapy plus autologous marrow transplant.<sup>172</sup> This trial demonstrated a definitive advantage for patients receiving an autologous transplant. Autologous HSCT is the accepted treatment for patients with chemo-sensitive relapsed or primary refractory Hodgkin disease.<sup>173</sup> Patients who achieve a second CR following salvage treatment have the best outcomes with this approach with over 50% of patients achieving a long-term cure. There have been no randomized studies comparing TBI-containing to chemotherapy-alone conditioning regimens, but generally radiation-based regimens are avoided in those patients who have previously received radiation therapy. Recently, the incorporation of the CD20 monoclonal antibody, rituximab, into chemomobilization and conditioning regimens have been shown to improve outcomes.<sup>23</sup> The incorporation of radiolabeled antibodies into conditioning regimens is being explored.<sup>24</sup>

Allogeneic transplantation has been explored in patients with large-cell lymphoma and Hodgkin disease who have failed to achieve a suitable response to salvage chemotherapy or who have relapsed following an autologous HSCT with variable success. Treatment-related mortality has been high with full-intensity regimens; however, reduced-intensity regimens have been better tolerated and offer hope for cure in select patients.<sup>174,175</sup> In addition, encouraging results have been reported with reduced-intensity allogeneic transplants with indolent lymphomas and CLL.<sup>176,177</sup>

### Breast Cancer

Breast cancer once constituted the most common indication for high-dose chemotherapy followed by autologous HSCT. More recently, a series of randomized trials failed to demonstrate an improvement in long-term progression-free or overall survival in patients with high-risk<sup>178,179</sup> or metastatic breast cancer.<sup>180</sup> Apart from participation in a clinical trial, this approach is no longer justified.

### Future Directions

Fifty years have passed since Thomas and colleagues' first attempts at allogeneic HSCT. The field has advanced so that this therapy can now be offered to more patients with less risk for acute and long-term toxicity. Despite these advances, the challenge remains the discovery of new strategies that will improve disease-free survival without associated treatment-related mortality. Autologous and allogeneic HSCT remain curative for a minority of patients with advanced, refractory disease. Broadly applied, dose-intensification has not been able to significantly affect outcomes for this group of patients because of the overlap between toxicity and efficacy. Undoubtedly tomorrow's success will come through the incorporation of "targeted"

therapies that offer the hope of decreasing relapse without adding additional toxicity. In addition, new strategies for harnessing the immunotherapeutic potential of a GVL effect while reducing the risk GVHD will make allogeneic transplantation a more widely applied modality.

# Umbilical Cord Blood: A Reliable Source of Stem and Progenitor Cells for Human Transplantation

**Suhag H. Parikh<sup>1</sup> & Joanne Kurtzberg<sup>2</sup>**

<sup>1</sup> Assistant Professor, Pediatric Stem Cell Transplant Program, Duke University Medical Center, Durham, North Carolina, USA

<sup>2</sup> Chief, Pediatric Blood and Marrow Transplant Program, Duke University Medical Center, Durham, North Carolina, USA

The first successful allogeneic hematopoietic stem cell transplantation was performed in 1968 by Dr. Robert Good. The patient, who had severe combined immunodeficiency (SCID), received marrow from a sibling as the source of stem cells. Since then, thousands of patients have been cured of life-threatening hematologic disorders—malignant and nonmalignant—establishing the field of marrow transplantation. Chapter 35 provides an overview of allogeneic transplantation with an emphasis on the traditional sources of hematopoietic stem cells—namely, marrow and peripheral blood. Over the years, the National Marrow Donor Program (NMDP) in the United States and registries in other parts of the world have recruited, typed, and maintained databases on millions of voluntary unrelated adult donors. Despite the large number of registered donors, approximately two-thirds of the patients in need of a transplant are still unable to find a suitable marrow donor in a timely manner. This problem is even more of a concern for patients belonging to ethnic minorities. The need to breach the HLA barrier—to be able to perform transplants with partially HLA-mismatched donors—was realized by early investigators. However, the outcomes of partially mismatched hematopoietic stem cell transplants from marrow or mobilized peripheral blood, with or without T-cell depletion, have been suboptimal. This is mainly because of a higher incidence of graft failure, severe graft-vs-host-disease (GVHD), and poor immune reconstitution, leading to increased infection-related mortality. There has been a desperate need for stem cell sources that could result in adequate engraftment with acceptable rates of GVHD in the partially mismatched transplant setting.

The first part of this chapter focuses on the use of umbilical cord blood (UCB) as one such alternative source of hematopoietic stem and progenitor cells and describes the rapid emergence of its role in clinical hematopoietic transplantation. Recent research suggests that UCB applications may well extend beyond

the realm of hematopoietic reconstitution, with tremendous potential for the field of regenerative medicine. The latter part of the chapter provides an overview of the cord blood banking system.

## Cord Blood: Biology and Transplantation

The idea of using cord blood for hematopoietic transplantation arose from interactions among a group of physicians and scientists in the early 1980s. Using blood from near-term mouse donors, Dr. Ted Boyse at Memorial Sloan Kettering Cancer Center demonstrated reconstitution of hematopoiesis in lethally irradiated mice. In parallel, Dr. Hal Broxmeyer in New York and later in Indiana, performed early experiments characterizing the hematopoietic stem and progenitor cells in human UCB. He demonstrated that cord blood was a rich source of these cells, that they had higher proliferative capacity, and also that they could be readily cryopreserved.<sup>1</sup>

Hematopoietic stem and progenitor cells derived from cord blood are biologically different from those derived from marrow or mobilized peripheral blood, as evidenced by a large amount of data that has emerged from several groups studying stem cell biology. In-vitro studies of the sources show both quantitative differences, ie, a higher frequency of more primitive hematopoietic progenitor cells in UCB than in marrow, and functional differences, ie, a higher replating potential of UCB-derived colonies on semisolid cultures than of those derived from marrow. In-vivo studies show similar differences. Nonobese diabetic (NOD)/SCID repopulating cell assays indirectly measure the self-renewal and proliferative capacities of stem cells. Experiments have shown that the SCID-repopulating cell (SRC) frequency in UCB is three-fold higher than in marrow and sixfold higher than in mobilized peripheral blood, suggesting that UCB contains a higher proportion of primitive hematopoietic stem and progenitor cells.<sup>2</sup>

It is important to distinguish the hematopoietic stem and progenitor cells derived from cord blood and/or marrow from “embryonic stem cells.” Embryonic stem cells are *pluripotent* or

*totipotent* cells (cells capable of giving rise to all three basic germ layers—ectoderm, endoderm, and mesoderm) derived from the inner cell mass of the early embryo. With continued natural development of the embryo, the embryonic stem cells become more and more lineage committed, thus giving rise to cells of mostly one germ layer, but sometimes two. Such development results in a hierarchy of more restricted stem cells. Terms such as *multipotent*, *tissue restricted*, *adult*, or *somatic* stem cells are applied to these more committed stem cells. For example, liver stem cells give rise to hepatocytes; muscle stem cells give rise to muscle; and the hematopoietic stem or progenitor cells give rise to all three elements of blood—erythrocytes, leukocytes, and platelets. Marrow, as well as UCB, is rich in these more lineage-restricted multipotent hematopoietic cells, with some differences as alluded to above.

Pluripotent embryonic stem cells, at the current level of development, are not yet in clinical use. One reason is the development of teratomas in animal models. Clearly, these cells are highly proliferative and further studies are needed before they are ready for clinical application. Some investigators have raised concerns regarding epigenetic developmental abnormalities. Human egg harvesting is an invasive procedure. Not only are human eggs difficult to obtain, but ethical issues and religious beliefs make this an extremely controversial topic, because it involves the loss of human embryos. Therefore, despite their enormous potential, clinical therapeutic use of embryonic stem cells is unlikely to become a reality in the near future.

Conversely, marrow has been successfully used for hematopoietic transplantation for more than three decades. Furthermore, mobilized peripheral blood has been used, and now cord blood is increasingly being used as a cell source for transplantation. Taken together, these studies imply two important points: 1) that cord blood is a rich source of hematopoietic stem cells and 2) that there is a preponderance of more primitive types of stem cells in cord blood as compared to marrow or peripheral blood.

### **First Umbilical Cord Blood Transplantation: Proof of Principle**

In 1988, the use of cord blood as a source of hematopoietic stem cells was reported following an elaborate international, multi-institutional collaboration, when a 6-year-old boy from the United States with Fanconi anemia underwent successful transplantation in Paris.<sup>3</sup> The source of the donor cells was HLA-identical UCB from his unaffected sibling. Twenty years after the procedure, he is durably engrafted, immunologically competent, healthy, and cured of his hematologic condition. This outcome proved that cord blood harvested from a single donor contained a sufficient dose of stem cells for successful reconstitution of a pediatric patient's aplastic marrow.

### **Matched Sibling Donor UCB Transplantation**

This success led to an increasing number of matched related cord blood transplant procedures in the following years (~60 transplants over the next 5 years). Apart from demonstrating

acceptable rates of engraftment, it became clear from this early experience that among matched related donor transplants, cord blood caused less GVHD as compared to marrow, and that this property of cord blood might allow transplantation across genetic/HLA barriers. In 1992, the first public unrelated cord blood bank was established at the New York Blood Center by Dr. Pablo Rubinstein to explore the use of banked UCB from unrelated donors for hematopoietic stem cell transplantation.<sup>4</sup>

### **Unrelated-Donor UCB Transplantation**

In 1993, the first unrelated UCB transplantation was performed in a 3-year-old child with recurrent T-cell acute lymphoblastic leukemia. The outcomes of 25 successive transplants with unrelated UCB banked at the New York Blood Center, and transplanted at Duke University, were reported in 1996.<sup>5</sup> Important observations in these patients and subsequent reports from other centers and registries including the New York Blood Center and the European Cord Blood Registry (Eurocord)<sup>6-8</sup> demonstrated the following:

1. Unrelated cord blood could engraft in the marrow of children undergoing myeloablative therapy for leukemias and genetic diseases.
2. Reasonable outcomes could be achieved using partially HLA mismatched grafts.
3. The incidence and severity of acute and chronic GVHD was lower and milder than that seen with matched unrelated marrow transplants.
4. There was preservation of graft-vs-leukemia effects.<sup>9</sup>
5. Cell dose strongly correlated with clinical outcomes including time to engraftment and probability of overall engraftment and survival.
6. Engraftment times were observed to be slower than those of marrow or mobilized peripheral blood.

### **Prospective Study: COBLT**

Cord blood banking efforts in the United States were stimulated by the National Heart, Lung, and Blood Institute, which funded a prospective multicenter clinical trial of unrelated cord blood transplantation—the Cord Blood Transplantation Study (COBLT)—from 1997 to 2004. Three unrelated cord blood banks were established with funding provided through this study and all three banks established and followed common quality standards and standard operating procedures (SOPs). These SOPs addressed donor recruiting and screening. For screening, donors were evaluated for events in their medical history that would exclude them as donors (eg, multiple pregnancy, prematurity, placental deformity, self or a sibling diagnosed with cancer, prior receipt of a transplant, or demonstration of high risk behaviors likely to increase the chance of infection with blood-borne infectious diseases). SOPs were also established and validated for obtaining donor consent; obtaining medical histories; obtaining blood samples from maternal donors; cord blood collecting, processing, testing, cryopreservation, and storage; as well as searching for and releasing cord blood units for transplantation.<sup>10</sup>

Twenty-six transplant centers participated in this prospective clinical trial designed to examine the safety and efficacy of unrelated cord blood transplantation in infants, children, and adults with malignancies; children with congenital immunodeficiency disorders; and children with inborn errors of metabolism. The study participants employed common preparative regimens, prophylaxis against GVHD, and supportive care measures. Results in children with malignant and nonmalignant conditions were favorable, with 55% survival in children with malignancies and 78% survival in children with nonmalignant conditions. Results in a very high-risk group of adults were inferior to those seen in children and in individuals receiving marrow from an unrelated donor. Subsequent studies in adults, reported by single centers or registries, revealed more encouraging results.<sup>11,12</sup> The cumulative incidence of engraftment by Day 42 after transplantation was approximately 80% in all study strata including adults and children as well as children with malignant diseases, inborn errors of metabolism, and immunodeficiency syndromes. Factors adversely affecting engraftment or survival included lower cell doses, pretransplant cytomegalovirus seropositivity in the recipient, non-European ancestry, and greater HLA mismatching.

### Retrospective Studies

Over the nearly 15 years since the first unrelated-donor cord blood transplantation, more than 10,000 such procedures have been performed at more than 150 centers scattered throughout the world. Retrospective analyses of several of these patients have led to similar conclusions as the early studies. A minimum cell dose of  $3$  to  $3.5 \times 10^7$  nucleated cells/kg has been defined as a prerequisite for optimal clinical outcomes.<sup>13</sup> Efficacy of unrelated cord blood transplantation has been shown for children and adults with leukemias<sup>9,11</sup> and children with a variety of nonmalignant disorders including hemoglobinopathies,<sup>14</sup> immunodeficiencies,<sup>15,16</sup> and inborn errors of metabolism.<sup>17</sup> A majority of transplants have been mismatched at one or two HLA loci. Yet, a recent retrospective comparative analysis from the Center for International Blood and Marrow Transplant Research (CIBMTR) of unrelated donor graft sources—cord blood vs marrow—showed a comparable 5-year leukemia-free survival in children with acute leukemia who received allele-matched marrow vs one- or two-antigen mismatched cord blood transplants. The analysis suggests that 6/6 matched cord blood may yield superior survival, even though the comparison fell short of statistical significance.<sup>18</sup> Unfortunately, there have not been any prospective randomized clinical trials comparing unrelated cord blood and marrow to date.

### Inherited Metabolic Disorders and Unrelated UCB Transplantation

Cord blood transplantation has been particularly effective in the treatment of young infants and children with certain inborn errors of metabolism, eg, mucopolysaccharidoses such as Hurler syndrome and leukodystrophies such as Krabbe disease.<sup>17,19,20</sup> These diseases are examples of lysosomal storage

disorders, which result from single gene defects leading to specific enzyme deficiencies. These deficiencies cause defective lysosomal breakdown and accumulation of a toxic substrate, which in turn leads to progressive involvement of multiple organs, and eventually premature death. In these patients, durably engrafted cord blood cells of donor origin provide the missing or defective enzyme. Most patients with untreated Hurler syndrome usually die between 5 to 10 years of age from progressive cardiac and pulmonary involvement. They also suffer from severe bony abnormalities, corneal clouding, massive hepatosplenomegaly, and severe neuroregression. Engrafted cord blood cells have the ability to cross the blood-brain barrier and have been shown to effectively prevent neurodevelopmental progression, a beneficial outcome that is not expected with the alternative approach of recombinant enzyme replacement therapy.<sup>21</sup> Unrelated cord blood transplantation, when performed before the age of 2 to 3 years, leads to correction of cardiac, pulmonary, liver, and neurologic damage and improves survival.<sup>19</sup> In fact, a recent risk factor analysis of 146 patients from the European Group for Blood and Marrow Transplantation (EBMT) suggests that cord blood could be the preferred stem cell source in this disease.<sup>22</sup> Similarly, in patients with leukodystrophies, cord blood transplantation in the presymptomatic phase of the disease can prevent demyelination in the central and, often, the peripheral nervous systems.<sup>20</sup>

### Advantages and Disadvantages of Cord Blood Transplantation

Cord blood transplantation has several advantages over marrow or peripheral blood stem cell transplantation, the most significant of which is that cord blood transplantation can be performed successfully from unrelated donor with one or two HLA mismatches (Table 36-1). In the setting of marrow or

**Table 36-1.** Advantages and Disadvantages of Cord Blood

#### Advantages

- Increased immune tolerance
  - Less restrictive HLA barriers increase access to transplantation therapy for patients lacking fully matched donors
- Decreased incidence and severity of GVHD
- Increased safety
  - Less risk of viral contamination
  - Easier access
  - Ready availability
- Minimal donor attrition
- Easier recruitment of minority donors
- Noncontroversial source of stem cells

#### Barriers to Success

- Slower engraftment times
  - Possibly related to inadequate cell content in some single units, particularly for larger patients
- Cell dose limitations
- One-time usage
- Potential for transmission of genetic diseases
- Expensive infrastructure for banking

peripheral blood transplantation, however, this same degree of HLA mismatching causes unacceptable rates of acute and chronic GVHD and is prohibitive. With the current level of cord blood inventories and allowing for up to two antigen mismatches, a cord blood donor can be found for >90% of patients. There are other practical advantages to the use of allogeneic cord blood, such as increased certainty and promptness (<2 weeks vs 2 months) of obtaining the donor unit, less donor attrition, decreased risk of infections, absence of risk to mother or infant, and a higher likelihood of recruiting donors belonging to ethnic minorities. Last but not the least, cord blood may have more plasticity as suggested by the experience from transplantation in inherited metabolic disorders.<sup>19,22</sup>

There are also significant limitations dictated mainly by the kinetics of cord blood engraftment. The majority of single cord blood units may not have enough of a cell dose to be of benefit for adult patients. Delayed neutrophil and platelet engraftment often leads to more prolonged inpatient stay and higher acuity of supportive care, thus significantly increasing the cost of the transplant. Recent approaches combining two UCB units for a single transplant procedure have resulted in increased rates of engraftment in adults.<sup>23</sup> There is also a limited ability to perform posttransplant donor-derived cellular therapy such as donor lymphocyte infusions.

## Cord Blood Banking

The advances in clinical cord blood transplantation would not be possible without parallel evolution of a formal system of cord blood banking throughout the world. This involves collection of

the cord blood and subsequent processing and cryopreservation until it can be used clinically.

### Cord Blood Collection

Umbilical cord blood is the portion of the infant's blood contained in the placenta, which typically would be discarded at birth. As discussed, cord blood is a rich source of multipotent hematopoietic stem and progenitor cells. Properly performed, cord blood collection can be accomplished without physical risk to the mother or infant donor, from the delivered placenta (ex utero) or during the third stage of labor (in utero). Many public cord blood banks employ dedicated staff to perform ex-utero collections away from the delivery room so that the privacy of the family is preserved and clinicians are not distracted from their usual practices [Fig 36-1 (A)]. Alternatively, obstetricians or midwives perform in-utero collections while waiting for the placenta to deliver. In either case, after sterile preparation, the umbilical vein is punctured with a 17-gauge needle attached to a sterile, closed-system collection bag containing citrate-phosphate-dextrose anticoagulant which is positioned lower than the placenta [Fig 36-1 (B)]. Blood flows from the placenta, through the cord into the bag over approximately 5 to 10 minutes [Fig 36-1 (C)]. Experienced collectors harvest an average of 110 mL from a single placenta. The cord blood unit is labeled and subsequently shipped to the cord blood bank for processing, testing, cryopreservation, and storage.<sup>24</sup>

There are two types of cord blood banks—public and private. Unrelated transplant programs employ public banks as their source of donor UCB units. These units are donated on a voluntary basis by women delivering healthy infants at term. Private banks, which are for-profit entities, store “directed donations”

**Figure 36-1.** Ex-utero cord blood collection. The placenta is delivered by usual obstetric techniques. After cutting and clamping the cord, operating room personnel place the placenta in a bucket and transport it to the collection room. There it is placed in a collection stand (A) on a clean chuck pad. The fetal side is placed down and the umbilical cord is pulled through an opening in the tray. The cord is tethered, cleansed with betadine and alcohol, and punctured with a 17-gauge needle attached to a collection bag (B). Blood drains by gravity over 5 to 10 minutes into the attached bag, which contains 25 mL of citrate-phosphate-dextrose anticoagulant (C). After the blood collection is complete, the needle is removed from the cord, the tubing is sealed, and the cord blood unit is transported to the processing laboratory for volume reduction, testing, cryopreservation, and long-term storage.

collected by obstetricians from infants born into families who intend to use the cord blood for the infant from whom it came (autologous donation) or for another family member in need of future transplantation therapy.

Cord blood collection in public cord blood banks today requires obtaining maternal consent. Guidelines for several aspects of cord blood banking are provided by the Institute of Medicine (IOM).<sup>25</sup> By consenting, the infant's mother agrees to the following:

1. The donation of her infant's cord blood is voluntary.
2. She gives permission for her blood and the cord blood to be tested for blood-borne pathogens, eg, human immunodeficiency virus, hepatitis B and C viruses, syphilis, human T-cell lymphotropic virus, and West Nile virus, and agrees to give a detailed family medical history.
3. The cord blood is not being stored for personal use by the infant or other relatives and, instead, it will be listed on a public registry of unrelated donors and made available to patients in need of donors for unrelated transplantation.
4. She may be contacted in the future by the bank to obtain follow-up information on the infant's health.
5. Measures will be used to protect her confidentiality and that of her infant.

Unlike adult donor registries, the identities of cord blood donors are not revealed to the recipients and a recipient cannot contact the donor in the future. Most banks maintain a confidential link between the unit information (stored as a bar-code label) and the mother's demographic information with the aim of being able to contact the family in the future, should the unit test positive for a new disease not anticipated by the family.

Timing of maternal consent can vary. The vast majority of cord blood banks believe that consent should be obtained from the mother before collection of the cord blood, preferably in the late third trimester and before onset of labor. Despite efforts to recruit women during the third trimester of pregnancy and obtain their consent well before the onset of labor, many pregnant women in labor come to the hospital interested in cord blood donation but without having given prior consent. Some centers have addressed this situation by asking pregnant women in early labor to sign a short or "mini" consent form allowing only the collection of the cord blood and maternal samples. Then after she recovers from the delivery someone meets with her to educate her and obtain full consent allowing for processing, testing, cryopreservation, and storage.

### Cord Blood Storage

As commercial, private cord blood banking has proliferated, its ethical justification has been widely debated.<sup>26,27</sup> Generally, an initial storage fee of \$1000-1500 is charged, followed by a yearly storage fee of approximately \$100. While there are a few clear indications for this practice (eg, a sibling with cancer, a family history of hemoglobinopathy, marrow failure, congenital immunodeficiency syndrome, or inborn error of metabolism), the vast majority of families who store cord blood with private banks

pay to have access to stem cells in the future for use in treating degenerative diseases or problems related to injuries or aging. Currently, there is no evidence that this future use will be feasible or efficacious in such circumstances.

Many private banks aggressively advertise their services. References in such advertising to rare and not-yet-tested applications for cord blood transplantation address the concerns of new parents wanting to provide every possible advantage for their newborn child.<sup>28</sup> In addition to messages that may be exploitative, marketing may be inaccurate or misleading. One common reason offered by some private banks for storing autologous cord blood is to have a source of stem cells for transplantation if the child were to develop leukemia. However, most children with childhood leukemias can be cured with conventional chemotherapy alone and in those who do not respond to this approach, allogeneic transplantation is the treatment of choice. Furthermore, leukemic cells have been found in autologous cord blood of infants who later present with leukemia from 1 to 11 years of age.

With increasing use of cord blood transplantation, public banks face other challenges. Procuring and providing units for public use in unrelated allogeneic transplantation has involved funding from third party sources for the creation of the inventory. Currently, there are approximately 14 public cord blood banks in the United States and approximately 30 more worldwide. All of these banks struggle financially because the revenues gained from sale of UCB units for transplantation are not sufficient to support the basic operations of a bank that is in the process of building inventory. There is also no requirement for public cord blood banks to list their inventories on a single registry available to all transplant centers. Thus, transplant centers must be knowledgeable about and search multiple banks and registries to find the best donor for each patient.

In 2004, after appropriation of \$20,000,000 by the US Congress to increase the inventory of cord blood units in US public banks, the Health Resources Services Administration (HRSA) asked the IOM to perform a study to determine the best way to organize public cord blood banking and distribution to patients undergoing unrelated transplantation, the results of which were published in April 2005.<sup>25</sup> In brief, the IOM recommended that HRSA contract with eligible banks to procure approximately 150,000 new, ethnically diverse, unrelated donor cord blood units over the next 5 years. The units will need to meet quality standards as defined by an advisory board, the Food and Drug Administration, and other accrediting agencies. They will also have to be listed on a computerized, Web-based system created to allow searching of all unrelated cord blood and adult donors from a single point of access (SPA).

Since the publication of the IOM study, the US Congress passed legislation that appropriated funds to establish a National Cord Blood Program. The WC "Bill" Young Stem Cell Transplantation Act, is federally funded and administered through HRSA. Selected cord blood banks have been chosen to participate in the National Cord Blood Inventory, which is

tasked with building a high-quality, ethnically diverse inventory of 150,000 new UCB units to be listed on a combined registry for adult and cord blood donors. Under this new program, patient advocacy must be provided and transplant outcomes collected and evaluated. There is also provision for a SPA for patients and doctors searching for a suitable stem cell HLA match—be it from marrow, peripheral blood, or cord blood. The legislation also instituted mandatory reporting of transplant outcomes by all transplant centers in the United States to the SCTOD (Stem Cell Transplant Outcomes Database), a contract awarded to the CIBMTR. HRSA administers contracts for the banks directly, whereas the other programs (adult stem cell and cord blood coordinating centers, SPA, and SCTOD) were awarded to, and are all administered through, the NMDP.

## Future Directions

Umbilical cord blood from related and unrelated donors, matched or mismatched at one or two antigens, is now widely regarded as an alternate donor source to matched marrow or peripheral blood for allogeneic transplantation in children as well as adults for a variety of malignant and nonmalignant disorders. This use of cord blood dramatically increases the accessibility of hematopoietic stem cell transplantation. Retrospective analysis of large patient datasets does not show a survival difference and prospective randomized clinical trials comparing these graft sources are needed. Despite its favorable impact on the field of hematopoietic transplantation, time to engraftment remains a weakness and strategies to improve engraftment rates and speed of engraftment are needed. Several new approaches are being investigated, including combining two cord blood units<sup>23</sup> and combining a cord blood unit with cells from a haploidentical donor.<sup>29</sup> Investigations are also ongoing to study reduced-intensity conditioning regimens in order to decrease the toxicity associated with transplantation. A federal mandate has provided an impetus for the cord blood banking community to increase the cord blood inventories throughout the country and to streamline efforts into creation of a national cord blood banking program. Increasing inventories, especially for minorities, will result in availability of better matched cord blood units and improved outcomes in this segment of the population. These developments in cord blood banking are thus expected to complement the growth of clinical allogeneic cord blood transplantation. There has been increasing new evidence in recent years suggesting presence of pluripotent cells in cord blood that hold vast potential in treatment of degenerative disorders involving several organs other than hematopoietic system, such as liver, brain, heart, eyes, endocrine organs, and bones.<sup>30</sup>

# Alternatives to Transfusion: Perioperative Blood Management

**Lynne Uhl**

Assistant Professor of Pathology, Harvard Medical School, and Director, Division of Laboratory and Transfusion Service, Beth Israel Deaconess Medical Center, Boston, Massachusetts, USA

Recognition of blood supply limitations and concern for potential deleterious effects of transfusion have promoted the concept of integrated programs for blood management in the surgical setting.<sup>1</sup> Perioperative transfusions account for more than half of the estimated 20 million blood components transfused annually.<sup>2</sup> Logically, if measures are taken to reduce this utilization, both the pressure on resource allocation as well as the risks associated with allogeneic transfusion could be reduced. The scope of blood management is broad and includes several different options, some of which can be initiated before patient hospitalization, others of which occur during the intraoperative period or the postoperative period (Table 37-1). This chapter covers the various aspects of blood management, which present alternatives to allogeneic transfusion.

**Table 37-1.** General Principles of Blood Management

1. Formulate a plan of care for avoiding and controlling blood loss tailored to the clinical management of individual patients, including anticipated and potential procedures.
2. Employ a multidisciplinary treatment approach to blood conservation using a combination of interventions.
3. Manage blood utilization proactively and be prepared to address potential complications.
4. Promptly investigate and treat anemia, preferably preoperatively.
5. Exercise clinical judgment and be prepared to modify routine practice when appropriate.
6. Consult promptly with senior specialists experienced in blood conservation at an early stage if there is physiologic deterioration or if complications arise.
7. Restrict blood drawing for laboratory tests.
8. Decrease or avoid the perioperative use of anticoagulants and antiplatelet agents.

## Blood Management in the Preoperative Period

Blood management strategies should begin during the preoperative phase of patient management. During the preoperative evaluation of a patient, it is important to carefully review a patient's personal and family history to assess for potential bleeding risks. For example, family history of von Willebrand disease or specific factor deficiency (eg, Factor XI deficiency) identifies a patient who is potentially at risk for significant blood loss. Also important is the review of medication history for presence of drugs that interfere with either primary or secondary hemostasis (eg, aspirin, aspirin-containing compounds, antiplatelet agents, anticoagulants). Additionally, evidence of anemia, either through history or laboratory assessment, should be determined. If present, measures to increase red cell mass before surgery should be recommended (eg, nutritional supplementation with iron).<sup>1</sup>

## Autologous Blood Donation

The practice of preoperative autologous blood donation (PAD) gained widespread use in the early 1980s when there was a growing concern about transfusion-transmitted hepatitis and human immunodeficiency virus.<sup>3-5</sup> However, several reviews of PAD programs suggest that their role in transfusion management has declined, an observation confirmed by national data on blood procurement (Table 37-2).<sup>6-9</sup> The decline is attributed to reduced risk for transfusion-transmitted disease and improved surgical techniques leading to reduced blood loss, as well as the acceptance of lower transfusion thresholds.<sup>6</sup> Further questions about the efficacy of PAD were raised in the systematic review published by the Cochrane Collaboration.<sup>10</sup> Results of this review showed that although PAD is associated with an overall reduction of allogeneic blood exposure, patients participating in PAD have a higher likelihood of transfusion (allogeneic and autologous blood) compared with patients who do not participate in PAD. Reasons for this include lower preoperative hemoglobin concentrations, resulting in increased probability

of requiring intraoperative and/or postoperative blood transfusion and, possibly, more liberal use of transfusion based on the fact that there is “blood in the bank.”<sup>11</sup> The findings of Billote et al,<sup>12</sup> in particular, suggest that PAD has limited utility for reducing the need for allogeneic transfusion, even for procedures associated with significant blood loss. In this well-designed, randomized, controlled study the investigators examined the usefulness of PAD for reducing the need for allogeneic transfusion in patients undergoing unilateral primary total hip replacement. The patient population consisted of surgical candidates who were not anemic (predonation hemoglobin greater than or equal to 12 g/dL) and the collection protocol required that the last unit be collected no later than 2 weeks before surgery. Additionally, patients with significant comorbidities (including severe or unstable cardiac disease, uncontrolled hypertension, symptomatic carotid or vertebral artery stenosis, a history of bleeding diathesis, or bacteremia) were excluded from the study. Standardized transfusion guidelines for allogeneic and autologous transfusion used intraoperatively, included: 1) acute blood loss (>25% blood volume), 2) tachycardia attributed to hemoglobin-responsive hypoxia and unresponsive to intravenous fluid administration, 3) a hemoglobin concentration <7 g/dL in healthy patients, and 4) a hemoglobin concentration of <8 g/dL in patients with significant comorbid disease (eg, heart disease). In the postoperative period, indications for autologous transfusion included a hemoglobin concentration of <11 g/dL in the immediate postoperative recovery period and <10 g/dL in the subsequent postoperative period. As summarized in Table 37-3, important findings of this study included the observation that no patient required allogeneic transfusion; furthermore, patients randomly assigned to the nondonation cohort did not require transfusion, whereas those in the PAD cohort received a total of 42 autologous Red Blood Cell (RBC) units. Also significant was that 34 (41%) of the 82 autologous units collected were not transfused.<sup>13</sup> This report has led many in the field of transfusion medicine to question the role of PAD in blood conservation, particularly because it is associated with a relatively high wastage of units.

**Table 37-3.** Randomized Controlled Trials Examining Autologous vs Allogeneic RBC Use in Patients Undergoing Hip Replacement Surgery

| Variable                              | Cohort     |            |
|---------------------------------------|------------|------------|

### Considerations for a Successful PAD Program

Traditionally, PAD has been advocated for patients who are undergoing procedures associated with significant blood loss (procedures associated with >90% likelihood of requiring transfusion), such as orthopedic joint replacement, cardiothoracic procedures, vascular surgery, and radical prostatectomies.<sup>14</sup> In contrast, PAD is unnecessary for patients scheduled for procedures with little anticipated blood loss, for example, vaginal hysterectomies.<sup>14</sup> To optimize the success of PAD, several factors should be considered. Studies have shown the endogenous erythropoietic response to PAD is modest, and can be negatively affected by poor nutritional status and/or anemia of chronic disease. Thus, an assessment for history of chronic disease or chronic blood loss, as well as general nutritional status should be performed to determine if PAD is appropriate. Based on several studies (Table 37-4), the standard phlebotomy schedule of 1 unit/week in patients who are otherwise healthy (nonanemic and iron replete) can lead to an 11% to 19% expansion of red cell mass (equivalent to 1.0–1.75 RBC units).<sup>16,17</sup> More aggressive phlebotomy programs (eg, 2 units/week) promote a more robust erythropoietic response (equating to 2–3 RBC units) that is enhanced with the addition of exogenous erythropoietin administration.<sup>18–21</sup>

Complications and Adverse Effects of PAD

The incidence of donor reactions in the autologous blood donor population appears to be similar to that of allogeneic donors, ranging from 2% to 5%.<sup>22,23</sup> As with allogeneic donations, risk factors include first-time donation, female gender, and decreasing age.<sup>23</sup> The majority of reactions are mild and generally vasovagal in origin<sup>11</sup>; however, recent assessments question whether the side effects merit the time and effort put into autologous donation, particularly in the pediatric population.<sup>24</sup> A recent study demonstrated a dramatic reduction (21%) in donor reactions by the simple ingestion of 0.5 L of water within 10 minutes of the donation episode.<sup>25</sup>

The transfusion of autologous blood has many of the same complications as transfusion of allogeneic units, including bacterial contamination, hemolysis resulting from errors in the administration of units, and volume overload. Advantages and disadvantages of PAD are summarized in Table 37-5. Because mortality from allogeneic blood transfusion is now more likely the result of administrative error<sup>26</sup> rather than blood-transmitted infection,<sup>27</sup> the risks of banked autologous blood units are similar to banked allogeneic blood units.

Erythropoietin

Erythropoietin, as discussed in Chapter 2, is a key regulator of erythropoiesis. Briefly, endogenous erythropoietin is released by renal cortical interstitial cells in response to tissue hypoxia.<sup>28</sup> The released hormone then exerts an effect on colony-forming unit erythroid precursors in the marrow, promoting cellular differentiation and maturation.<sup>28</sup> Additional actions include enhanced hemoglobin synthesis and release of reticulocytes into the systemic circulation.<sup>28</sup>

Table 37-5. Autologous Donation

| Advantages                                                    | Disadvantages                                                               |
|---------------------------------------------------------------|-----------------------------------------------------------------------------|
| 1. Prevents transfusion-transmitted disease                   | 1. Risk of bacterial contamination or volume overload remains               |
| 2. Prevents red cell alloimmunization                         | 2. Does not eliminate risk of administrative error with ABO incompatibility |
| 3. Supplements the blood supply                               | 3. More costly than allogeneic blood                                        |
| 4. Provides compatible blood for patients with alloantibodies | 4. Wastage of blood not transfused                                          |
| 5. Prevents some adverse transfusion reactions                | 5. Causes perioperative anemia and increased likelihood of transfusion      |

As noted above, the erythropoietic response to blood loss anemia is modest. The discovery that compensatory hematopoiesis is better enhanced through the administration of exogenous erythropoietin (recombinant erythropoietin) spawned several clinical trials investigating the role of erythropoietin therapy in the preoperative setting. Patients scheduled to undergo surgical procedures associated with significant blood loss (eg, major orthopedic, cardiovascular, and urologic surgical procedures) were specifically evaluated.<sup>29-35</sup> As summarized in Table 37-6, the clinical trials in the orthopedic patient population, using a variety of dosing regimens, demonstrated benefit; preoperative hemoglobin concentrations increased and allogeneic transfusions were reduced. Patients with preoperative hemoglobin concentrations ranging between 10 and 13 g/dL appeared to benefit the most from preoperative

administration of erythropoietin.<sup>31</sup> On the basis of the results of these clinical trials, erythropoietin therapy gained US regulatory approval in 1996 for perioperative use in patients scheduled for elective, noncardiovascular surgical procedures. Several trials in orthopedic patient populations have confirmed the positive impact of erythropoietin administration on reducing allogeneic red cell transfusion, particularly when coupled with iron repletion.<sup>36,37</sup> However, despite the evidence of benefit, the use of erythropoietin has not been widely adopted. Deterrents to the general use of erythropoietin include the inconvenience of self-administration, restrictive reimbursement by insurance companies, concern for thrombosis (particularly in the cardiovascular surgical patient population<sup>38</sup>), and lack of demonstrable cost-effectiveness with respect to patient morbidity and mortality.<sup>39</sup> However, as the enthusiasm for PAD declines, it is possible that more general use of erythropoietin in the preoperative setting will increase.

## Intraoperative/Postoperative Strategies

### Acute Normovolemic Hemodilution

Acute normovolemic hemodilution (ANH) is the immediate preoperative removal of whole blood and its replacement with an

acellular fluid (in general, a combination of crystalloid and colloid) in order to maintain a normovolemic state. The practice stemmed from the early days of open-heart surgery when “blood pooling,” the intentional removal of whole blood, was employed as a means to sequester platelets, thus avoiding contact activation via exposure to the extracorporeal circuit and consequent development of postoperative coagulopathies.<sup>40,41</sup> Soon thereafter, it was recognized that additional potential benefits of ANH included a reduction of red cell loss, because the hematocrit of the blood shed during intraoperative procedures is less. For example, in theory, a 2-L blood loss in a patient with a 45% hematocrit, or the equivalent of 900 mL of red cells, could be reduced to 400 mL of red cells following hemodilution to a hematocrit of 20%. Several reports illustrating the mathematical modeling of hemodilution suggest that the benefit of ANH, in terms of reduction in significant red cell loss, is realized only in cases where extreme hemodilution (eg, a reduction in hematocrit to 21% or lower) is undertaken and the surgical blood loss volume is large (in excess of 1.5 L) (Fig 37-1).<sup>43-45</sup>

### Safety and Efficacy of ANH: Clinical Studies

ANH is quite a straightforward procedure. Following induction of anesthesia, blood is withdrawn into standard blood collection bags containing anticoagulant-preserved solution. Upon

**Figure 37-1.** The theoretic relationship between the number of Red Blood Cell units saved as a function of estimated blood loss following acute normovolemic hemodilution to a minimum hematocrit of 28% (open symbols) or a hematocrit of 18% (shaded symbols) for a patient with a blood volume of 5 liters and an initial hematocrit of 45%. Replacement strategies were either to infuse mL-for-mL of blood lost (circle symbols) or to transfuse so as to maintain the hematocrit at the minimal hematocrit (square symbols).

(Reprinted with permission from Goodnough et al.<sup>42</sup>)

completion of the blood collection process, the units are labeled with the patient's name and stored at room temperature within the operative suite. The collected units of blood are then reinfused to the patient at the close of the procedure, in reverse order. The first unit collected, and therefore the last unit transfused, has the highest hematocrit and concentration of clotting factors and platelets. Although ANH decreases the arterial oxygen content of the circulating blood, compensatory mechanisms including increased cardiac output and decreased systemic vascular resistance might be expected, in theory at least, to maintain adequate tissue oxygen delivery (Table 37-7).<sup>46</sup>

Mathematical models suggest that ANH is not very effective in reducing the amount of red cells lost, and may put some patients at risk for untoward complications related to iatrogenically induced ischemia.<sup>43</sup> Clinical studies, as well, have shown little sparing of allogeneic RBC transfusion with the use of ANH. In a recent meta-analysis, Siegel et al<sup>47</sup> examined 42 studies of ANH that met the inclusion criteria of being randomized, controlled trials of either large-volume or low-volume ANH in a surgical population. The studies were conducted from 1972 through 2002, and a majority involved patients undergoing cardiothoracic surgery, followed by trials in hip arthroplasty. It was evident from this analysis that there was an insignificant reduction in the relative risk (RR) for allogeneic transfusion for patients managed with ANH [RR, 0.96; 95% confidence interval (CI), 0.90-1.01]. A study of selected patients undergoing hip arthroplasty demonstrated no significant reduction in the number of allogeneic transfusions in patients randomly assigned to ANH vs standard transfusion therapy.<sup>48</sup> The authors appropriately point out that their data may have been affected by transfusion practices that were more conservative than expected (ie, acceptance of a lower hemoglobin concentration), inability to accomplish ANH in all patients randomly assigned to the ANH arm because of technical

**Table 37-7.** Compensatory Mechanisms Following Hemodilution and the Creation of an Acute Anemia

- Increased cardiac output
- Increased stroke volume
- Slight increase in heart rate (not clinically significant)
- Reduced blood viscosity and systemic vascular resistance leading to decreased afterload
- Increase blood flow to oxygen-dependent tissues—beyond the cardiac output increase
- Increase in oxygen extraction in end organs
- Increased coronary blood flow

difficulties (primarily poor venous access precluding blood collection), and protocol violations (particularly in the ANH arm). The study of Sanders et al<sup>49</sup> in which patients scheduled to undergo major gastrointestinal surgery for which total blood losses were anticipated to be >40%, also failed to demonstrate benefit of ANH vs standard transfusion practice with respect to reduced allogeneic blood transfusion in the operative or postoperative period. Still other studies have supported the use of ANH as a means to avoid allogeneic transfusion. Casati et al<sup>50</sup> reported on a study of patients undergoing off-pump coronary artery bypass surgery who were randomly assigned to undergo either ANH or standard transfusion management. The protocol included ANH of 17% total blood volume (moderate ANH), use of red cell recovery and infusion, and a restrictive transfusion strategy (hemoglobin of 8 g/dL). Patients undergoing ANH received statistically significantly fewer RBC units and were more likely to have been transfused as a consequence of surgical bleeding rather than postoperative anemia. The authors concluded that ANH offers the potential to reduce allogeneic red cell exposure in this particular surgical population. The mixed reports regarding the clinical effectiveness of ANH as a conservation strategy result, in large part, from the heterogeneity in the methods of ANH (large volume vs moderate volume), the surgical procedures, and the transfusion management protocols. This inconsistency signals the need for larger and more rigorous clinical trials examining the benefit of ANH.<sup>51</sup>

Although efficacy of ANH is not clearly established, it poses little risk of harm to the patient. Furthermore, it appears to be a low-cost procedure compared to other alternatives directed at procurement of autologous blood.<sup>51</sup>

### Intraoperative Autologous Blood Recovery and Reinfusion

Intraoperative red cell recovery and reinfusion of autologous blood represent another approach to reduction in allogeneic transfusion. In general, their use has been restricted to surgical procedures in which 1) the estimated blood loss is anticipated to be more than 20% of a patient's blood volume or 2) greater than 10% of patients undergoing the procedure require transfusion

**Table 37-8.** General Indications for Use of Intraoperative Blood Recovery Procedures\*

| Specialty    | Surgical Procedure                      | Comments                                                        |
|--------------|-----------------------------------------|-----------------------------------------------------------------|
| Cardiac      | Valve replacement                       |                                                                 |
|              | Redo bypass grafting                    |                                                                 |
| Orthopedics  | Major spine                             |                                                                 |
|              | Bilateral knee replacement              |                                                                 |
|              | Revision hip replacement                |                                                                 |
| Urology      | Radical retropubic prostatectomy        | Individualized by surgeon                                       |

(and the mean transfusion requirement is >1 unit). Table 37-8 lists commonly accepted indications. Recovery techniques include collection of blood by direct suctioning from the operative field as well as recovery of blood from surgical sponges. Following recovery, the blood may or may not be further manipulated. Devices available for postcollection processing of shed blood fall into two main categories: 1) hemofiltration, whereby shed blood is drawn into the autotransfusion device, which is equipped with an integral filtration device; the collected product is then simply filtered (ie, there is no washing of the product) and reinfused to the patient<sup>52</sup> and 2) red cell wash systems, whereby shed blood is collected and subsequently processed by automated devices that wash the shed blood free of cellular debris and other contaminants as well as concentrate the recovered red cells.<sup>52,53</sup>

### Efficacy

The evidence that use of cell recovery and reinfusion promotes avoidance of allogeneic blood transfusion is not solid. A recent review of 51 published trials on cell recovery and reinfusion involving primarily cardiac and orthopedic patients revealed several methodologic problems in this area of investigation, including small numbers of study subjects, heterogeneity in transfusion practice (protocol-driven vs transfusion at the investigators' discretion), and either no reference to whether the study was blinded, or clear indications that the study was not blinded.<sup>54</sup> Despite these concerns, the authors, after applying rigorous review criteria,

**Table 37-9.** Possible Contraindications to Intraoperative Blood Recovery\*

### Pharmacologic agents

Clotting agents (Avitene, Surgicel, Gelfoam, etc)  
Irrigating solutions (Betadine, antibiotics meant for topical use)  
Methylmethacrylate  
Anticoagulants

### Contaminants

Urine  
Bone chips  
Fat  
Bowel contents

determined that use of red cell recovery and reinfusion reduced the relative risk for perioperative allogeneic RBC transfusion exposure by 39% (RR = 0.61; 95% CI, 0.52 to 0.71). Furthermore, their analysis showed a more pronounced reduction for allogeneic red cell exposure in orthopedic patients vs cardiac patients (58% compared to 23%, respectively). A critical question is whether a reduction in the relative risk for allogeneic red cell exposure equates to a meaningful reduction in volume of allogeneic red cell transfusion. Unfortunately, of the 51 studies analyzed, only 27 reported data on the volume of allogeneic red cells transfused. Based on these available data, use of cell recovery and reinfusion reduced the average number of allogeneic RBC transfusions by only 0.67 unit/patient (95% CI, 0.89 to 0.45 unit). However, when analyzed in terms of a carefully constructed economic model, the cost/benefit ratio of intraoperative recovery supported its use as an effective measure to reduce allogeneic red cell exposure.<sup>55</sup>

### Complications

Although seemingly straightforward, transfusion of recovered blood is not without potential risks, and for some clinical situations, the practice is contraindicated (Table 37-9). However, it is important to recognize that many contraindications are relative, not absolute, because there are limited data to support the danger of cell recovery in these situations.<sup>52</sup> For example, studies of tumor surgeries in which cell recovery has been employed as a blood conservation measure have not demonstrated an increase

in either incidence of metastatic disease or death, but have resulted in reduced allogeneic red cell transfusion.<sup>57-59</sup>

The literature is peppered by reports of disseminated intravascular coagulation and acute renal failure secondary to reinfusion of recovered blood that was either filtered or inadequately washed, improper use of the devices, inadvertent use of hypo- or hypertonic wash solutions resulting in compromised products, and air embolism caused by inadequate venting of collection/infusion bags.<sup>52</sup> Patient factors appear to play a major role in risk for complications; for example, concern for bacterial contamination of recovered blood is probably valid in a case of major abdominal trauma with significant bowel injury, but not as much in elective cases of abdominal surgery, where the surgical setting is much more controlled.<sup>60</sup> Similarly, the concern for renal damage secondary to hemolyzed red cells following recovery may be warranted in patients with underlying renal pathology or in patients who are hypotensive, thus at risk for suboptimal renal perfusion.<sup>60</sup> Such concerns may be more valid for postoperatively recovered blood, where hemofiltration devices are more commonly used.<sup>61</sup>

### Postoperative Autologous Blood Recovery and Reinfusion

Postoperative recovery of blood involves the collection of blood from surgical drains followed by reinfusion, with or without processing. Blood recovered by hemofiltration (in contrast to systems where recovered products are washed as part of the recovery process) can be dilute, partially hemolyzed, and contain high concentrations of cytokines and cellular debris.<sup>62-64</sup>

The safety and the benefit of the use of unwashed blood obtained from surgical drains following orthopedic surgery remain in question.<sup>65</sup> Although the results of a recent randomized clinical trial<sup>66</sup> evaluating the effectiveness and safety of postoperative recovered blood demonstrated a reduction in allogeneic transfusion in the study arm (vs control), this study was plagued by several confounding variables, including mixed surgical types with unequal randomization, lack of characterization of the recovered product, and variable transfusion thresholds.<sup>65</sup> Similar concerns about heterogeneity of study population and variable transfusion practices were also highlighted by Carless et al<sup>54</sup> in their systematic review of perioperative cell recovery and suggest the need for further study of the role of such devices in perioperative blood management.

### Summary

The blood needs of surgical patients can be managed by many alternatives to allogeneic transfusion. However, several factors (eg, patient baseline hematocrit, cardiac performance, anticipated surgical blood loss) affect their practicality of use and cost-effectiveness. Hence, effective use of these alternatives, either alone or in combination, requires the prospective identification of appropriate surgical candidates who will need transfusion and

who may truly benefit from blood conservation. The primary impetus to avoid allogeneic transfusion is no longer based on the safety of the blood supply, but rather on evidence that blood conservation is safe and of value for individual patients.

## Blood Components to Achieve Hemostasis for Surgery and Invasive Procedures

**Walter H. Dzik**

Co-Director, Blood Transfusion Service, Massachusetts General Hospital, and Associate Professor of Pathology, Harvard Medical School, Boston, Massachusetts, USA

Blood components are frequently transfused to patients undergoing invasive procedures and surgery. As illustrated by the cases below, decisions regarding transfusion before invasive procedures can be complex.

### Case 1

A 49-year-old man is transferred to your hospital because of fever, altered mental status, and thrombocytopenia (platelet count 35,000/ $\mu$ L). Because the diagnosis of thrombotic thrombocytopenic purpura (TTP) was considered by the referring institution, neither the referring physicians nor your clinical team want to administer platelet transfusions. Although a diagnostic lumbar puncture (LP) was considered important by the referring hospital, the platelet count was considered too low to safely perform an LP and so it was not done. You are called to organize plasma exchange, not only to treat the patient, but also to produce a higher platelet count so that an LP can be safely performed. *Comment: There is absolutely no evidence that a diagnostically important LP should be delayed because of a platelet count of 35,000/ $\mu$ L. In fact, there is evidence demonstrating that an LP is safe at this level of thrombocytopenia (discussed below). You recommend that the LP be done without administration of platelets. The procedure results in no hemorrhagic complication. The results of the LP demonstrate acute bacterial meningitis, the diagnosis of which was unfortunately delayed by the failure to do an important diagnostic test in a patient with fever and altered mental status. The patient does not have TTP.*

### Case 2

Following an extended period of endotracheal intubation, a 60-year-old man, currently in the intensive care unit (ICU), needs a tracheotomy tube and feeding gastrostomy tube placed at the bedside. The platelet count is 40,000/ $\mu$ L and the international normalized ratio (INR) is 1.3. The patient has either medication-related or immune-mediated consumptive thrombocytopenia and does not respond to platelet transfusions. He has recently

received intravenous immunoglobulin. You are told that the surgeon “absolutely refuses” to do the procedure without the prior infusion of four doses of platelets (equivalent to 24 units) with an additional two doses available to “run in” during the procedure. You are also supporting the transfusion needs of a trauma patient (gunshot wound) currently in the operating room (OR); another OR patient who is receiving a heart transplant; and a patient who is scheduled for an aortic aneurysm repair later this evening. You have 12 doses of platelets available and inform the ICU team that you cannot commit six doses of platelets to a bedside tracheotomy-gastrostomy case. The medical ICU team replies that your decision will mean that the patient will not receive his urgently needed tracheotomy and they request that you come up to the floor to explain to a concerned family why you are denying the patient his essential care. *Comment: There is no evidence that the request for preprocedure platelets is medically justified. The use of infusions “run in” during the procedure is largely theatrical. You are correct to manage a limited inventory of platelets by assigning them to active surgical patients who are more likely to benefit from platelet transfusions. The response of the medical ICU team, who attempt to twist the dynamic implying that you are denying the patient essential care, is completely inappropriate. Nevertheless, this sort of attempted coercion occurs commonly. You discuss the issue with the individuals assigned to do the tracheotomy and review with them the published risks on bleeding (described below). Weighing the risks and benefits, they decide to proceed with the bedside tracheotomy and gastrostomy without any preprocedure blood infusions. The procedure goes smoothly with an estimated blood loss of <10 mL.*

### Case 3

A previously healthy 64-year-old man with pneumonia and sepsis requires placement of a central line for hemodynamic monitoring and vascular access. The patient has an INR of 1.6. Because of hypoxia, decreased urine output, and presumed decreased left ventricular performance, circulatory overload is a concern. Despite this, the presiding house-staff physician requests 4 units of fresh frozen plasma (FFP) to “correct the coagulopathy” before central line placement. When you question this decision, the house-staff member acknowledges that he

is “nervous” about placing the line and that “he would feel more comfortable if the patient got FFP first.” *Comment: There is no evidence that preprocedure FFP will benefit this patient undergoing central line placement. Transfusion of this patient, for whom volume overload is a legitimate concern, in order to increase the comfort level of the physician is not appropriate.*

## Current Challenges

As illustrated by the cases presented above, three basic challenges confront our understanding of the proper transfusion support of patients undergoing surgery or invasive procedures. First, there is no consensus on what extent of bleeding should be prevented or should demand treatment. For example, no clinician would transfuse a patient to prevent or to “treat” a 2-cm superficial skin hematoma at the site of insertion of a central venous catheter. While such procedure-related bleeding is not desirable, it is acceptable and represents largely a temporary cosmetic adverse event of little consequence. In contrast, all clinicians would wish to avoid a hemothorax resulting in a collapsed lung, transfusion of 4 units of Red Blood Cells (RBCs), and placement of a chest tube for drainage. The challenge is to understand where the degree of reasonable and acceptable bleeding ends and where the extent of excessive bleeding begins. How much bleeding is acceptable differs for patients depending upon their entire medical status, the nature and urgency of the procedure, and the expected benefit to be gained. The amount of acceptable bleeding differs for each anatomic site. Opinions about excessive bleeding are also influenced by each clinician’s experience and expectations.

A second challenge in transfusion support is the contrast between the use of blood components for *prevention* of bleeding and the use of blood therapies for the *treatment* of bleeding. Although transfusions given as therapy to bleeding patients have an unquestionable rationale, the same cannot be said for transfusions given to prevent bleeding before surgery or invasive procedures. Blood components given before an invasive procedure are likely to benefit patients who have severe derangements of hemostasis or who offer a clear history of bleeding complications following similar procedures. However, blood component therapy given to patients before procedures solely on the basis of abnormal laboratory tests is of uncertain value. Indeed, there is scant medical evidence, if any, that preprocedure therapies are of any benefit when given to patients with mild to moderate abnormalities of laboratory tests of hemostasis. There is also no evidence that a prophylactic strategy is superior to a treatment-of-bleeding strategy. From a risk-to-benefit perspective, prophylactic transfusion strategies can verge on the absurd. Most clinicians have witnessed patients receiving 10 units of platelets and plasma in an attempt to avoid the potential loss of one-tenth of one unit of blood, a hemorrhage that would not have required treatment had it occurred. Nevertheless, prophylactic infusion of blood components is an extremely common medical practice. If indeed prophylactic treatments are of no value for most patients, and if such

treatments cause their own complications in a fraction of recipients, then large numbers of individuals are suffering adverse consequences of such treatments with no attendant benefit.

A third challenge in the area of procedure-related bleeding is to understand the relative value of blood component therapies compared with other agents that promote hemostasis. Although transfusions of platelets or FFP are often used, some patients would fare better were they to receive topical hemostatic agents, medications such as fibrinolytic inhibitors, or ligation of a bleeding vessel by a well-placed suture.

Thus, the decision-making for each patient should consider the following three questions: 1) What extent of bleeding is acceptable? 2) What is the evidence to suggest that any treatment should be given before the procedure? and 3) What is most appropriate therapy to achieve hemostasis? An overview of these considerations is shown in Fig 38-1.

## Preprocedure Blood Components as Prophylaxis Against Bleeding

The last decade has seen explosive growth in the number and variety of invasive procedures performed outside of the OR. In fact, far more invasive procedures are performed outside the operating room than within the OR. Many patients who undergo invasive procedures will have abnormalities on routine laboratory tests of hemostasis. It is very common, although medically unproven, for clinicians to administer blood components to such patients in the expectation of reducing the risk or severity of procedure-related bleeding. The decision to transfuse blood components as prophylaxis before a bedside procedure is subject to three major criticisms.

### Mild-to-Moderate Abnormalities of Common Laboratory Tests Do Not Identify Patients at Increased Risk of Procedure-Related Bleeding

In an excellent review of hemostasis during surgery,<sup>1</sup> Kitchens summarizes the predictive value of coagulation screening tests in three large survey studies representing nearly 4500 patients.<sup>2-4</sup> These studies found that, in the absence of any history of bleeding, the positive predictive value of an abnormal coagulation screening test as a means to forecast bleeding was only 3%. Thus, the great majority of patients (97%) with abnormal coagulation screening tests will have no increased bleeding at surgery. In a systematic review of the published evidence that a prolonged INR would predict bleeding at the time of an invasive procedure, Segal and Dzik<sup>5</sup> found no evidence to conclude that abnormal preprocedure test results should be used as an indication to transfuse blood components. A similar conclusion was drawn by Holland and Sarode.<sup>6</sup>

A common clinical error is to declare that a patient has a coagulopathy because the patient has an abnormal INR or activated partial thromboplastin time (aPTT). This error is epidemic and patients are routinely referred to as “coagulopathic” based

**Figure 38-1.** Overview of blood support for surgery and invasive procedures.

**Figure 38-2.** The nonlinear relationship between the concentration of coagulation factors and coagulation test results. The concentration of factors (y-axis) is shown as a function of the international normalized ratio (INR) or prothrombin time (PT, in seconds). In general, a concentration of 30% is adequate for biologic hemostasis. Note that when starting at an elevated INR, a small increase in the concentration of factors will have a large impact on the measured INR. In contrast, an equivalent rise in the concentration of factors will have a negligible effect on mildly elevated INR values. The curve is a generalized view and will vary for individual patients.

solely on an elevated laboratory test. Clinicians will claim that the indication to transfuse blood was “to correct the patient’s coagulopathy.” Each of these commonly expressed viewpoints fails to consider evidence that an abnormal laboratory test does not, by itself, imply a breakdown in physiologic hemostasis. Indeed, mild to moderate prolongations of the INR or aPTT are completely consistent with normal hemostasis. This is because of the physiologic reserve of coagulation factors and the fact that the laboratory tests are designed to give results outside the range of normal *before* factor deficiencies reach levels of significant physiologic depletion.<sup>7</sup> See Fig 38-2.

Six aspects of the INR and aPTT make these tests poor predictors of hemorrhage.

1. *The relationship between coagulation factors and the prothrombin time (PT) and aPTT is nonlinear.* The exponential relationship between the concentration of clotting factors and the test result is shown in Fig 38-2. This relationship may not be fully appreciated by those who expect a simple dose-response effect from infusion of clotting factors.

2. *Mildly abnormal test results occur among patients with biologically normal coagulation.* In the same way that physiologically adequate tissue oxygenation does not require that the

hemoglobin concentration be in the normal range, physiologic hemostasis does not require that the INR or aPTT value be in the normal range.

**3. INR and aPTT tests overestimate deficiencies in the upper limb of the cascade and underestimate deficiencies in the lower limb.** The INR assay is dominated by the level of Factor VII in the sample. Patients who have mildly reduced levels of Factor VII that are well within the range for adequate hemostasis and who have normal levels of other factors, will have a prolonged INR result. Reduced, but adequate, levels of Factor VII are very common in hospitalized patients because of decreased hepatic synthesis, vitamin K depletion, antibiotics, subclinical impairment of the enterohepatic circulation, and catabolic states with decreased protein synthesis. A very common flaw in the literature is to equate correction of the INR with correction of a hemostatic defect. This misunderstanding has given undo merit to “treatments” that elevate the Factor VII level and produce a dramatic effect on the INR regardless of whether they improve physiologic hemostasis. The same principle is true for the aPTT.

**4. The tests overestimate the extent of coagulation factor depletion if more than one factor is reduced.** Burns et al<sup>8</sup> observed the following in a series of clever in-vitro mixing studies: When plasma containing 50% activity of a single clotting factor was mixed with an equal volume of normal plasma (yielding a mixture with 75% activity of the single deficient factor), the INR and aPTT of the mixture was normal. However, when two plasma samples, each deficient in different factors, were combined with normal plasma samples such that the resulting mixture contained 75% activity of two coagulation factors and 100% of the rest, the resulting INR and aPTT values were prolonged. Thus, for patients with multiple mild factor deficiencies—such as those with liver disease or vitamin K depletion—coagulation tests are prolonged out of proportion to the degree of hemostatic defect that would be assumed based on inherited single-factor deficiencies. With multiple mild deficiencies, patients with factor levels well within the range of normal will show abnormal test results.

**5. Whereas the INR and aPTT are useful tests to analyze the defect in patients with disorders of fibrin formation, neither test was designed to predict bleeding.** Given that clinical hemostasis depends on the complex interrelationships between the blood vessel wall, cellular elements of the blood, platelet number and function, fibrin formation, and fibrinolysis, it is not surprising that the INR and aPTT prove unable to predict who will bleed during surgery. The uncertainty that attends any invasive procedure is stressful for clinicians. This stress coupled with the understandable strong desire to prevent bleeding complications may have seduced clinicians into conferring upon these laboratory tests the power to foresee the future—a power they never have had, and never will.

**6. Most important, these tests are insufficient to assess global hemostasis.** The INR and aPTT focus on fibrin formation in vitro using a highly artificial assay, rabbit brain extracts, synthetic phospholipids, and without the contribution from biologically important molecules such as protein C and thrombomodulin.

**Figure 38-3.** “Box-and-whiskers” plot of the median change in international normalized ratio (INR) resulting from transfusion of Fresh Frozen Plasma (FFP). The change in INR measured within 8 hours of transfusion of FFP is shown. All patients had INR values  $<1.7$  before transfusion. Used with permission from Abdel-Wahab.<sup>10</sup>

This can lead to incorrect conclusions regarding hemostasis. For example, Mannucci et al<sup>9</sup> have shown that thrombin generation in patients with cirrhosis is incorrectly measured by standard INR and aPTT tests.

### FFP Given Before a Procedure Fails to Correct the Abnormal Coagulation Test Result

For patients with mild to moderate prolongation of the INR or aPTT, there is ample evidence to demonstrate that routine doses of FFP fail to “normalize” the coagulation test. This fact does not prove, by itself, that such transfusions have no value. Rather, the observed findings challenge the commonly expressed opinion that the indication for preprocedure FFP is “to correct” the “coagulopathy” as demonstrated by an elevated INR. Abdel-Wahab and colleagues<sup>10</sup> reported the effect of FFP on the INR in 121 patients transfused with 324 units of FFP. All patients had INR values ranging from 1.1 to 1.85 before transfusion and repeat INR values measured within 8 hours of receiving 1 to 6 units of FFP. Transfusion of FFP resulted in normalization of INR values in  $<1\%$  of patients and decreased the INR value half-way to normal in 15% of patients. The median decrease in INR as a result of transfusion was a negligible 0.07. See Fig 38-3.

Holland and Brooks<sup>11</sup> extended these findings to a larger cohort of adult and pediatric patients treated at the University of Oklahoma. They observed that transfusion of FFP had no effect on the INR values for patients with INRs in the range of 1.7. At higher levels of INR before transfusion, FFP exerted an effect. The effect of a unit of FFP on the INR was linear ( $r^2 = 0.82$ ) for INR values above 1.7 and was represented by an INR change of 0.37 to 0.47. Thus, for a patient with an INR equal to 3, each unit of FFP would be expected to reduce the INR by 0.64. Other studies have also found that FFP fails to normalize laboratory tests.<sup>12-17</sup>

The effect of FFP transfusion on the INR is seen in Fig 38-2. Because the volume of distribution of different

coagulation factors is larger than the intravascular space, 2 units of FFP would be expected to increase the concentration of coagulation factors by 5% to 15%. When the pretransfusion INR is below 1.7, a 10% increase in coagulation factors will have a trivial effect on the measured PT. This fact leads to the following common sequence of events. Because a patient's INR exceeds the local threshold value, FFP is infused and a bedside procedure is performed without checking for any effect of transfusion on the INR. The procedure goes smoothly and the successful outcome is attributed to the transfusion. However, had the INR been measured after the FFP infusion, the clinician would have observed that the posttreatment INR was still above the clinician's own personal threshold. This simple finding combined with the successful procedure outcome makes two points: first, that the treatment failed to "correct" the abnormality; and second, that the procedure was safely performed despite an INR value that was above the clinician's own personal threshold.

*There is no evidence that prophylactic transfusions given before an invasive procedure will limit the extent of bleeding more effectively than therapeutic transfusions given after a procedure.* Kitchen's review noted that only 3% of patients with abnormal coagulation screening tests actually experience surgery-related bleeding. If one were to accept the undocumented opinion that 4 units of FFP and 6 units of platelets given before a procedure would actually decrease the extent of bleeding at the time of the procedure, then 100 candidate patients with abnormal tests would collectively require 1000 units of components as preprocedure prophylaxis. Of these 100 patients, 97 would receive transfusion unnecessarily, encountering a fixed transfusion risk for no benefit. Alternatively, if no preprocedure products were infused, then three patients would experience bleeding that could then be treated with blood components. For the same resource, each one of these three patients would have available as many as 133 units of FFP and 200 units of platelets per patient, representing a quantity of blood support that would certainly be more than adequate to treat bleeding. Thus, from the perspective of both the patient who bleeds and the patient who does not bleed, it would seem that treating well the patient who is actually bleeding is more valuable than an approach that transfuses the vast majority of blood components to individuals who do not need them.

### Toxicity Resulting from Preprocedure Transfusions

If the benefit from prophylactic transfusions is negligible, then even small transfusion risks drive risk-to-benefit considerations away from prophylactic transfusion. Recent studies highlight the susceptibility of ICU patients to toxicities of transfusion. These patients frequently undergo bedside procedures and receive preprocedure transfusions. Khan et al<sup>18</sup> published an important paper documenting that FFP and platelet transfusions are associated with the development of acute lung injury in ill medical patients. They studied 841 consecutive critically ill patients admitted to intensive care at the Mayo Clinic. Of these, 298 (35%) were transfused. Acute lung injury developed more

commonly (25% vs 18%,  $p = 0.025$ ) in transfused patients. Transfused patients remained two-fold more likely to develop acute lung injury than nontransfused patients even when other risk factors for lung injury were accounted for. Of interest, the risk of lung injury was associated with transfusion of FFP or platelets rather than RBCs. Because other studies<sup>19</sup> have found that the most common indication for FFP outside of surgery was prophylaxis before an invasive procedure, the findings of Khan et al underscore the potential adverse effects on critically ill patients from unnecessary exposure to FFP and platelets.

A follow-up study from the same medical center confirmed concerns that FFP and platelet transfusions were associated with acute lung injury in intensive care patients. Gajic et al<sup>20</sup> reported on 901 transfused patients. Of these, an astounding 74 (8%) developed objective signs of acute lung injury within 6 hours of transfusion. When adjusted for patient characteristics, the risk of transfusion-related acute lung injury (TRALI) was significantly higher for each of the following blood donor characteristics: female donor, history of multiple pregnancies, positive test for granulocyte or HLA antibodies, and concentration of phosphatidylcholine in the product. This paper suggests that TRALI is far more common among intensive care patients than has been previously recognized. The high frequency of TRALI in susceptible patients should, by itself, call for a reappraisal of the risk-to-benefit ratio surrounding the transfusion of blood components to nonbleeding patients.

## Preprocedure Bleeding Risk for Specific Bedside Procedures

### Central Venous Catheter Insertion

Serious complications of central venous catheter placement are rare and include pneumothorax, air embolus, and hemothorax.<sup>21</sup> Significant bleeding following subclavian vein catheterization occurs in patients with perfectly normal hemostasis and results from inadvertent laceration of the subclavian artery.<sup>22</sup> Among patients with advanced liver disease, the insertion of a central venous catheter for transvenous hepatic biopsy provides an excellent model to demonstrate the failure of abnormal coagulation tests to predict bleeding complications at the time of central line placement. Goldfarb and Lebec<sup>23</sup> reported results on central line insertions in 1000 consecutive patients with liver disease, all of whom had abnormalities of laboratory coagulation tests. Only one patient experienced a significant hematoma. Foster et al<sup>24</sup> performed central line insertions on 259 patients with advanced liver disease awaiting transplantation. All patients had serious laboratory derangements including a mean platelet count of 49,000/ $\mu$ L, aPTT equal to 97 seconds, and INR mean of 2.0. No preprocedure products were given and no important bleeding complications occurred.

In an interesting report by Petersen et al,<sup>25</sup> 516 consecutive patients received internal jugular cannulations before cardiac surgery. Of these, 252 (49%) were deliberately fully

anticoagulated with heparin before surgery with a target aPTT of 1.5 times control. Central lines were placed while the patients were anticoagulated. For another 264 patients, anticoagulation was reversed before line insertion. An observer, unaware of the anticoagulation status of each patient, assessed the insertion site. Of the 22 hematomas observed, 13 were found in anticoagulated patients and nine were in nonanticoagulated persons. None of the patients with hematomas required treatment beyond topical care. Of note, among 22 episodes of inadvertent puncture of the carotid artery, the incidence of subcutaneous hematoma formation was the same in both the anticoagulated patients (four of 12 patients with carotid puncture) and the nonanticoagulated patients (three of 10 patients with carotid puncture).

Fisher et al<sup>26</sup> reported results among 658 cannulations that were evenly balanced among internal jugular and subclavian vein insertions. All patients had advanced liver disease and abnormal coagulation tests. The median INR was 2.4 (range, 1-16) and the median platelet count was 81,000/ $\mu$ L (range, 9000-1,088,000/ $\mu$ L). In 580 cases, the INR was  $>1.5$ ; in 531 cases the platelet count was  $<150,000/\mu$ L; and in 453 cases both abnormalities were present. Preprocedure FFP or platelets were not given routinely. One patient, with near normal coagulation tests, had a bleeding complication attributed to technical mishap. Superficial skin hematomas and mild oozing at the puncture site were observed. Logistic regression analysis identified INR values  $>5.0$  ( $n = 137$ ) or platelet counts  $<50,000/\mu$ L ( $n = 146$ ) as statistically associated with a higher incidence of superficial hematomas or site oozing, respectively. The greatest predictor (odds ratio, 8.0) of a procedure-related hematoma was a failed guidewire attempt ( $n = 54$ ). This paper underscored the fact that technical mishaps remain the dominant cause of hematoma formation, and that bleeding complications other than skin hematoma or oozing are rare regardless of the coagulation test results. The paper suggests that patients with an INR  $>5$  or a platelet count  $<50,000/\mu$ L are at a higher risk for simple skin hematoma or oozing following central line placement. Similar studies documenting that

abnormal screening tests are not an indication for preprocedure FFP or platelet transfusions were reported by others.<sup>27-29</sup>

## Liver Biopsy

Closed liver biopsy has generally been considered one of the higher risk bedside invasive procedures. Several features may account for this reputation: patients with liver disease often have multiple derangements of coagulation tests and are known to have truly impaired global hemostasis; biopsies are performed without the aid of direct pressure on the wound site; patients undergoing biopsy may have vascular malignancies. Indeed, sensitive studies using ultrasound analysis have detected small intrahepatic hematomas in as many as one-quarter of the patients who undergo a liver biopsy.<sup>30</sup> For these reasons, there is a strong desire to identify which patients are at increased risk for bleeding. Some programs will not perform closed biopsies on patients with certain locally determined abnormalities of hemostatic screening tests. These patients may receive an open surgical biopsy, a transjugular biopsy, a laparoscopic biopsy,<sup>31</sup> or a biopsy followed by gelfoam plugging.<sup>32</sup>

More than 25 years ago, Ewe et al<sup>33</sup> performed an informative and unique study in which patients underwent liver biopsy using a laparoscope. Following the procedure, the investigators left the laparoscope in place and measured the duration of bleeding from the site of the biopsy. Among 200 consecutive patients with a variety of nonmalignant liver disorders, most patients had at least one abnormal coagulation test but none were treated with blood components before the procedure. The study showed that there was no correlation between the length of time the liver bled after puncture and the preprocedure laboratory values. See Fig 38-4.

Terjung et al<sup>34</sup> reviewed bleeding outcomes among 629 percutaneous liver biopsies performed in 574 patients. No patient had a severe derangement of clotting tests, but some patients had INR values as high as 1.4 and platelet counts below 60,000/ $\mu$ L. Preprocedure transfusions were only rarely given (4%). Bleeding

**Figure 38-4.** Lack of correlation between bleeding from the site of liver biopsy and preprocedure coagulation test or platelet count. The duration of bleeding from the site of puncture of the liver (y-axis) is plotted as a function of the preprocedure platelet count (left-hand panel) or the preprocedure coagulation test (expressed as % activity, right-hand panel). There is no correlation between preprocedure laboratory test results and the duration of bleeding. Used with permission from Ewe.<sup>33</sup>

was defined as: “clinically overt” ( $n = 10$ , 1.6%); a postprocedure decline in hemoglobin  $>2\text{ g/dL}$  ( $n = 45$ , 7.1%); or a hematoma detected after the procedure among 292 patients receiving ultrasound ( $n = 31$ , 11%). Using multiple logistic regression analysis, no correlation was found between bleeding risk and the mild to moderate abnormalities in the preprocedure INR, aPTT, platelet count, or bleeding time.

In a prospective study, Makris et al<sup>35</sup> measured INR, aPTT, thrombin time, fibrinogen, bleeding time, and platelet count in 104 patients before liver biopsy. All patients underwent computed tomography scanning 24 hours after the procedure to assess bleeding. More than 50% of patients had one or more abnormalities of laboratory screening test results. INR values ranged as high as 2.0 and platelet counts were as low as 50,000/ $\mu\text{L}$ . Only two patients demonstrated procedure-related bleeding and both of these had *normal* preprocedure laboratory test results.

Other studies examined the role of preprocedure laboratory testing or preprocedure infusion of blood components to prevent bleeding. All studies (except one) found no evidence for the predictive value of screening tests or the clinical value of preprocedure blood component prophylaxis.<sup>36-40</sup> One study suggested that a prolonged preprocedure skin bleeding time assay was associated with bleeding after biopsy, but this small study involved only nine patients with bleeding, three of whom had received marrow transplants.<sup>41</sup>

Given the strong (albeit unfounded) reliance on the INR as a key measure of hemostasis in liver disease and given the dependence of the INR test on Factor VII, it is not surprising that investigators might explore the role of recombinant Factor VIIa given before liver biopsy. Jeffers et al<sup>42</sup> studied 63 patients with a mean INR of 2.0 who received recombinant Factor VIIa in doses ranging from 5 to 120  $\mu\text{g/kg}$  10 minutes before biopsy. Hemostasis at 10 minutes failed in 30% of patients, most of whom were given a postprocedure dose of 80  $\mu\text{g/mL}$ . No toxicity was observed. This study unfortunately lacked a control group and no follow-up testing for hematoma formation was performed. Although the ability of recombinant Factor VIIa to improve the INR in patients with liver disease is undeniable, the fundamental question is whether preprocedure treatment with it is superior to treatment with FFP or to no treatment at all. This would be best answered in a prospective, randomized, controlled clinical trial. The evidence for and against the use of recombinant Factor VIIa for patients without hemophilia was reviewed in a recent Cochrane report.<sup>43</sup>

### Thoracentesis and Paracentesis

Given the lack of evidence in favor of preprocedure transfusions for central venous catheter placement or for closed liver biopsy, it is not surprising that published evidence also fails to support the use of preprocedure prophylaxis for less invasive procedures such as thoracentesis or paracentesis. McVay and Toy<sup>44</sup> reported a retrospective review of outcomes in 608 consecutive procedures (391 paracenteses, 207 thoracenteses, and 10 both procedures). Patients were not transfused before the procedure.

No patient had serious bleeding. The proportion of procedures that were accompanied by a decline in hemoglobin was the same in the group with normal INR/aPTT values as in the group with abnormal INR/aPTT values. A decline in hemoglobin following the procedure also did not correlate with the preprocedure platelet count. The change in hemoglobin was not different among 87 patients with both thrombocytopenia and prolonged coagulation times compared to those with normal values.

Bleeding following paracentesis was examined by Webster et al,<sup>45</sup> who reported a retrospective analysis of 179 outpatients. Four patients developed intra-abdominal or abdominal wall bleeding that required a transfusion of RBCs. The INR values of these four were indistinguishable from those of the 175 patients who did not bleed.

### Gastrointestinal Endoscopy and Biopsy

The use of aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs) and procedure-related bleeding was addressed by Shiffman et al.<sup>46</sup> Of 694 patients who underwent either upper endoscopy with biopsy or colonoscopy with biopsy or polypectomy, half had recently taken either aspirin or NSAIDs. Four patients had serious bleeding requiring hospitalization or treatment—two in the group taking NSAIDs/aspirin and two in the group not taking these medications. After colonoscopy, minor bleeding requiring no therapy was significantly more common in the group taking NSAIDs (6%) than among those taking no medication (2%) (odds ratio, 3).

### Procedures on the Upper Airway, Bronchoscopy, and Transbronchial Lung Biopsy

Special care to provide good hemostasis is prudent when procedures are being performed on the oropharynx, trachea, or bronchi, given that excessive bleeding can be rapidly fatal. Tonsillectomy was an early subject for studies assessing preoperative screening. As with other surgical procedures, the predictive value of an isolated abnormal coagulation screening test for bleeding at tonsillectomy or adenoidectomy is very poor. The majority of patients who bleed during these procedures have normal presurgical tests.<sup>47,48</sup>

Tracheotomy is commonly performed in very ill patients in intensive care, many of whom may have abnormal laboratory tests for coagulation. Auzinger et al<sup>49</sup> partially addressed the approach to such patients in a prospective study of procedure-related bleeding in a cohort of 60 patients with severe liver disease undergoing percutaneous tracheotomy. Patients ranged in age from 18 to 60 years of age and had high severity of illness scores. All but two patients had derangements of laboratory coagulation tests or platelet count. Coagulation abnormalities could not be corrected in 25 patients and 13 patients had platelet counts  $<30,000/\mu\text{L}$ . Only one patient had excessive bleeding (defined as  $>150\text{ mL}$ ), which was external (extratracheal). No patient required open surgical revision. Kluge et al<sup>50</sup> reviewed a 6-year experience with tracheotomy performed in 42 patients with thrombocytopenia. The mean platelet count was 26,000/ $\mu\text{L}$ .

Two patients (<5%) demonstrated excess bleeding. Beiderlinden and colleagues<sup>51</sup> found a low incidence of procedure-related bleeding in 136 patients of whom 18 were known to have a significant coagulopathy. Similar results were found by Ben Nun et al<sup>52</sup> who reported the absence of significant procedure-related bleeding in 157 patients of whom 12 had coagulation abnormalities that could not be normalized despite factor replacement or cessation of anticoagulation. Although these studies all include small numbers of patients with abnormal coagulation tests and do not exclude the possibility that bleeding complications might be slightly higher among patients with measured defects in coagulation, the publications taken together certainly refute the notion that mild to moderate prolongation of the INR or aPTT or mild to moderate thrombocytopenia represent absolute contraindications to safe tracheotomy.

Bronchoscopy and biopsy was directly addressed in an early study by Kozak and Brath.<sup>53</sup> They reviewed 274 patients undergoing 305 fiberoptic bronchoscopy and biopsy procedures at a tertiary care institution. Abnormal coagulation screening tests were found in 10% (n = 28) of patients. Overall, 35 patients bled, and 32 of these had normal preprocedure laboratory values. Three patients had severe bleeding and each of them had normal preprocedure test results. Although the authors noted no utility for prebronchoscopy tests of hemostasis, the number of patients with defined hemostatic abnormalities was too few to develop risk ratios with small confidence intervals (CIs). Further evidence that preprocedure coagulation tests are not a suitable guideline for preprocedure transfusion comes from the work of Diette et al.<sup>54</sup> They reported a retrospective review of 720 fiberoptic bronchoscopies performed over a 1-year period at Johns Hopkins. Using multivariate analysis, they found that bleeding did not correlate with coagulation parameters or platelet count, and that performing a transbronchial biopsy did not independently increase the risk of bleeding. Postprocedure hemoptysis and bleeding (>25 mL) were associated with prior lung transplant (odds ratio, 3.4; 95% CI, 1.3-8.6) and long procedure time (odds ratio, 2.5; 95% CI, 1.2-5.0). The higher incidence of bleeding among lung transplant recipients may relate to anatomic causes such as fragile tissue from poor nutrition or chronic exposure to steroids, mucositis from immune suppression and superinfection, or elevated pulmonary vascular pressures. Bjortuft et al<sup>55</sup> monitored blood loss following 105 consecutive transbronchial lung biopsies and found no correlation with the INR, aPTT, bleeding time, or platelet count. Herth et al<sup>56</sup> studied whether aspirin ingestion increased the extent of bleeding at the time of bronchoscopy and transbronchial lung biopsy. Of 1217 patients, 285 were taking aspirin at the time of the procedure. Bleeding complications occurred in 57 patients (4.7%). The incidence of minor (1.8 vs 2.9%), moderate (1.1 vs 1.4%), and severe (0.8 vs 0.9%) bleeding was not statistically different in those who took aspirin and those who did not. This report provides clinical evidence that there is no requirement to discontinue aspirin ingestion before transbronchial biopsy, nor is the history of recent or current aspirin use an appropriate indication for preprocedure

platelet transfusion. Laboratory tests failed to correlate with bleeding in a separate report by Weiss et al.<sup>57</sup>

In an interesting animal study, Brickey et al<sup>58</sup> did transbronchial biopsies in 18 swine who were treated with escalating doses of warfarin. The object of the study was to determine the INR level at which excess bleeding would occur following the invasive procedure. Excess bleeding was defined as  $\geq 100$  mL blood loss among  $\geq 50\%$  of animals. To the surprise of the investigators, the warfarin-treated animals did not develop excessive postprocedure bleeding despite the fact that 11 of the 18 animals had INR levels >7 at the time of the biopsy. Three highly anticoagulated animals died from spontaneous, nonpulmonary hemorrhage from ruptured ovarian cysts. The authors concluded that INR elevation did not correlate with bleeding following transbronchial lung biopsy in this animal model.

### Renal Biopsy

Davis and Chandler<sup>59</sup> examined the predictive value of hemostasis tests obtained before biopsy of renal allografts. It should be noted that a renal allograft is placed in the pelvic area close to the skin surface and is accessible to biopsy. The template bleeding time, INR, aPTT, platelet count, and thromboelastograph results were examined in 120 patients. Bleeding was defined either as  $\geq 4\%$  decline in hematocrit or as ultrasound evidence of a perirenal hematoma. Overall, 21% of patients showed evidence of mild bleeding, two showed evidence of hematoma on ultrasound, and none required transfusion for bleeding. Most patients with bleeding had normal test results before biopsy. A weakness of this study is that only a few patients had moderate to severe abnormalities of coagulation. Procedure-related bleeding among 70 patients with combined liver and kidney disease who underwent transjugular renal biopsy was reported by Jouet et al.<sup>60</sup> The published literature is not sufficient to draw any strong conclusions regarding hemostatic defects and bleeding at the time of renal biopsy. Because patients undergoing a renal biopsy may have platelet dysfunction from renal insufficiency, it would seem that desmopressin might be a very useful agent to administer before biopsy.

### Epidural Anesthesia, Diagnostic Lumbar Puncture, Neurosurgical Procedures

Because bleeding in the closed space of the subarachnoid or epidural region can produce paraparesis or paraplegia following lumbar puncture, avoiding preventable bleeding is more important for lumbar punctures and epidural anesthesia than for most invasive procedures.

Nevertheless, several studies provide evidence that thrombocytopenia is not a major contraindication to diagnostic LP. Howard et al<sup>61,62</sup> reported an extensive experience with >5000 LP procedures performed in 958 children with leukemia. These children received repeat LPs for administration of intrathecal chemotherapy. Despite the fact that platelets in these children may have been dysfunctional because of leukemia or antibiotics, there were few hemorrhagic complications. Some 170 LPs were performed in patients with platelet counts between 10,000 and 20,000/ $\mu$ L;

742 LPs were performed in patients with platelet counts between 20,000 and 50,000/ $\mu$ L; and 858 LPs were performed in patients with platelet counts between 50,000 and 100,000/ $\mu$ L. Platelet transfusions were not given before the procedure. No patient developed spinal hematoma or a clinical bleeding complication. The authors defined a “bloody” LP as one with  $>500$  red cells/ $\mu$ L. In contrast, normal blood has  $\sim 5 \times 10^6$  red cells/ $\mu$ L. Using this very conservative definition of procedure-related bleeding, they noted that the likelihood of finding  $>500$  red cells/ $\mu$ L in the spinal fluid was slightly higher in patients with platelet counts  $<100,000/\mu$ L compared to those with counts  $>100,000/\mu$ L (odds ratio, 1.5; 95% CI, 1.2-1.8). However, among patients with counts  $<100,000/\mu$ L, the likelihood of an LP with  $>500$  red cells/ $\mu$ L did not increase as the platelet count declined to levels as low as 10,000/ $\mu$ L. The authors concluded that a platelet count of 10,000/ $\mu$ L was adequate to perform a routine LP for administration of intrathecal chemotherapy. A smaller but similar retrospective study extended these same conclusions to adults with leukemia. Vavricka et al<sup>63</sup> reviewed records of 195 LPs performed on 66 adult patients (age 18-68) over a 6-year period. No patient developed spinal hematoma or clinical hemorrhagic complications. As found by Howard et al,<sup>61,62</sup> patients with platelet counts  $<100,000/\mu$ L were more likely to have microscopic bleeding ( $>500$  red cells/ $\mu$ L). The authors recommended that prophylactic transfusions be given only if the platelet count were  $<20,000/\mu$ L. These studies provide evidence that an LP, if of diagnostic importance, should not be delayed or withheld because of thrombocytopenia.

Other studies, with smaller numbers of patients, also found no relationship between hemorrhagic complications of LP and the platelet count. For example, Waldman et al<sup>64</sup> used a small (25-gauge) needle to administer morphine via a caudal block to 19 patients with platelet counts  $<50,000/\mu$ L without bleeding complications. Rasmus et al<sup>65</sup> reported that none of 14 women with platelet counts ranging from 15,000/ $\mu$ L to 100,000/ $\mu$ L developed complications from epidural anesthesia given at the time of childbirth. Hew-Wing et al<sup>66</sup> reviewed the literature on the issue of epidurals and thrombocytopenia and could find no case report of a thrombocytopenic patient who developed a hematoma after epidural anesthesia. However, they did identify one report of eight cases of spinal subdural hematoma complicating LP among leukemia patients.<sup>67</sup>

In contrast to thrombocytopenia, the chance of peridural hematoma appears to be increased among patients with full-dose anticoagulation who undergo placement or removal of an epidural catheter for spinal anesthesia. In patients with low-dose anticoagulation undergoing vascular surgery, Rao and El-Etr<sup>68</sup> did not find evidence of epidural hematomas following placement of either an epidural catheter ( $n = 3164$ ) or a subarachnoid catheter ( $n = 847$ ) using a 17-gauge needle. The mean heparin dose was 10,500 units per 24 hours. Catheters were left in the spinal space for 24 hours and were then removed while patients were still being treated with heparin. No patients developed peridural hematomas. In a similar manner, low-dose heparin was not associated with spinal hematoma in over 5000 patients

undergoing spinal or epidural anesthesia.<sup>69</sup> However, with full-dose anticoagulation, the risk may increase. For example, Ruff and Dougherty<sup>70</sup> reported five cases of paraplegia among 342 patients who received a diagnostic LP and then were administered full-dose heparin (exact dose not stated). In addition, the introduction of low-molecular-weight heparin treatment in the United States was accompanied by an observed increase in reported spinal hematomas among patients with epidural catheters, estimated to occur at a rate of 1 in 10,000 patients.<sup>71</sup>

In this author's experience, neurosurgeons are often strong advocates for preprocedure transfusions before invasive procedures. Some neurosurgeons will flatly refuse to perform procedures they believe to be otherwise clinically indicated solely based on mild to moderate abnormalities of the preprocedure laboratory results. Against this position is the report by Schramm et al<sup>72</sup> who reviewed outcomes among 1211 patients having neurosurgical procedures at the Royal Melbourne Hospital in Australia. Consecutive neurosurgical procedures were examined for a period of 1 year to identify preoperative risks for bleeding. The authors tabulated not only clinical features such as the presence of malignancy or renal failure, liver disease, trauma, history of alcohol use, malabsorption, history of prior surgical bleeding, and medications, but also results of laboratory tests including the INR, aPTT, and platelet count. Three groups of surgical procedures were examined: craniotomies ( $n = 675$ ), spinal surgeries ( $n = 400$ ), and other ( $n = 136$ ). The authors found that 17% of preoperative laboratory tests were abnormal. Using logistic regression analysis to identify factors associated with bleeding, they found that neither prolongation of the INR nor depression of the platelet count predicted excessive surgical bleeding. However, two independent predictors of bleeding were found. First, procedure-related bleeding was associated with a small percentage of patients ( $n = 14$ ; 1%) who gave a history of bleeding and who demonstrated a prolonged aPTT (odds ratio = 24; 95% CI, 4-150). These patients may have had von Willebrand disease. Second, procedure-related bleeding was found among a larger number of patients ( $n = 675$ ; 56%) in association with craniotomy regardless of all other factors examined (odds ratio, 10; 95% CI, 2-54).

### Angiography

The increasing use of interventional radiology and cardiology has created a new cohort of patients at risk for arterial bleeding following angiography. Not surprisingly, there is little evidence that preprocedure blood components are indicated for angiographic procedures. Darcy et al<sup>73</sup> prospectively studied 1000 consecutive patients undergoing femoral arterial puncture for diagnostic or therapeutic vascular procedures. Analysis was restricted to patients with INR values  $<1.5$ . The incidence of hematoma formation was the same in patients without any abnormality of the preprocedure INR (9.7%) as those with abnormal results (8.1%). Neither the INR nor the aPTT was predictive of hematoma formation and each test had a  $<10\%$  positive predictive value. However, hematoma formation was more common among patients with platelet counts  $<100,000/\mu$ L, with

the use of catheters larger than 5 Fr, and among patients with a documented history of bleeding disorders.

### **Recommendations**

Prospective, controlled trials in which patients with similar degrees of abnormal hemostasis are randomly assigned to receive or not receive preprocedure blood components are needed to be able to make firm recommendations on the value of prophylactic transfusions before bedside invasive procedures. Given the low incidence of any form of hemorrhagic complications even among patients with known defects, such studies should be designed as multicenter trials in order to accrue a sufficient number of patients to have adequate statistical power. In the absence of such studies, the current literature can serve to suggest some guidelines for the clinical approach to bedside procedures. There is a substantial lack of evidence that mild to moderate abnormalities of the INR or aPTT can be or should be used as an indication to administer preprocedure FFP. Profound thrombocytopenia ( $<20,000/\mu\text{L}$ ), although a poor predictor of bleeding, arises more commonly than prolongation of the INR or aPTT as an independent risk factor for procedure-related bleeding. Indeed, severe thrombocytopenia ( $<20,000/\mu\text{L}$ ) represents not only a more correctable defect but also a greater absolute defect in hemostasis than mild to moderate prolongation of coagulation times. On the basis of the published literature, preprocedure transfusions are not routinely required for patients with an INR  $<3$  accompanied by a platelet count  $>50,000/\mu\text{L}$ ; nor are they required for patients with  $>20,000/\mu\text{L}$  platelets accompanied by an INR  $<1.7$ . For patients with mixed coagulation disorders (for example, patients with platelet counts in the range of 20,000 to 50,000/ $\mu\text{L}$  accompanied by an INR in the range of 1.7 to 3.0) individual decisions regarding the risk of bleeding are needed. These decisions may be influenced by experience of the operator, technical factors, anatomy, and disease-related comorbidities.

When deciding on the clinical approach to a particular patient, clinicians and laboratorians should recognize that any strategy of prophylactic blood transfusions triggered solely by laboratory screening test results is not supported by published evidence. Clinicians must recognize that mild to moderate abnormalities of laboratory screening tests do not necessarily define a clinical defect in hemostasis. In addition, the decision to transfuse blood components for hemostasis is completely defensible when transfusions are given to arrest bleeding, but are difficult to justify as prophylaxis. As is true throughout clinical medicine, the best decisions are made in the context of each patient's full clinical picture rather than on the basis of laboratory values alone.

---

### **Transfusion of Blood Components to Treat Bleeding**

The principal question in addressing transfusion therapy for the bleeding patient is to decide whether the bleeding is primarily localized or generalized.

### **Local Treatments for Local Bleeding**

Upon removing a large kitchen knife from a stab wound to the chest and seeing copious blood emerge from the wound, no physician would elect to treat the problem by ignoring the wound and infusing FFP in the antecubital vein. Yet, countless patients with local bleeding are treated this way every day. Patients with bleeding varices, bleeding ulcers, bleeding from central lines, or bleeding postoperatively from surgical sites are frequently given blood component infusions to stop local bleeding, when a direct approach to the site of bleeding would be more effective. Systemic infusion of blood components for local bleeding is most common in patients who have mild abnormalities of coagulation tests, presumably under the unsupported assumption that the local bleeding results from hemostatic defects reflected by these laboratory tests. While systemic infusion of FFP or platelets may contribute to improved hemostasis at the site of tissue injury and bleeding, transfusions are secondary to a direct approach to hemostasis.

Suture ligation of a damaged vessel remains the single most effective hemostatic treatment for localized bleeding and, if technically possible, should always be considered the treatment of choice. For bleeding from vessels that cannot be ligated, a variety of other choices exist including: electrocautery, injection sclerosis of vessels, argon-laser beam coagulation, and direct packing and compression.

### **Topical Agents: Collagen, Cellulose, and Gelatin**

A variety of topical agents are used routinely during surgery to improve hemostasis, especially at sites of bleeding that cannot be approached by ligation. None of these agents are perfect and all rely upon creating a surface for platelet adhesion and fibrin clot formation. Although useful for oozing, they are washed away by vigorous bleeding and are no substitute for suture. The available compounds are sterile and can be left inside the body, where they dissolve. There is very little known toxicity to these agents. Commercially available agents include products based on collagen (Avitene, C.R. Bard, Murray Hill, NJ; FloSeal, Baxter, Deerfield, IL), cellulose (Surgicel, Johnson & Johnson, New Brunswick, NJ), and gelatin (Gelfoam, Pfizer, New York, NY). For more information, the reader is referred to a fine review by Jackson.<sup>74</sup>

### **Topical Sealants**

In some situations, topical application of blood components to the site of bleeding can be therapeutic. A common example is the use of "fibrin sealant." Fibrin sealant consists of the simultaneous application of topical fibrinogen (usually supplied as 1-2 units of cryoprecipitate) plus topical thrombin. Fibrin sealant will not stanch massive bleeding, but it can prove very useful for sites where a suture cannot be placed. Fibrin sealants are also provided commercially. Currently, Tisseel VH (Baxter) is licensed for use in the United States. It consists of separate vials containing either purified human fibrinogen plus aprotinin or purified human thrombin. Fibrin sealants may also be packaged with a

pump used to spray the sealant on a bleeding surface. Fibrin-based sealants have also been incorporated into dressings that may be applied to the site of bleeding to provide not only direct pressure but also local high concentrations of fibrin for clot formation. Fibrin sealant dressings are under active investigation for use by the military and for trauma applications. Fibrin sealant sprays have been used in cardiac or vascular surgery, especially to address bleeding along lines of vascular anastomosis. Liquid fibrin sealants are used in burn care, liver surgery, maxillofacial surgery, neurosurgery, and some orthopedic surgery.<sup>74</sup>

### Topical Thrombin

Topical thrombin of bovine origin is available as a powder, packaged as 5000 units or 20,000 units. It is usually reconstituted in a diluent and applied at concentrations of 1000-2000 units/mL. It may also be applied directly in powdered form to the site of bleeding. Thrombin is also marketed as a liquid in a spray pump bottle. Recently, the Food and Drug Administration approved both a human thrombin (Evithrom, Johnson & Johnson) and a recombinant thrombin (Recothrom, ZymoGenetics, Seattle, WA). The use of bovine-derived thrombin has been associated in a minority of patients with the development of antibodies directed against bovine coagulation proteins in the preparation. These antibodies include Factor V antibodies and thrombin antibodies. In some patients, these antibodies can cross-react with human coagulation proteins, resulting in the development of a coagulation inhibitor. In some of these patients, the inhibitor can be clinically significant and represents a serious adverse effect of bovine thrombin. However, clinically significant inhibitors are very infrequent and this risk of inhibitor formation should be further reduced with the advent of human and recombinant thrombin. Thus, direct thrombin application remains a useful adjunct to topical hemostasis.

### Topical Antifibrinolytics

In surgical cases, such as trauma surgery, some patients may have substantial diffuse oozing with no defined vessel to ligate. For such bleeding, direct packing and closure with subsequent return to the OR for definitive hemostasis can be lifesaving. In addition to simple packing with sterile gauzes, some clinicians believe there is benefit to packing bleeding sites with gauzes made wet with applied thrombin, antifibrinolytics (eg, Amicar, Xanodyne Pharmaceuticals, Cincinnati, OH), or platelets. The author's institution uses gauzes applied with antifibrinolytics in selected patients.

### Treating Wound Fibrinolysis

The serosal cavities of the body are lined by tissues that are rich in fibrinolytic proteins such as tissue plasminogen activator. When blood enters such cavities it undergoes rapid clot lysis. This accounts for the observed finding that blood in the pericardial space, the pleural space, the peritoneal space, or in joint spaces exists as a liquid that can be extracted with a needle. Blood extracted from such cavities will not clot *ex vivo* because it has

already undergone complete clot lysis. An example of this is seen with the unclottable blood collected into canisters from chest tube drains. A common problem after chest surgery is bleeding into the pleural and mediastinal space. In some patients, if blood drainage is incomplete, the local environment surrounding the bleeding wound site can become bathed in fibrinolytic blood. Thus, wound bleeding into intrapleural, intramediastinal, or intra-abdominal sites can result in an unfavorable cycle in which bleeding into the cavity undergoes clotting and lysis and the fibrinolytic process breaks down clots and results in more bleeding. The principal treatment for this condition is removal or drainage of blood from the body cavity, a therapy underscored by the time-honored surgical practice of washing out retained blood. However, when this is not possible, wound fibrinolysis may occur and simple infusion of blood components is not likely to be effective. For these patients, a short course of a systemic antifibrinolytic agents (eg, Amicar) may be beneficial.

### Treatment of Generalized Bleeding

#### Skin and Mucous Membrane Oozing

Visible, annoying, distasteful, frightening, and unsightly skin and mucous-membrane bleeding often demands attention even if not life-threatening. Often a sign of thrombocytopenia or impaired platelet function, skin and mucous-membrane bleeding may also result from drug eruptions, mucositis, burns, or other damage to skin. Platelet transfusions may be given to patients with petechiae under the assumption that skin bleeding is a harbinger of more serious life-threatening bleeding to come. It is difficult to prove or refute this contention, but petechiae or mucosal bleeding in conjunction with thrombocytopenia would seem a far more logical indication for prophylactic platelet transfusion than a platelet count alone. For patients who are refractory to platelet transfusions as a result of alloimmunization, oral or intravenous antifibrinolytics have been used.

#### Purpura and Soft-Tissue Bleeding

Purpura and soft-tissue bleeding may imply a serious hemostatic defect and are nearly always worthy of investigation. An exception is "senile purpura"—a largely cosmetic problem limited to the extensor surfaces of the forearms in elderly patients with visibly fragile skin. Purpura generally suggests an abnormality in fibrin formation and treatment is directed at the underlying defect. When no specific hemostatic abnormalities are found, the cause may prove to be vasculitis, drug purpura, amyloidosis, or even factitious. Vasculitic bleeding can range from dermal bleeding, as seen in palpable purpura, to life-threatening hemorrhage as seen in pulmonary vasculitis. Rare coagulation defects, such as Factor XIII deficiency, dysfibrinogenemias, or conditions with excessive fibrinolysis may result in purpura without striking abnormalities found on routine laboratory tests. Aneurysms and vascular anomalies can sometimes present as confusing cases of unexpected bleeding. Patients with persistent recurrent gastrointestinal bleeding may have Osler-Weber-Rendu disease (hereditary hemorrhagic telangiectasias). In some patients, the

external telangiectasias that provide the clue to the diagnosis are subtle and limited to the oral mucosa. Vitamin C deficiency (scurvy) typically results in gum bleeding and perifollicular petichiae, but more substantial bleeding with large plate-like areas of skin and soft-tissue purpura may also occur. Unrecognized von Willebrand syndrome or platelet storage pool disorders can result in unexpected bleeding, although most patients with serious examples of these conditions will give a history of easy bruising, heavy menstrual bleeding, iron deficiency, or prior surgical hemorrhage.

### Small Vessel Bleeding During Surgery

Diffuse small vessel bleeding during surgery is not uncommon. In many cases, such generalized bleeding is a sign of a recognizable and correctable hemostatic disorder. Anesthesiologists and surgeons caring for patients undergoing major surgery need access to basic coagulation tests with rapid turnaround time. Usually the patient with diffuse oozing at the end of surgery has developed dilutional thrombocytopenia or dilutional depletion of coagulation factors and these conditions can be corrected by transfusion. In other cases, the results of intraoperative coagulation testing point more toward disseminated intravascular coagulation. This condition should be anticipated if the patient has experienced prolonged hypotension with tissue hypoperfusion and ischemia. In this author's experience, a commonly overlooked cause of diffuse small vessel bleeding is fibrinolysis. With hypotension, pressors, and acidosis, patients will release tissue plasminogen activator from vascular sites. The plasmin that is formed localizes preferentially to fibrin. Therefore, even before a patient will demonstrate fibrinogenolysis (with low systemic fibrinogen levels), the patient will first develop fibrinolysis with dissolution of previously formed clot. In this early fibrinolytic response, there is no measurable abnormality of the circulating blood except for the presence of increased concentrations of D-dimers as a sign of fibrin clot dissolution. Indeed, some degree of fibrinolysis is nearly universal in surgery. Thus, the observation in the OR that the patient is oozing from surgical sites that were previously well clotted should be taken as a sign of the possibility of increased clot lysis. Fibrinolysis is not corrected by infusions of FFP, which may only serve to add plasminogen and create more plasmin. If the bleeding is sustained and if there are no contraindications to the use of an antifibrinolytic agent, then a single bolus dose or a loading dose followed by a brief infusion of an antifibrinolytic may prove very useful.

### Conclusion

James Blundell administered the first human blood transfusions in the early years of the 19th century to treat patients who were actively bleeding. When viewed from an evidence-based perspective, little has changed in 200 years. Blood component therapy remains a remarkable lifesaving treatment of unquestionable value in patients with significant bleeding. Transfusion

of blood to bleeding patients rests on solid principles of resuscitation, tissue oxygenation, and the repletion of vital elements of hemostasis. In stark contrast, transfusion given as prophylaxis based on abnormal screening tests offers unfavorable risk-to-benefit and cost-to-benefit ratios.<sup>75</sup> Clinical research using the outcome measure of bleeding should be conducted to refine the indications for blood use at surgery and before invasive procedures. Better tests of hemostasis are needed. In the meantime, many lives will be saved by transfusion given to bleeding patients. In some cases, these transfusions will directly arrest bleeding by replacing depleted elements of hemostasis. In many more cases, transfusion will serve as an exquisite life-support measure while other interventions are used to stop hemorrhage.

# Transfusion Therapy in the Care of Trauma and Burn Patients

**Ellen C. Omi<sup>1</sup> & Richard L. Gamelli<sup>2</sup>**

<sup>1</sup>Assistant Professor of Surgery, Division of Critical Care, Trauma and Burn, Loyola University Medical Center, Stritch School of Medicine, Maywood, Illinois, USA

<sup>2</sup>The Robert J. Freeark Professor and Chairman, Department of Surgery, Director, Burn and Shock Trauma Institute, Chief, Burn Center, Loyola University Medical Center, Stritch School of Medicine, Maywood, Illinois, USA

In 1915, Lewisohn published the first reports of collecting blood in sodium citrate at Mount Sinai Hospital in New York, and by 1917, the first military blood bank was set up by Major Oswald H. Robertson of the United States Army. What drove the technology in blood transfusion and storage was the demand for transfusion during World War I.<sup>1</sup> Although the first described blood transfusion was performed in the early 19th century, widespread acceptance of transfusion therapy did not occur until Landsteiner described the ABO blood groups. Experience gained during World War I and the Spanish Civil War led to technologies to collect, store, and transfuse blood in emergencies. Bernard Fantus in 1937 opened the first blood bank in the United States at Cook County Hospital in Chicago. The use of the preservative acid-citrate-dextrose was implemented by the end of World War II, further expanding the ability to store blood.<sup>2</sup> During this same period, the importance of resuscitation in the treatment of shock and trauma was recognized and the use of crystalloids began.

The ability to store blood in large quantities was a boon for trauma surgery. The liberal use of group O Rh-negative blood during the Vietnam War significantly reduced mortality.<sup>3</sup> Coupled with rapid transport time, aggressive fluid resuscitation, and early operative intervention for patients not responding to resuscitation, this advance marked the beginning of modern trauma surgery. The lessons learned from wartime experience with the resuscitation of injured patients were applied to the civilian injured, and by the late 1960s, organized prehospital emergency services were rapidly transporting patients to trauma centers.

The use of blood for the resuscitation and treatment of thermally injured patients was advocated as early as the 1920s and 1930s.<sup>4</sup> Blood and blood components have since been part of various treatment regimens and burn formulas for the initial resuscitation of burn patients. The ready availability of blood and blood components has improved survival among elderly patients and patients with associated medical problems who otherwise would not have tolerated a low hemoglobin level. Intraoperative transfusion has

allowed wider, more aggressive débridement procedures, thereby decreasing the number of surgical procedures needed by a patient.

The current indications for transfusion in trauma and burn care recognize the merits of this form of treatment but acknowledge the practical considerations regarding transfusion. The limitations of the blood supply are apparent. In the United States, more than 14 million units of Whole Blood and Red Blood Cells (RBCs) are transfused yearly to approximately 5 million recipients, with most transfusions being administered in the perioperative period. RBCs have a limited shelf life and are discarded after 42 days. In addition, the incidence of transfusion reactions and of the transmission of hepatitis was well documented by the 1970s. The risk of transmission of human immunodeficiency virus or hepatitis C virus are each estimated to be 1 in approximately 2,000,000 units of blood.<sup>5</sup> On a yearly basis, approximately 35 patients die per year of hemolytic transfusion reactions (mostly from ABO-incompatible transfusion), transfusion-related acute lung injury, or bacterial contamination.<sup>6</sup>

Concerns have also been raised about the possible immunosuppressive effects of transfusion, citing associations between transfusion and infections or recurrence of malignancies.<sup>7,8</sup> In addition, it is known that 50% of severely injured patients who survive the immediate posttrauma phase are at increased risk for the development of the systemic inflammatory response syndrome and may be vulnerable to immunomodulatory effects of transfusions. Although a transfusion is still a lifesaving treatment in the appropriate circumstances, the foregoing observations have led to a more judicious use of blood and blood components as the risk-to-benefit considerations are more fully understood. Current blood use in treating trauma and burns, therefore, must combine judgment and careful assessment of the risk-to-benefit ratio.

## Shock

### Definition of Shock

Shock is defined as inadequate organ perfusion and tissue oxygenation. After trauma, the most common type of shock is hemorrhagic. Neurogenic shock after high cervical spinal injuries and septic shock after penetrating trauma also are possible. After burns,

hypovolemic shock is caused by fluid sequestration at the site of injury and in unburned injured tissue as a systemic response to injury and by evaporative loss caused by loss of the dermal barrier.

A critical goal in the care of trauma and burn patients is optimization of oxygen delivery and prevention of tissue hypoxia. Although it would be ideal if there were a simple laboratory value that could identify the need for transfusion to optimize oxygen delivery, such a magic bullet does not exist. The decision to administer transfusion must be based on an understanding of the role of hemoglobin in the definition of oxygen delivery.

Oxygen delivery ( $\text{DO}_2$ ) is the product of arterial oxygen content ( $\text{CaO}_2$ ) and cardiac output (CO):  $\text{DO}_2 = \text{CaO}_2 \times \text{CO}$ . Arterial oxygen content is a measure of both hemoglobin-bound and free oxygen. It is calculated with the following equation:

$$\text{CaO}_2 = (1.34 \times \text{SaO}_2 \times \text{Hb} \times 10) + (0.003 \times \text{PaO}_2)$$

The left term of the equation ( $1.34 \times \text{SaO}_2 \times \text{Hb} \times 10$ ) calculates the amount of oxygen bound to hemoglobin. The constant 1.34 is an estimate of the mean volume of oxygen in milliliters that can be bound to 1 g of fully saturated normal hemoglobin,  $\text{SaO}_2$  is oxygen saturation, and Hb is the hemoglobin in g/dL. Ten is a correction factor converting g/dL to g/L. The right term of the equation ( $0.003 \times \text{PaO}_2$ ) is the estimation of the dissolved component of arterial oxygen content.  $\text{PaO}_2$  is the partial pressure of arterial oxygen and the constant 0.003 is the solubility coefficient of oxygen in blood at normal body temperature and atmospheric pressure. From this equation, it is apparent that dissolved oxygen contributes little to total  $\text{CaO}_2$  at atmospheric pressure. This contribution would be increased with the use of hyperbaric oxygen, which increases the amount of oxygen dissolved in the blood.

Oxygen consumption ( $\text{VO}_2$ ) is a measure of total oxidative metabolism and is a product of the arteriovenous oxygen difference ( $\text{CaO}_2 - \text{CvO}_2$ ) and the cardiac output (Q). In most cases, oxygen consumption is independent of hemoglobin concentration over a wide range of oxygen delivery values; compensation occurs through increases in cardiac output and oxygen uptake by the tissues. The oxygen extraction ratio, the ratio between oxygen consumption and oxygen delivery, is approximately 25% to 30% under normal conditions. However, different tissues have a variable ability to increase oxygen extraction, further increasing tissue oxygen availability in those tissues. The heart is at maximal oxygen extraction under baseline conditions and depends on increased delivery to meet increasing oxygen demands.

It has been shown in experiments in dogs that, in the normovolemic state, cardiac output progressively increases with decreases in hematocrit to a level of  $8.6\% \pm 0.4\%$ , after which time the dogs went into heart failure.<sup>9</sup> This occurs through reductions in blood viscosity and an increase sympathetic nervous activity.<sup>10</sup> The change in blood viscosity decreases total peripheral vascular resistance, increases postcapillary venular flow, and increases venous return.<sup>10</sup> The increased sympathetic activity results in increased cardiac contractility,<sup>11,12</sup> and increased venomotor tone.<sup>10</sup> As the hematocrit decreases from

**Figure 39-1.** Unrecognized flow-dependent oxygen consumption ( $\text{VO}_2$ ) under normal conditions and in a trauma state. Critical oxygen delivery ( $\text{DO}_2$ ) in anesthetized adult is 330 mL/minute/ $\text{m}^2$ . The normal oxygen delivery index is 450 mL/minute/ $\text{m}^2$ . The survivor response after normal resuscitation is 600 mL/minute/ $\text{m}^2$ . Used with permission from Moore et al.<sup>13</sup>

the normal value to 30%, oxygen delivery increases to approximately 110% of baseline level.<sup>10</sup> It has been demonstrated in dog models that these compensatory mechanisms allow maintenance of oxygen delivery and uptake until the hematocrit decreases to approximately 10%, after which there is a marked decline.<sup>11</sup>

The relationship between oxygen delivery and oxygen consumption is biphasic (Fig 39-1). At less than a critical level of oxygen delivery, consumption is related to delivery in a linear manner. At greater than critical oxygen delivery, consumption is independent of delivery, the flow-independent portion of the curve.<sup>10</sup> Analysis of patients under anesthesia showed that the critical value of oxygen delivery differentiating flow-dependent and flow-independent oxygen consumption is 333 mL/minute/ $\text{m}^2$ .<sup>14</sup> Shoemaker et al<sup>15</sup> compared survivors with nonsurvivors of elective surgery. They found that nonsurvivors had lower myocardial performance indicators, higher pulmonary artery pressures and pulmonary vascular resistance, and lower oxygen delivery than did the survivors. A study by Boyd et al<sup>16</sup> showed a reduced mortality rate and reduced incidence of postoperative complications if inotropic agents were used to increase cardiac output with a target oxygen delivery of 600 mL/minute/ $\text{m}^2$ .

After major trauma, several factors alter the  $\text{DO}_2/\text{VO}_2$  relation. First,  $\text{VO}_2$  increases to 150 mL/minute/ $\text{m}^2$  to repay ongoing oxygen debts and to support the systemic inflammatory response syndrome. At the same time, peripheral oxygen extraction is impaired, which decreases the slope of the flow-dependent portion of this relation (Fig 39-1). It is possible that a trauma patient with a normal  $\text{DO}_2$  of 450 mL/minute/ $\text{m}^2$  may be on the flow-dependent portion of the curve.<sup>17</sup> Bishop et al<sup>18</sup> found that resuscitating to supranormal values of vital signs, urine output, and pulmonary artery catheter parameters decreased the risk of multiple organ failure and death, but the results of this study have not been duplicated despite numerous attempts.<sup>19-21</sup> In fact, some studies have shown an increase in the mortality of critically ill surgical and medical patients with the use of dobutamine to augment oxygen delivery and consumption parameters.<sup>22</sup> What seems to be a common observation in these studies is

**Table 39-1.** Blood Losses and Classes of Shock Based on Patient's Initial Presentation

|                               | Class I             | Class II       | Class III             | Class IV              |
|-------------------------------|---------------------|----------------|-----------------------|-----------------------|
| Blood loss (mL)               | Up to 750           | 750-1500       | 1500-2000             | >2000                 |
| Blood loss (% blood volume)   | Up to 15            | 15-30          | 30-40                 | >40                   |
| Pulse rate (beats/min)        | <100                | >100           | >120                  | >140                  |
| Blood pressure                | Normal              | Normal         | Decreased             | Decreased             |
| Pulse pressure (mm Hg)        | Normal or Increased | Normal         | Normal                | Normal                |
| Respiratory rate (breath/min) | 14-20               | 20-30          | 30-40                 | >35                   |
| Urine output (mL/hour)        | >30                 | 20-30          | 5-15                  | Negligible            |
| Mental status                 | Slightly anxious    | Mildly anxious | Anxious, confused     | Confused, obtunded    |
| Fluid replacement (3:1 rule)  | Crystalloid         | Crystalloid    | Crystalloid and blood | Crystalloid and blood |

Patient is a 70-kg man.

These guidelines are based on the 3-for-1 rule. This rule derives from the empiric observation that most patients in hemorrhagic shock need as much as 300 mL of electrolyte solution for each 100 mL of blood loss. Applied blindly, these guidelines can result in excessive or inadequate fluid administration.

Used with permission from American College of Surgeons Committee on Trauma.<sup>27</sup>

that achieving adequate or supranormal oxygen delivery serves more as a prognosticator of survival than an endpoint of resuscitation. Trauma patients who do not respond to resuscitation, or to augmentation with inotropes to supranormal hemodynamic parameters, are at higher risk of mortality when compared to the patients who are resuscitated successfully or respond to inotropic support.

In the care of critically ill patients in whom maximal increases in cardiac output have occurred without the necessary improvements in oxygen delivery needed to reach the flow-independent portion of the curve, transfusion is considered to optimize oxygen delivery. However, this strategy may not be effective for patients in whom oxygen delivery is adequate.<sup>23</sup>

### Hemorrhagic Shock and Classification

Hemorrhage results in decreased cardiac output and total body ischemia, which cannot be corrected until circulating volume is restored. Acute loss of intravascular volume results in increased vascular tone and redistribution of blood flow to the heart and brain at the expense of cutaneous, splanchnic, and renal vascular beds. Acidosis develops as tissues switch from aerobic to anaerobic metabolism. This acidosis initially facilitates the unloading of oxygen at the tissues with a shift of the oxygen dissociation curve to the right. Urine output decreases as the kidneys work to retain water and sodium in response to decreased renal perfusion.

Without transfusion therapy, this correction requires the movement of fluid and protein from the interstitium to the plasma, or transcapillary plasma refill.<sup>24</sup> Initially triggered by a decrease in capillary hydrostatic pressure, this results in movement of protein-free fluid from the interstitium to the plasma. A second phase involves movement of protein into the plasma space in support of plasma oncotic pressure. This results in restoration of plasma volume and protein concentration with reduced oxygen-carrying capacity resulting from loss of red cell mass

by hemorrhage—that is, normovolemic anemia. Transcapillary refill is capable of sustaining a relatively fixed level of plasma volume, equal to approximately two-thirds of the initial plasma volume, irrespective of the rate of bleeding. Laboratory studies have shown that plasma refill reaches 33% by 0.5 hour after hemorrhage, and 50% by 3 hours, allowing fairly rapid restoration of circulating blood volume.<sup>25,26</sup> The amount of transcapillary refill is a function of the severity of pressure-driven hemorrhage but does not correlate with arterial pressure or cardiac output.

In evaluating injured patients, it rapidly becomes apparent that trauma patients are an extremely heterogeneous population. Each patient's resuscitative needs are different but can be broadly anticipated on the basis of initial hemodynamic status and the response to resuscitative efforts. The American College of Surgeons Committee on Trauma,<sup>27</sup> in an effort to guide and standardize the initial resuscitation of trauma patients, has defined four classes of shock (Table 39-1). Whereas crystalloid resuscitation alone is adequate for Class I and II shock, early consideration should be given to administering blood to patients in Class III and IV shock.

### The Trauma Patient

There are two distinct clinical settings in the care of the trauma patient. The first is the prehospital setting and the second is the in-hospital setting. Treatment of hemorrhagic shock starts in the prehospital setting with control of external bleeding. Once the patient is in the trauma bay, in-hospital management begins and it is perhaps best for the purposes of this chapter to approach this setting in multiple phases. The first phase is the initial resuscitation followed by either an intraoperative phase to stop bleeding or to definitively treat injuries, or a phase of observation, as in the management of solid organ injury. The

“intraoperative” phase can also take place in the angiography suite where bleeding can be controlled, most often in the presence of retroperitoneal and pelvic bleeding from pelvic fractures. The final phase of the care of the trauma patient is the recovery phase. Each of these phases differs with respect to the triggers and indications for transfusion therapy depending on the types of injuries that are inflicted and the type of patient that has sustained the injuries.

### Initial Resuscitation Phase of the Trauma Patient

Initial evaluation of a trauma patient, or the primary survey (ABCDEs), requires an assessment of the airway (A), breathing and ventilation (B), circulation (including the control of external hemorrhage) (C), neurologic status or disability (D), and exposure (E) of the patient. The initial resuscitation fluid of choice after trauma is an isotonic crystalloid solution, usually lactated Ringer's solution, and is often initiated in the prehospital clinical setting. The American College of Surgeons Committee on Trauma Advanced Trauma<sup>27</sup> recommends insertion of two large-bore intravenous catheters and immediate infusion of 2000 mL warmed crystalloid solution (or 20 mL/kg for a child). Because shock after trauma most often is hypovolemic, the response to initial fluid resuscitation determines subsequent resuscitative measures. The risk of hypothermia must be recognized and prevented during the resuscitation phase.

The response to fluid resuscitation determines which, if any, subsequent resuscitative measures are needed. A patient with minimal injury and normal vital signs with initial crystalloid resuscitation is called a *responder* to fluid resuscitation. The condition of these patients, by definition Class I or II hemorrhagic shock, remains hemodynamically normal without ongoing resuscitation. Such patients need evaluation and management of the injuries, but rarely need transfusion during the initial evaluation.

A patient in compensated shock, defined as hypovolemia coexistent with normotension but with serious metabolic derangement, often is difficult to identify. The conventional endpoints of resuscitation—heart rate, blood pressure, and urine output—are crude assessments of the adequacy of resuscitation. Early identification of compensated shock is facilitated by recognition of a transient response to fluid resuscitation. Patients in Class III shock often have hypotension and tachycardia, but vital signs improve or normalize in response to initial fluid resuscitation. During observation, such patients have physiologic signs of shock and need aggressive ongoing resuscitation to maintain relatively normal vital signs. Early identification of the site of hemorrhage and prompt surgical intervention minimize the period of hypoperfusion and the subsequent risk of multiple organ dysfunction. Transfusion with crossmatched or type-specific blood is indicated.

A patient in Class IV, or uncompensated, shock has pallor, diaphoresis, and apathy—clinical signs and symptoms that must be correctly interpreted. These patients also have tachycardia, hypotension, and tachypnea not responsive to aggressive fluid resuscitation with crystalloid and blood transfusion. Any injured

or burned patient who is cool and tachycardic is in shock until proven otherwise. These patients are described as *nonresponders*, in that their vital signs do not improve with aggressive resuscitative techniques. In this population, early identification of the site of hemorrhage and surgical intervention are paramount to survival. Early transfusion with group O RBCs is indicated.

The decision regarding early administration of blood, that is, in the trauma department, should be reserved for patients who have a transient response to initial resuscitation or those who have no response to resuscitation. These two groups have lost more than 30% of their blood volume or are still actively bleeding. Laboratory values of hemoglobin or hematocrit do not typically play a role in the determination of the need for blood transfusion in this patient population, but rather the clinical signs and symptoms of hemorrhage and response to resuscitation are the main determinants of the patient's estimated blood loss. Transfusion of blood in the trauma department must not delay definitive surgical intervention, and these patients should be transported to the operating room urgently.

In a retrospective study with 1000 trauma patients, Knottenbelt<sup>28</sup> found an interesting correlation between initial low hemoglobin level and mortality. He found that patients who came to medical attention in shock and died had significantly lower hemoglobin levels than did patients who did not arrive for treatment in shock. The mean hemoglobin levels of patients who died of hemorrhagic causes were significantly lower regardless of initial blood pressure. In this study, 48% of patients received no prehospital resuscitation, indicating that hemodilution was not the cause of a low initial hemoglobin level. Knottenbelt hypothesized that patients with a low hemoglobin level may have suffered blood loss exceeding their compensatory mechanisms. He concluded that a low initial hemoglobin level indicated severe, ongoing blood loss.

Once the decision to administer RBC transfusion has been reached, there are several options for the type of blood used. Blood ideally should be typed and crossmatched before transfusion, although this can take as long as 1 hour in many blood banks. This is an unacceptably long delay for a patient in Class III or IV shock. An alternative is transfusion of type-specific blood. Transfusion of type-specific blood is associated with a processing delay of 20 to 30 minutes, which in some circumstances still may be an unacceptable delay. In most trauma units, group O RBC units are immediately available and the most rapidly available choice in the care of trauma patients in hemodynamically unstable condition not responding to crystalloid resuscitation. Numerous studies have shown that administration of group O RBC units is a safe and rapid means by which to restore circulating red cell volume in a patient in severe shock.

It is of paramount importance to assess the adequacy of resuscitation; however, the search continues for valid markers. Many believe that base deficit accurately reflects the hemodynamic and tissue perfusion changes associated with shock and resuscitation.<sup>29</sup> Serum lactate is a reliable marker of hypoperfusion in hemorrhagic shock, because failure to clear lactate within 24 hours of injury has been associated with increased mortality.<sup>30</sup> Although serum markers may be helpful for guiding

the treatment of trauma patients, they are at best only a global measure of perfusion. Organ-specific monitoring, therefore, may be useful in ensuring adequate end-organ perfusion. Ivatury et al<sup>31</sup> have proposed gastric tonometry for such monitoring. They documented improved survival among patients whose gastric pH normalized within 24 hours. Other methods of measuring endpoints of resuscitation in the trauma patient include sublingual pCO<sub>2</sub> monitoring, tissue oxygen and carbon dioxide electrodes, and near infrared spectroscopy (NIRS) for the measurement of skeletal muscle oxyhemoglobin levels. Baron et al demonstrated in trauma patients with torso injuries that sublingual capnometry was able to differentiate between patients with varying amounts of blood loss<sup>32</sup> and was able to predict survival in hypotensive trauma patients equivalent to lactic acid levels and base deficit.<sup>33</sup> Measurement of skeletal muscle tissue oxygenation by two probes placed within the deltoid muscle include the polarographic tissue oxygen monitor (Licor, Integra, Plainsboro, NJ) and the NIRS (InSpectra, Hutchinson Technology, Hutchinson, MN). Each of these have been studied in the trauma patient.<sup>34</sup> They have not yet found a role in guiding resuscitation, but are predictive of postinjury complications. NIRS measures skeletal muscle oxyhemoglobin levels. It has been shown to be predictive of multiple organ failure in the trauma patient and has the added advantage that it is noninvasive.<sup>35</sup> Although these devices have the potential to help guide resuscitation, currently they are only adjuncts to other endpoints of resuscitation in the trauma patient and no particular one has been adopted widely.

## Intraoperative Phase of the Trauma Patient

### General Issues

The initial surgical treatment of a trauma patient involves rapid control of bleeding. In the case of severe abdominal trauma, this may necessitate use of “damage control” techniques or rapid packing of the abdomen to achieve hemostasis and rapid control of injuries to hollow viscera.<sup>36</sup> “Damage control” allows the quick, sometimes temporary control of bleeding so the anesthesia team can administer intravenous fluids and rapidly restore intravascular volume. The use of heated ventilator circuits prevents heat and moisture loss, but does not provide heat gain. The amount of heat lost from a normal person at room temperature is negligible, but it does become important in environments where inspired air is low temperature, such as the prehospital setting in cold climates.<sup>37</sup> Warmed intravenous fluids reduce the risk of hypothermia by preventing ongoing heat loss and provide some heat gain.<sup>38</sup> Ten liters of warmed intravenous fluids infused to a 70-kg male will increase the body temperature about 1.4°C. This contributes to the prevention of subsequent coagulopathy and acidosis associated with reduced body temperature and the infusion of large volumes of crystalloid and blood, which may be much cooler than body temperature. The use of “damage control” operative techniques in the care of the trauma patient is necessary when these physiologic factors are present.

The decision to perform intraoperative transfusion can be somewhat complex and involves both the surgeon and the

anesthesiologist. Despite a traditional hemoglobin-based transfusion trigger of 10 g/dL, numerous studies have documented the safety of a lower hemoglobin level.<sup>39,40</sup> In a study of Jehovah's Witness patients with anemia undergoing elective surgery, Spence et al<sup>39</sup> found that active bleeding was an independent predictor of survival only when hemoglobin level decreased to less than 4 g/dL. Low hemoglobin levels became an independent predictor of mortality only when they decreased to less than 3 g/dL. The application of these data to the care of a trauma patient must be tempered with the recognition that hemoglobin levels obtained during active hemorrhage may be falsely elevated because the intravascular and interstitial spaces have not equilibrated. In addition, the compensatory mechanisms of chronic anemia require more time to develop than that afforded by acute hemorrhage. Although results of these studies support the concept that the use of an arbitrary hemoglobin transfusion trigger is probably inappropriate, the intraoperative decision to administer transfusion must be based on an assessment of the patient's overall physiologic condition and the severity of ongoing blood loss.

Autotransfusion of the patient's blood has become a widely accepted practice in elective surgery and can be used as an adjunct to transfusion in the care of trauma patients. The benefits of this practice include the conservation of the blood supply and avoidance of complications related to allogeneic transfusion. Although intraoperative blood recovery and reinfusion has been successfully used in cases of thoracic trauma, its use in patients with abdominal injuries has not been universally applicable because of the risk of contamination from injuries to hollow viscera. The blood is typically anticoagulated with citrate or heparin, washed with normal saline, and then reinfused. Systems relying on filtration, rather than washing, were associated with disseminated intravascular coagulation and other complications and are generally no longer in use, with the possible exception of the reinfusion of mediastinal drainage fluid, which is largely defibrinated, following cardiac surgery.

### Solid Organ Injury

At the beginning of the 1900s, the mortality rate for nonoperative management of splenic injuries was 100%; thus, splenectomy was readily accepted as the standard of care for splenic rupture. However, King and Schumaker reported on overwhelming postsplenectomy sepsis among infants who had undergone splenectomy.<sup>41</sup> Despite this report, the practice of splenectomy remained unchallenged through the first half of the 20th century, until pediatric surgeons began to realize that children in hemodynamically stable condition with splenic injuries could be safely observed. With the advent of improved imaging techniques, including computed tomography (CT) of the abdomen and pelvis, splenic injuries can be identified in patients with normal hemodynamic values. The pediatric experience has been extended to the treatment of adults who have sustained trauma but who are in hemodynamically stable condition. Benefits of splenic preservation include avoidance of overwhelming post-splenectomy sepsis and avoidance of unnecessary laparotomy.

In the 1990s, these principles were extended to the nonoperative treatment of selected patients with liver trauma.<sup>42</sup>

In determining whether a patient needs operative therapy for a splenic injury, the most important factor is hemodynamic stability. Patients in hemodynamically unstable condition (approximately 35% of adult patients with splenic injury and 3% in children<sup>42</sup>) need exploration and splenectomy. Splenorrhaphy is an option, but with the nonoperative management of many splenic injuries, it is not utilized in the adult trauma patient with failed nonoperative management. Generally, surgery is indicated in the worst of the splenic injuries that have failed nonoperative management and require removal. Splenorrhaphy is generally reserved for preservation of the spleen when it is an incidental finding upon laparotomy and not a source of major hemorrhage, especially in the immunologically immature pediatric patient.<sup>43,44</sup> However, 65% of patients with splenic injury arrive in hemodynamically stable condition and are candidates for nonoperative treatment. Nonoperative management fails when hemodynamic instability necessitates exploration, or hemoglobin level decreases, necessitating transfusion, but there is some variation between practitioners regarding the criteria for operative intervention. Most patients with splenic injury do not need transfusion. However, children under the age of 5 have a higher risk of postsplenectomy sepsis. The relative risk of a 1- or 2-unit transfusion (if the patient is in otherwise stable condition) seems a reasonable alternative to splenectomy.<sup>45</sup> Adjuncts to improve the success of nonoperative management of splenic injuries include the use of angiography. Schurr et al<sup>46</sup> described a contrast blush on helical CT scans of the spleen. This finding corresponded to a traumatic pseudoaneurysm on an angiogram and can be successfully treated in the hemodynamically stable patient.

In 1990, Knudson et al<sup>47</sup> described 52 patients with blunt liver trauma who were observed carefully with serial CT. No failures of nonoperative management were reported. This was followed by a report<sup>48</sup> from the group at the University of Tennessee at Memphis, documenting the safety of nonoperative management of even the most severe liver injuries. The authors found transfusion requirements were markedly lower than for patients with severe liver injury who underwent surgery. The only criterion for initial nonoperative management was hemodynamic stability. As with splenic trauma, early identification of contrast extravasation on helical CT scans of the liver with subsequent angiographic embolization of the bleeding vessel has improved the success rate of nonoperative management.<sup>49</sup>

### Recovery Phase of the Trauma Patient

The time between operative or nonoperative treatment of a patient who has sustained trauma until discharge from acute care may be the period in which transfusion can be decreased the most without compromising the patient's condition. During this period, there is no ongoing blood loss, so dramatic changes in hematocrit are not expected. The decision to administer RBC transfusion during this period should be based not on

maintaining an arbitrary hematocrit but on results of assessment of the physiologic need for transfusion.

Traditional teaching that all patients should have a hematocrit of 30% (or a hemoglobin level of 10 g/dL) for optimal oxygen delivery has not been borne out in recent studies. Persons with normal blood volume and normal cardiopulmonary function tolerate hemoglobin levels as low as 5 g/dL.<sup>50</sup> A prospective, randomized controlled trial in the care of critically ill patients demonstrated patients younger than 55 years or patients with Acute Physiology and Chronic Health Evaluation II (APACHE II) scores less than 20, may have a reduced mortality if a restrictive transfusion strategy is adopted and hemoglobin levels are maintained at 7 to 9 g/dL.<sup>51</sup> The same reduction in mortality is not seen in a subgroup analysis of resuscitated critically ill trauma patients or brain-injured patients. In fact, those transfused to maintain the hemoglobin level of 7 to 9 g/dL vs 10 to 12 g/dL did not have any difference in outcomes.<sup>52,53</sup> However, further prospective trials should be performed to confirm these findings, especially in a high-risk population such as brain-injured patients. Moderate to severely brain-injured patients may warrant earlier operative management of solid organ injury, especially stable patients with splenic injuries, because of the association of hypotension with increased mortality. If the mortality from the brain injury is worse with hypotension, nonoperative management of moderate splenic injuries in the stable patient may not be worth the risk of failure and exposure to hypotension. Hypothermia is associated with mortality in patients with brain injury and is also a result of severe hemorrhage and transfusion in the trauma patient.<sup>54</sup> Decisions to administer RBC transfusion should be based on evidence of symptomatic anemia, including chest pain, dyspnea, fatigue, and significant tachycardia. In the absence of symptoms, RBC transfusion is not warranted. A more liberal transfusion trigger is probably warranted in the care of those with underlying severe cardiovascular disease.

### Complications of Massive Transfusion Therapy

Massive transfusion has been defined as replacement of a patient's entire blood volume in 24 hours, transfusion of more than 10 RBC units, or replacement of more than 50% of the circulating blood volume within 3 hours.<sup>55,56</sup> Massive resuscitation with fluids and blood components after hemorrhagic shock is associated with complex metabolic derangements and high morbidity and mortality rates. The clinical hallmark of severe hemorrhagic shock is the lethal triad of acidosis, hypothermia, and coagulopathy (Fig 39-2).

Banked blood undergoes a number of metabolic and structural changes.<sup>56</sup> When it is transfused in large volumes, the blood can theoretically cause severe derangements in physiologic values. It appears, however, that the severity and duration of shock rather than the volume of transfused blood are the primary determinants of physiologic derangement and ultimately patient outcome.<sup>57,58</sup> It is vital that patients receiving massive transfusion also receive adequate fluid resuscitation such that oxygen delivery and organ perfusion are maintained. Survival after

**Figure 39-2.** The lethal triad.

massive transfusion is no longer uncommon. One patient received 186 units of blood and blood components within 12 hours and had a successful outcome.<sup>59,60</sup>

One problem associated with massive resuscitation is the occurrence of microvascular bleeding, or so-called medical bleeding. This is to be clearly differentiated from surgical bleeding. Medical bleeding is associated with mucous membrane bleeding, oozing from surgical wounds and raw tissue surfaces, oozing from catheter sites after application of direct pressure, and generalized petechiae and enlarging ecchymoses.<sup>61</sup> It has been recommended that prophylactic transfusion of platelets and Fresh Frozen Plasma (FFP) be administered according to the volume of RBCs transfused.<sup>61-63</sup> However, this practice pattern may not decrease the risk of microvascular bleeding and may markedly increase the number of donor units transfused.

Several studies have evaluated changes in levels of coagulation factors and platelet count and their role in microvascular bleeding after trauma and massive transfusion.<sup>62-64</sup> These studies document a decrease in both coagulation factors and platelet counts. One explanation is the development of a washout phenomenon, or dilutional coagulopathy, resulting from the use of stored blood deficient in both platelets and coagulation factors.<sup>64</sup> Although dilution appears to play a role in thrombocytopenia and coagulopathy after massive resuscitation, it does not account for all changes after massive transfusion.

In a regression analysis of thrombocytopenia after massive transfusion, Reed et al<sup>61</sup> found that only 35% of the decrease in platelet count could be attributed to dilution. They found further that 50% of patients with microvascular bleeding needed large volumes of platelet transfusions well after the period of massive resuscitation. This finding suggested that factors in addition to dilution must play a role in persistent thrombocytopenia in these patients. In a related study,<sup>64</sup> investigators hypothesized that platelet consumption accounted for this persistent thrombocytopenia, which was related to the pathophysiologic response accompanying lung injury, brain injury, massive tissue injury, sepsis, and endothelial damage.

Several authors have examined the concentration of coagulation factors to determine whether dilution plays a contributing role. Martin et al<sup>65</sup> found that although levels of coagulation factors decreased significantly at the end of a shock insult, the levels remained much higher than those considered adequate for normal hemostasis. Reed et al<sup>61,62</sup> evaluated coagulation studies

in the treatment of patients who received massive transfusions. They found mild to moderate prolongation of prothrombin time (PT) and partial thromboplastin time (PTT) were common in this patient population but were not predictive of microvascular bleeding. Regression analysis showed that 15% to 35% of the elevation of the PT and PTT could not be attributed to coagulation factor deficiencies. This finding indicated that other, unidentifiable factors had a role in the elevation of the PT and PTT.

Although no one study alone can confirm which patients at risk of microvascular bleeding will benefit from transfusions of platelets and FFP, certain tests are more useful than others. A PT less than 1.3 times control value has a 94% predictive value in indicating the absence of microvascular bleeding. Although the sensitivity of PT or PTT in identifying microvascular bleeding is only 50%, values greater than 1.8 times control value are 96% specific for microvascular bleeding. Bleeding time is of no value in determining which patients will have microvascular bleeding. The most sensitive laboratory predictors are a platelet count less than 50,000/ $\mu$ L and a fibrinogen level less than 0.5 g/L, with a combined sensitivity of 87% and a negative predictive value of 96%. This has led to the following recommendations: platelet transfusion for patients with a platelet count less than 100,000/ $\mu$ L and evidence of microvascular bleeding; prophylactic platelet transfusion for patients with a platelet count less than 50,000/ $\mu$ L; and administration of supplemental FFP or cryoprecipitate to patients with fibrinogen levels of 0.8 g/L or less.<sup>62</sup>

Hypothermia is a contributing factor to platelet and coagulation factor dysfunction after massive transfusion. Villalobos et al<sup>66</sup> studied the effects of hypothermia on platelets in dogs and found that thrombocytopenia was caused by sequestration of platelets by the liver, spleen, and other sites in the portal circulation rather than by platelet destruction. No change in platelet production was found during either cooling or rewarming.

Reed et al<sup>67-69</sup> reported on coagulation factor dysfunction secondary to hypothermia. Standard coagulation testing in the laboratory typically is performed at 37°C. This method detects clotting abnormalities only if the actual factor content is decreased. The function of the coagulation cascade, however, depends on enzymatic activity, which can be adversely affected by hypothermia. The result is prolongation of clotting times even in the face of normal factor concentrations. Investigators<sup>68</sup> found that the PTT was prolonged at all temperatures less than 35°C and that the PT was prolonged at temperatures less than 33°C. They concluded that if clinical oozing exists in a patient with hypothermia and results of coagulation studies performed at 37°C are within the normal range, rewarming the patient is more appropriate and more effective than empiric transfusion of FFP.

Recognition of the contributions of hypothermia to the development of medical bleeding has revolutionized the field of trauma surgery. The concept of the “damage control” laparotomy has been reborn. In this procedure, all efforts are directed at control of surgical bleeding and containment of intra-abdominal contamination. However, the operation is truncated to minimize the “on-table” time. The patient often is closed with laparotomy packs in place

in a temporary abdominal wall closure.<sup>34</sup> The patient is returned to the surgical intensive care unit, where aggressive rewarming and resuscitation continue. Only when acidosis, coagulopathy, and hypothermia have been corrected is the patient returned to the operating room for definitive management of injuries.

It is suggested that storage of blood longer than 14 days is related to the side effects, and in many trauma centers with a large demand for blood components, many of the older units of blood in circulation are sent to high-volume centers where they will more likely be used before their expiration. In other words, trauma patients in busy trauma and medical centers tend to receive older blood. Transfused leukocytes have been implicated as the cause of many transfusion reactions, but older blood also has red cell morphology changes, adenosine triphosphate depletion, 2,3-diphosphoglycerate depletion, and other biochemical changes (see Chapter 4). Use of prestorage leukocyte-reduced blood components should in theory reduce the immunomodulatory side effects of blood transfusion, but there are many other contributing factors that alter blood in storage.<sup>70</sup> It has been demonstrated that trauma patients with multiple organ failure who were transfused in the first 12 hours of admission received more blood that was greater than 14 days old.<sup>71</sup> In addition, blood greater than 14 days old was an independent predictor of serious infection.<sup>72</sup>

Currently, the use of whole blood is limited to the military and war-related trauma. Although it is possible to move refrigerators and freezers close to areas of combat, storing platelets at the proper temperature and working within the expiration date are challenging. Thus, the military uses whole blood transfusion or their “walking donor” program. Whole blood transfusion is utilized as a lifesaving therapy in combat with otherwise untreatable coagulopathy in the absence of appropriate blood components.<sup>73</sup> Whole blood is not used in the civilian trauma center. A retrospective review of patients who received whole blood transfusion from January 2001 to December 2004 revealed that of the 5294 transfusions given to 3287 patients, 545 units of whole blood were transfused to 87 (3%) patients.<sup>74</sup> The United States military advocates the use of whole blood transfusion only for victims with life-threatening injuries and hemorrhage.

## The Burn Patient

### Initial Resuscitation of the Burn Patient

The large number of resuscitation formulas available for use in the treatment of thermally injured patients is a tribute to the fact that no one formula is an accurate predictor of the fluid requirements of every patient. No formula replaces the role of the physician, who must continually assess the adequacy of resuscitation. Ongoing controversies about resuscitation involve the use of colloid, the differences between adults and children, and the influence of inhalation injury on fluid requirements.

In the first 24 hours of resuscitation, most patients need 2 to 4 mL/kg of fluid per percentage of total body surface area (BSA) burned. This fluid is given as lactated Ringer’s solution. The first

half of the calculated requirement is given over the first 8 hours, measured from time of injury, not from the beginning of resuscitation. The rest is given over the next 16 hours (Parkland formula).<sup>75,76</sup> Children also need maintenance fluids containing dextrose in addition to the resuscitative fluid. The presence of inhalation injury increases the volume of fluid needed to achieve adequate resuscitation. Whether colloid is used in the first 24 hours is determined on a case-by-case basis; administration of colloid should not be routine, but is utilized in the severely burned patient who is not responsive to resuscitation. Regardless of the volume of resuscitative fluid initially chosen, ongoing resuscitation should be dictated by the patient’s response to resuscitation. Urinary output of 1 mL/kg/hour is an adequate measure of resuscitation.

Release of vasoactive mediators from injured tissue results in a diffuse capillary leak starting soon after injury. This loss of microvascular integrity results in extravasation of crystalloid and colloid solutions for the first 18 to 24 hours after thermal injury. This pathophysiologic process explains the enormous fluid requirements of burn patients for the first 24 hours. This is the reason that most burn resuscitation formulas incorporate the use of colloids after 24 hours—microvascular integrity apparently is restored at that time. After 24 hours, colloid remains largely intravascular. Colloid, generally 5% albumin, is infused at a dose based on burn size (generally 0.3 to 0.5 mL/kg per percentage of total BSA burned over 24 hours). During this period, crystalloid requirements decrease markedly.

### Transfusion Therapy in the Care of Thermally Injured Patients

As with severely injured trauma patients, thermally injured patients often have anemia throughout the hospital course. The cause of this anemia is very different from that of the anemia of trauma.<sup>77-81</sup> The factors that predominate as the cause of anemia vary with respect to time from injury; they must be considered in evaluation for transfusion.<sup>78,79</sup>

Soon after burn injury, anemia is caused by direct destruction of erythrocytes within the cutaneous circulation and by hemorrhage into the burn wound. As time progresses, the factors resulting in anemia include hemolysis of injured erythrocytes and blood loss during dressing changes. Further hemolysis also occurs as blood flows through injured tissue and burn eschar. Additional blood loss occurs during burn wound débridement, split-thickness skin grafting, and postoperative dressing changes. Because of the stress associated with thermal injury, blood loss can occur in the gastrointestinal tract, as well as from unnecessary “routine” blood work.

The response of burn patients to anemia is different from that of trauma patients.<sup>78-81</sup> Several, but not all, studies have documented an increase in erythropoietin level after thermal injury as well as a paradoxical decrease in reticulocyte numbers.<sup>80,81</sup> In a study with 27 patients, erythropoietin levels were inversely related to hemoglobin levels, but patients had persistent reticulocytopenia.<sup>81</sup> The results of this study suggested a relative resistance

to erythropoietin at the marrow level. An elevated level of circulating erythropoietin did not result in an expected increase in erythrocyte production. It appears that the erythropoietic response to thermal injury is inversely proportional to the size of the burn.<sup>80</sup> Results of studies of the use of recombinant erythropoietin in the management of postburn anemia have not been encouraging. A study with pediatric burn patients did not show a statistically significant increase in hematocrit for either burn patients or healthy volunteers, although increases in reticulocyte count occurred.<sup>77</sup> With no effect in either group, it is questionable if the dose or schedule of the drug was adequate. Similar studies in adult patients with 25% to 65% total BSA burns did not show a significant difference in reticulocyte counts, transfusion requirements, hemoglobin, hematocrit, or iron binding. There was, however, a significant increase in reticulocyte counts in patients with burns from 25% to 35%.<sup>82</sup> More studies with perhaps higher doses need to be performed to determine if erythropoietin is effective in this population at different doses or administration regimens, or if the benefit is not in the increase in the hemoglobin, but other properties of erythropoietin.

The relative resistance of the marrow of thermally injured patients to erythropoietin may be caused by an inhibitory factor in the serum. A study was performed in which serum from patients with more than 20% total BSA burned was cultured with mouse marrow. The authors found the number of erythroid colonies was significantly less in the presence of sera from burn patients even when erythropoietin was added to the system. When erythropoietin activity was assayed *in vivo*, no decrease in activity was detected. This finding suggests the inhibition did not occur at the level of the erythropoietin.<sup>79</sup> Another study showed that erythroid colony-forming cells appeared to return to normal as healing occurred. This study also showed that granulocytopoiesis and thrombocytopoiesis were unaffected and proceeded at an accelerated rate.<sup>78</sup> These authors postulated that redirection of the pluripotent stem cells away from the erythroid line to the granulocyte and monocyte cell lines may offer a survival advantage to burned patients because infection and sepsis are major sources of morbidity and mortality in this population.

As in the care of trauma patients, the safety of lower hemoglobin and hematocrit levels in the care of burn patients has been demonstrated.<sup>83,84</sup> Mann et al<sup>84</sup> retrospectively examined the transfusion requirements of patients with burns of more than 10% total BSA who needed at least one operation. They found a fivefold decrease from 1980 to 1990 in the volume of blood transfused per percentage total BSA without adverse cardiac complications or increased morbidity. Because of their findings, the authors recommended that healthy patients do not need transfusion unless the hematocrit decreases to less than 15% to 20% in patients who need one operation, or 25% in patients who need more than one operative procedure. As with trauma patients, thermally injured patients with underlying cardiovascular disease should be treated with a more liberalized transfusion policy. Sittig and Deitch<sup>83</sup> confirmed the foregoing findings and found a greater than a threefold decrease in transfusion

requirements when a more selective transfusion policy was implemented whereby 86% of blood transfused was given at the time of an operative procedure.

Intraoperative use of hemostatic agents can further decrease transfusion requirements. It is well known that intraoperative blood loss is the limiting factor of the extent of excision and grafting performed. Thrombin spray and laparotomy pads saturated with thrombin and epinephrine have been used extensively to limit intraoperative blood loss.<sup>83,85</sup> The use of tourniquets for excision and grafting of extremities has further decreased blood loss.<sup>86</sup> Fibrin sealants may prove effective. Results of preliminary studies of the use of intraoperative blood recovery techniques show recovery and reinfusion of approximately 40% of shed blood without adverse inflammatory or infectious complications.<sup>87</sup> As in the care of trauma patients, the importance of normothermia in preventing coagulopathy is recognized, and patients are aggressively warmed at the time of surgery.

---

## Adjuncts in Transfusion Therapy for Trauma and Burn Patients

Although crystalloid and blood are the standards in initial resuscitation of trauma patients, there is active investigational interest in developing alternative resuscitative materials. While it is clear that blood is an effective resuscitative fluid that rapidly expands circulatory volume and improves oxygen transportation, it has many disadvantages. It must be crossmatched; it has a short shelf life; it must be stored under closely monitored conditions; it is associated with a variety of immunologic and infectious complications; and its supply relies on the altruism of the donor population.

### Blood Substitutes (Oxygen Carriers)

There have been numerous attempts at developing synthetic products that will aid in oxygen-carrying capacity, mostly based on the use of solutions of hemoglobin-based oxygen carriers or perfluorocarbon emulsions. All of them offer the advantages of long shelf life, permissive storage conditions, absence of the need for compatibility testing, and virtual absence of infectious risks. Most oxygen carriers under development are based on either human or animal hemoglobin. The source of human hemoglobin is outdated RBCs. The disadvantage of human hemoglobin relates to a limitation in the availability of outdated RBCs; less than 3% of the 15.1 million units of blood donated in the United States are being discarded. Animal hemoglobin, particularly bovine hemoglobin, is potentially inexpensive and is readily available, although uncertainty regarding the purification of animal pathogens remains a concern as does the antigenicity of the components.<sup>88,89</sup>

Several companies are conducting efficacy trials of hemoglobin-based oxygen carriers. One company, Baxter Healthcare (Deerfield, IL) terminated work with a diaspirin cross-linked hemoglobin when multicenter trials with trauma patients with hypotension and stroke patients showed increased

multiple organ failure, acute respiratory distress syndrome, and mortality during interim review.<sup>90</sup> PolyHeme (Northfield Laboratories, Evanston, IL) has completed two Phase III trials and appears to lack the marked vasopressive effects of diaspirin cross-linked hemoglobin. A randomized, Phase II clinical trial of PolyHeme vs RBCs in the treatment of trauma patients showed a lower overall RBC transfusion requirement; there was no difference in circulating hemoglobin level, and there were no adverse events.<sup>91</sup> Comparison of patients who received PolyHeme during three different studies, and a historical control group composed of consecutive surgical patients who declined blood transfusion for religious reasons, showed a mortality rate of 25% in the PolyHeme group vs 65% in the group that did not receive the oxygen carrier.<sup>92</sup> A Phase III trial using PolyHeme as a resuscitative component in prehospital trauma patients has been conducted but the data have not yet been published. A bovine hemoglobin-based solution, Hemopure (Biopure Corporation, Cambridge MA), appears to have some vasopressor effects. One Phase III trial has been completed; plans for another Phase III trial are under discussion with the Food and Drug Administration. Hemopure has been licensed for use in clinical practice in South Africa since 2001. Sangart (San Diego, CA) has developed a PEGylated human hemoglobin product with minimal vasoactivity, which has entered Phase II clinical trials in Europe and the United States.<sup>93</sup>

Perfluorocarbons are synthetic molecules with high solubility for oxygen and carbon dioxide. Compared to blood however, their oxygen-carrying capacity is quite low, so patients must receive supplemental oxygen. The compounds are not derived from other animal products and, therefore, do not have the antigenic properties that accompany bioproducts. However, they can cause activation of complement, malaise, and flu-like symptoms; other side effects include thrombocytopenia, splenomegaly, and hepatomegaly. The perfluorocarbon emulsions are cleared by the reticulo-endothelial system relatively quickly with a half life of 12 to 24 hours. Currently, there are no perfluorocarbons in clinical trials mostly because of adverse effects found early in clinical trials and the lack of efficacy.<sup>89</sup>

## Colloid and Crystalloid Solutions

Although blood substitutes remain in clinical trials, other solutions have been evaluated for use in immediate resuscitation of trauma patients. It must be emphasized that colloid solutions are not effective in improving oxygen delivery in the hemorrhaging trauma patient. Colloid solutions are theoretically more efficient than crystalloid at restoring intravascular volume. The colloid-crystalloid debate is at least 50 years old. A potential indication for colloid administration is ongoing resuscitation of critically injured patients. The SAFE study<sup>94</sup> published in 2004 examined the choice of resuscitation with 4% albumin vs normal saline in intensive care units (burns were excluded) and found no difference in mortality at 28 days. The subgroup analysis of trauma patients was small, but mortality trended toward worsened mortality in the albumin group. Post-hoc analysis of the brain-injured

patients revealed higher mortality in patients who received albumin, especially in those with more severe brain injury.<sup>95</sup> There is little doubt that smaller volumes of colloid than of crystalloid are needed to restore intravascular volume and this is demonstrated in the studies described above. Meta-analysis from the Cochrane database has not found any mortality benefit to the use of colloids from the combined results of 63 eligible trials.<sup>96</sup>

To clarify the colloid vs crystalloid debate, several studies have examined outcomes, including survival and generation of extravascular lung water. Investigators in favor of crystalloid resuscitation argue that after severe trauma, there is depletion of interstitial volume as well as intravascular volume, a deficit not adequately addressed with colloid resuscitation. Crystalloid has been proposed as the best resuscitation fluid because it has been shown to restore the volume of both the intravascular and interstitial spaces without worsening pulmonary function.<sup>97</sup> Pulmonary lymphatic vessels increase their flow significantly in animals, and the increase likely occurs in humans, minimizing the development of pulmonary edema after crystalloid resuscitation. Proponents of colloid resuscitation, however, believe that resuscitation of the intravascular component alone is beneficial and that use of colloid may decrease the incidence of pulmonary edema.<sup>98</sup> Although this debate has been subjected to several meta-analyses, the results are conflicting because of highly heterogeneous patient populations and study designs.

Advocates of crystalloid use note the lower cost of crystalloids than of colloids, although larger volumes are needed to reach similar endpoints. Although colloids remain in the intravascular space, in states of increased vascular permeability, colloids can leak into the interstitium, increasing the colloid oncotic pressure of the extravascular space. This increased oncotic pressure can hamper mobilization of third-space fluids after the acute resuscitative phase has been completed. Velanovich<sup>99</sup> reviewed eight randomized, prospective trials comparing crystalloid to colloid resuscitation. He found a 5.7% relative decrease in mortality in the group receiving crystalloid resuscitation. When nontrauma trials were excluded, a 12.3% decrease in mortality favored crystalloid resuscitation.

## Hypertonic Saline Solution

Several studies have examined use of hypertonic saline solution in the resuscitation of animals and humans from shock. Hypertonic saline solution has the advantage of requiring smaller volumes to reach endpoints similar to those of standard crystalloid resuscitation. This makes hypertonic saline solution particularly attractive for use in the prehospital setting, but it does not aid in oxygen-carrying capacity. Administration of hypertonic saline solution has been shown to elevate mean arterial pressure and cardiac output and to increase renal, mesenteric, total splanchnic, and coronary blood flow. Hypertonic saline solution also causes a small and transient increase in circulatory volume by means of transcapillary refill. These effects are well established after controlled hemorrhage. However, the utility of hypertonic saline solution in the management of uncontrolled hemorrhage has yet to be firmly established.

Gross et al,<sup>100</sup> using a model of uncontrolled hemorrhage in rats, found increased blood loss and mortality after administration of hypertonic saline solution. They concluded that hypertonic saline resuscitation must be delayed until after definitive control of hemorrhage.<sup>100</sup> This study was criticized for its use of an anesthetic agent that may have exacerbated hypotension and affected the outcome. Coimbra et al<sup>101</sup> compared hypertonic saline and shed blood resuscitation with crystalloid and shed blood resuscitation in a model of hemorrhage and cecal ligation and puncture in rats. They found improved survival among animals resuscitated with hypertonic saline solution and shed blood, improvement in pulmonary histologic features, and decreased local peritoneal sepsis. They hypothesized that resuscitation with hypertonic saline solution caused less impairment in cellular immune function, possibly contributing to the improvement in survival that they documented.

In a prospective, randomized trial with 105 patients in hypovolemic shock, Younes et al<sup>102</sup> found that infusion of 250 mL of hypertonic saline solution was not associated with any complications and did not affect mortality. It did improve mean arterial blood pressure significantly, acutely expanded plasma volume 24%, and significantly reduced the volume of crystalloid and blood needed for resuscitation. A multicenter trial evaluated the use of hypertonic saline and dextran in the prehospital treatment of trauma patients with hypotension.<sup>103</sup> The investigators found improved survival among patients undergoing surgery who received 7.5% sodium chloride in 6% dextran 70 compared to those receiving the same volume of normal crystalloid solution. The difference reached statistical significance, although there was no overall improvement in survival rate. Use of hypertonic saline solution and dextran also appeared to be associated with a lower incidence of acute respiratory distress syndrome, renal failure, and coagulopathy. Reports by others have described a similar survival benefit among patients receiving hypertonic saline solution vs conventional resuscitative fluids in prehospital therapy for hypotension associated with trauma.<sup>104</sup> Two studies have looked at the immunomodulating effects of hypertonic saline (7.5%)/dextran (6%) in the resuscitation of trauma patients in hemorrhagic shock. These studies demonstrated the anti-inflammatory modulation of cytokines and cellular components that occur with the administration of this solution compared to normal crystalloid solutions (lactated Ringer's and 0.9% sodium chloride).<sup>105,106</sup>

### Recombinant Human Erythropoietin

Recombinant human erythropoietin (rHuEPO) does not have a role in the actively bleeding trauma patient, but has been studied in the treatment of critically ill patients with a prospective, randomized control study.<sup>107</sup> This study demonstrated an overall reduction in RBC transfusions for the patients receiving rHuEPO 40,000U weekly for three doses vs placebo. This effect was not observed until about 1 week following the administration of rHuEPO. Post-hoc subgroup analysis looked at trauma patients; nontrauma surgical patients; and nontrauma, nonsurgical medical patients. There was a trend in the trauma patients

receiving rHuEPO to have a lower mortality (4.8% receiving rHuEPO vs 10.4% receiving placebo), but this was not statistically significant.<sup>107</sup> The cost of rHuEPO balanced against the benefit of its use (avoidance of transfusion-related complications) does not justify its use in the critically ill patient if there is no mortality difference.<sup>108</sup> Corwin et al<sup>109</sup> repeated this study of rHuEPO in critically ill patients in 2007. The repeat study addressed the trend toward a mortality difference seen in the first study published in 2002. The results showed a difference in 29-day mortality in critically ill patients receiving rHuEPO (8.5% vs 11.4%,  $p = 0.02$ ), and specifically in trauma patients admitted to the intensive care unit for more than 48 hours (3.5% vs 6.6%,  $p = 0.04$ ). This difference in mortality was maintained at 140 days, but not seen in medical patients or nontrauma surgical patients. Unlike the previous study, there was no difference in the number of transfusions given between the treatment and placebo groups, which may be a reflection of the adoption of restrictive transfusion strategies in critically ill patients. In addition, post-hoc analysis showed there was a significant increase (20.3% vs 12.8%,  $p = 0.008$ ) in the treatment group for thromboembolic events. This increase in events was not demonstrated with patients who received early administration of heparin.<sup>109</sup>

Independent of the effects of rHuEPO on blood transfusion and hematocrit, there have been multiple animal studies demonstrating what are thought to be anti-inflammatory, neurogenic, and anti-apoptotic characteristics of the drug in brain-injured animal models. In many of these studies, prevention of post-injury brain atrophy, behavioral abnormalities, and cognitive dysfunction have been demonstrated.<sup>110,111</sup> What remains to be proven is the effect, if any, in the brain-injured patient in local and long-term outcomes.

### Recombinant Activated Factor VIII

Another agent that has been studied as an adjunct to transfusion in the trauma and burn patient is recombinant activated Factor VII (rFVIIa). This drug is licensed for the treatment of patients with Factor VII deficiency or Factor VIII inhibitors. It has been studied in hemorrhage associated with surgical procedures, trauma, and burns. The "lethal triad" of coagulopathy, hypothermia and acidosis is a well-known clinical scenario and resuscitation is often targeted to correct these variables. Administration of rFVIIa aims at correcting the coagulopathy limb and is known for being very effective in the nontrauma patient with bleeding disorders. For this reason, there is interest in finding a utility in the coagulopathic trauma patient.

A multicenter and multinational study was conducted to look at the effectiveness of rFVIIa in reducing the number of blood transfusions in severely injured blunt and penetrating trauma patients. There was a significant reduction in the number of transfusions required (reduction of 2.6 RBC units) and the need for massive transfusion was reduced from 33% to 14% (massive transfusion defined as >20 RBC units) in the severely injured blunt trauma population.<sup>112</sup> Adverse events, mortality, and other clinical endpoints were the same in each of the treatment groups;

however, there was a trend toward improvement in the incidence of acute respiratory distress syndrome in the blunt trauma treatment group and multiple organ failure in the penetrating trauma treatment group. The lack of effect on the number of RBC transfused in the penetrating trauma group could be related to the difference between surgical and medical bleeding. The administration to patients in combat with penetrating injuries appeared to decrease the number of transfusions by 20% in those requiring massive transfusion if it was received early (before transfusion of 8 RBC units) vs late (after 8 RBC units were given).<sup>113</sup>

Of concern with the use of rFVIIa is the risk for thromboembolic complications, especially when arterial injury is present. The incidence of thromboembolic complications with use of rFVIIa is from 3% to 9.4%<sup>112,114</sup> and can be a cause of severe morbidity and mortality. Dose-dependent or temporal relationships to thrombotic events have not yet been elucidated, but as this drug is used more as an adjunct to transfusion therapy in the severely injured patient, these details may be determined. Although the potential exists for therapeutic benefit, rFVIIa has not been studied in a prospective fashion in brain-injured trauma patients and there no recommendation for its use in this setting.

Use of rFVIIa has also been described in the burn patient. There is often major blood loss with the excision of burned skin and grafting. A single center pilot study of 18 patients<sup>115</sup> showed a significant decrease in the number of blood components transfused (0.9 vs 2.2,  $p = 0.0013$ ) and more specifically the number of RBC units transfused (0.5 vs 1.1,  $p = 0.004$ ) when rFVIIa (40 $\mu$ g/kg) was used at skin incision and redosed intraoperatively at 90 minutes. There was also a trend toward improved graft survival and reduction in multiple organ failure in the group receiving rFVIIa. This was, however, a pilot study and a study with better power should be conducted to confirm these results.

## Summary

Massive hemorrhage and its consequences of hypothermia, acidosis, and coagulopathy continue to be the leading cause of death during resuscitation of severely injured trauma patients. The early use of blood and blood components combined with aggressive crystalloid resuscitation and early surgical intervention has significantly decreased mortality. However, the risk of disease transmission has prompted reevaluation of the transfusion practices of both trauma and burn surgeons. Although it is recognized that these patients tolerate a lower hemoglobin level than was originally thought, the lower limit of safe hemoglobin level is not known. Although data from other surgical populations have helped to demonstrate that previously accepted transfusion triggers are not appropriate, the unique characteristics of injured patients do not allow universal application of these findings. It is possible to optimize transfusion practices once it is realized that injured patients experience distinct clinical phases based on time from injury. Although blood transfusion continues to be a lifesaving therapy, judicious use of blood and blood

components can provide maximal benefit and minimize unnecessary risk to the patient after injury.

# Transfusion Therapy in Solid-Organ Transplantation

**Glenn Ramsey**

Professor of Pathology, Northwestern University School of Medicine, Chicago, Illinois, USA

Recent clinical progress in organ transplantation has been tempered by the limited supply of organs.<sup>1</sup> The blood bank has a vital place on the hospital-wide team that makes transplantation possible for severely ill patients. Approximately 1% of all Red Blood Cell (RBC) and platelet transfusions and approximately 5% of all plasma and cryoprecipitate transfusions are used in organ transplantation surgery.<sup>2</sup> Blood banks also play an increasing role in recent efforts to prevent ABO- and HLA-mediated graft rejection.

In the United States, 257 programs perform organ transplantation. Table 40-1 shows the number of transplants of each organ performed in the United States in 2006.<sup>3</sup> Also shown are the 3-year graft and patient survival percentages for transplantation procedures performed on adults in the United States in 2001 with follow-up data through 2004. Pediatric results are similar.

## Organ Procurement

In the United States, organ procurement and allocation are regulated by the Health Resources and Services Administration (HRSA) of the Department of Health and Human Services. Under the authority of the National Organ Transplant Act [Title 42 US Code (USC), Section 273-274], HRSA oversees the Organ Procurement Transplant Network (OPTN) [Title 42 Code of Federal Regulations (CFR), Section 121].<sup>4,5</sup> The law for Medicare participation (42 USC 1320b-8) requires membership in the OPTN for all transplant centers (42 CFR 482.45) and organ procurement organizations (42 CFR 486.301-348). The OPTN in turn formulates policies required for its members.<sup>6</sup> The OPTN is administered by the United Network for Organ Sharing (UNOS) under contract with HRSA. Medicare also requires that hospitals

\*Waiting lists are as of September 2007. Survival rates are for transplantation procedures performed in 2001 with 3 years of follow-up evaluation.<sup>3</sup> Pancreas rates are averages of pancreas alone and pancreas after kidney.

DD = deceased donor; LD = living donor.

report deaths to the 58 organ procurement organizations for evaluation of organ donation eligibility.

As in transfusion medicine, blood group compatibility and disease transmission are of high concern for organ transplants. To reduce the risk of error, OPTN/UNOS policies specify that organ donors and transplant candidates each have two separate ABO typings performed, and the entry of these blood types into the national matching registry must be verified by a second person (OPTN Policies 3.1 and 3.2.4).<sup>6</sup> Medicare regulations also require these measures for organ donors (42 CFR 486.344). ABO errors in labeling or distribution are included in the OPTN/UNOS evaluation plan for assessing compliance with requirements.<sup>7,8</sup>

Organ transplants have transmitted not only blood-borne, transfusion-risk agents, including West Nile virus and *Trypanosoma cruzi* (Chagas' disease), but also other donor infections such as tuberculosis, methicillin-resistant *Staphylococcus*

*aureus*, rabies, lymphocytic choriomeningitis virus, and toxoplasmosis.<sup>9-11</sup> Donor-transmitted cancers occurred in 1 in 12,000 deceased-donor organ transplants in the United States. Although a history of cancer in an organ donor is not necessarily disqualifying, certain tumor types prone to occult metastasis are of extra concern, such as melanoma, lymphoma, and carcinoma of the breast, lung, colon, and kidney.<sup>12,13</sup>

OPTN/UNOS is authorized by federal regulation to establish policies for organ donor screening and testing. Their policies provide a list of infections and medical conditions that, if present, must be communicated to the transplant center. Donors must be tested for hepatitis B surface antigen (HBsAg); antibodies to human immunodeficiency virus (anti-HIV-1/2), hepatitis B core antigen (anti-HBc), hepatitis C virus (anti-HCV), human T-cell lymphotropic virus (anti-HTLV-I/II), cytomegalovirus (anti-CMV), and Epstein-Barr virus (anti-EBV); and a serologic test for syphilis (VDRL or RPR) (OPTN Policies 2.2 and 4.1).<sup>6</sup> The Food and Drug Administration (FDA) maintains a Web page with current information on infectious-disease tests cleared for organ and cadaver (non-heart-beating) donors.<sup>14</sup> These include several nucleic acid tests, although viral nucleic acid testing is not required by OPTN/UNOS. West Nile virus testing is not required, although HRSA issued a notice in 2004 that encouraged screening of living donors near the time of donation.<sup>15</sup>

Cadaver donations providing tissues are also subject to separate FDA tissue transplant safety regulations that focus on reducing the risk of relevant communicable diseases (21 CFR 1271). FDA-cleared cadaveric tests must be used for tissue donors when appropriate and available. Donors are ineligible to contribute organs or tissues if their infectious-disease tests are invalidated by excess hemodilution from recent transfusions or infusions, as defined in organ donor risk factors from the US Centers for Disease Control and Prevention (CDC) (OPTN Policy 4.1.1) and by tissue regulation (21 CFR 1271).<sup>5,6</sup>

OPTN/UNOS policies require prompt investigation of possible organ-borne infections and medical conditions, including look-back to other recipients from suspect donors (OPTN Policy 4.7).<sup>6</sup> A nationwide transplant safety sentinel network with a standardized donor identification system is under development in the United States.

The circulation of a brain-dead donor is maintained until the organs are harvested by transplantation surgeons. Sometimes blood component transfusions are needed for oxygenation and hemostasis. After cadaveric organs are removed, hearts and lungs must be used within 4 to 6 hours, livers within 12 hours, pancreata within 18 hours, and kidneys within 18 to 30 hours.<sup>1</sup> Preservative solutions are used during cold ischemia until transplantation.

## Organ Transplants

The systems for ranking the priorities of patients are specific for each organ and incorporate severity of illness. For each organ

within a region, the patient waiting lists are compiled according to ABO blood group. For each transplant procedure, two to four persons are on the waiting lists for the most commonly transplanted organs (Table 40-1). Organs and organ donors are still scarce. The need for organs has stimulated efforts to expand the supply by using organs from living donors and by splitting livers. Over one-third of US kidney transplants are from living donors.<sup>16</sup> The graft and patient survival rates are better than for renal transplantation from cadavers. A small number of liver transplants (4%) are from living donors, from whom the right lobe is removed. Both the graft split liver and the living donor's liver regenerate to normal size in a few weeks. Cadaveric livers sometimes are split (4%). The right lobe is given to one patient and the rest of the liver to another patient.

## Immunologic Barriers

The fundamental test for organ donation and transplantation is the ABO group, because solid organs almost always must be ABO compatible. Anti-A and anti-B bind to endothelial cells, setting off a cycle of complement fixation, vascular damage, and thrombosis that leads to ischemia and rejection. ABO-incompatible liver transplants are less susceptible to hyperacute rejection than are other organs but the risk of eventual rejection is still high. As group O RBCs are sometimes in shortest supply in relation to demand, so too are group O organs. Group O patients wait longer on average than other patients for nonemergency cadaveric transplantation.

HLA compatibility is also important for most organs, except the liver (see Chapter 57). Nonhepatic transplant candidates are assessed for HLA antibodies and their history of HLA exposure through pregnancy, transfusion, or prior transplant.<sup>6</sup> Recipient HLA antibodies against nonhepatic grafts lead to a much higher risk of acute and chronic rejection. After ABO compatibility, deceased-donor kidneys are first prioritized to recipients matched for all six HLA-A, -B, and -DR antigens, because these matches have slightly better graft survival. Kidneys can also be stored longer than other organs, permitting transport to a matched recipient. Kidney and pancreas transplants, together or separate, generally must be HLA Class I (T lymphocyte) cross-match-compatible before transplantation. OPTN/UNOS policy requires that heart and lung grafts also be prospectively HLA-compatible if the recipient has HLA antibodies or has been exposed. Livers do not require HLA matching or crossmatching. Leukocyte-reduced blood components are discussed below.

## Immunohematology

### Patient Alloantibodies

In the 1980s, 6% to 8% of adult recipients of kidney or liver transplants had clinically significant red cell alloantibodies. Another 8% of liver recipients developed antibodies after the

large number of transfusions given during surgery.<sup>17,18</sup> Both of these patient groups now receive fewer transfusions before and during surgery than in the past. Most patients with renal failure receive erythropoietin. Patients with cirrhosis often are treated to reduce variceal bleeding from portal hypertension with medications to reduce venous pressure ( $\beta$ -blockers, octreotide), sclerotherapy or band ligation of varices, and if necessary, transjugular intrahepatic portosystemic shunting. Consequently, pretransplantation red cell antibody problems are less frequent.

Advance screening for the presence of antibodies to non-ABO antigens is still advisable for candidates for liver transplantation. Some liver transplantation patients have multiple alloantibodies, or alloantibodies to high-frequency antigens; hence, the supply of antigen-negative units is limited. The following strategy has been successful in some programs: 1) give at least the first blood volume of RBCs as compatible, antigen-negative units; 2) after this degree of hemodilution of the antibodies, give unscreened or antigen-positive units; and 3) reserve additional antigen-negative units for after surgery, when transfusions return to small volumes and in anticipation of a possible anamnestic response after immune stimulation.<sup>19</sup>

When Rh-negative patients need large amounts of RBCs during liver or other organ transplantation, it may be necessary to give Rh-positive RBCs. Follow-up tests show that these patients usually do not make anti-D.<sup>20,21</sup> Transplantation immunosuppression greatly reduces the expected high rate of Rh sensitization among patients with normal immune function.

HLA alloantibodies against the donor can cause prompt rejection of renal and cardiac grafts. Candidates for these transplants undergo periodic HLA antibody tests, and then HLA cross-matching against donor lymphocytes to confirm compatibility.

Antibodies from Passenger Lymphocytes

As with hematopoietic stem cell transplants, organ transplants contain lymphocytes that sometimes can make antibodies against antigens in the recipient.<sup>22,23</sup> This is most common when group O organs are placed into non-group-O patients. OPTN/UNOS policies restrict the use of group O deceased-donor organs for non-group-O patients (OPTN Policy 3).<sup>6</sup> In the United States in 2005 there were about 500 excess group O deceased liver donors over the number of group O deceased-donor recipients, indicating that about 9% of deceased-donor liver transplants were from group O donors to non-group-O recipients.<sup>16</sup> In living-donor liver transplants, comparable statistics showed that about 20% of them (60 cases) were group O to non-group-O recipients.

In approximately 40% of liver transplant recipients and 10% of kidney recipients receiving an ABO-unmatched organ, the patient develops IgG antibodies from graft lymphocytes that react against his or her own A or B antigens. A few cases have been caused by group A or B organs in group AB patients. The patient's direct antiglobulin test becomes reactive 1 to 2 weeks after transplantation, and some of these antibodies produce sudden marked hemolysis. The antibodies typically persist for a few weeks. Immunoglobulin allotyping has proved that these

antibodies are of donor origin and are not patient autoantibodies. This phenomenon emerged after azathioprine for immunosuppression was replaced by cyclosporine, which is more permissive for secondary antibody responses, and it has occurred with tacrolimus as well.

Non-ABO red cell antibodies can develop in a similar manner if the organ donor has been alloimmunized against an antigen in the recipient. Rh and other antibodies have been reported, and some have caused temporary hemolysis.<sup>22,23</sup> Women donating kidneys to their children or their partner sometimes transmit pregnancy-induced antibodies. When an organ donor is found to have a clinically significant red cell alloantibody it is prudent to notify the organ procurement agency or in the case of a living donor, the recipient's physician. Then patients may receive RBC transfusions that are negative for the target antigen regardless of whether the patient is antigen positive or antigen negative.

Platelet antibodies have been transferred from organs of a donor who died of cerebral hemorrhage caused by immune thrombocytopenic purpura.<sup>24</sup> Perhaps any antibody-producing cells in the organ donor can be transferred temporarily to the recipient.

Blood Transfusion Needs

Table 40-2 shows recent data for mean blood component usage in nonhepatic organ transplantation. Primary cardiac transplantation without previous cardiac surgery is similar to routine cardiac surgery, but the use of components increases in operations for patients who have undergone previous sternotomy. The use

Table 40-2. Mean Blood Component Usage in Nonhepatic Organ Transplantation

Units are rounded to the nearest integer. Platelets are expressed as platelet concentrates, with apheresis units counted as 6 units. The cardiac transplantation range is from two centers. In one center, aprotinin reduced overall component transfusions in repeated sternotomy cases in a randomized study.<sup>25</sup>

of aprotinin in the care of patients undergoing second operations reduced overall blood component needs in a randomized study.<sup>25</sup> Patients undergoing transplantation after use of a cardiac support device need large amounts of blood, even when treated with aprotinin, in part because of anticoagulation before transplantation.<sup>26</sup> Double-lung transplantation uses more blood than does single-lung transplantation. Uncomplicated renal transplantation usually is a type-and-screen procedure, as is the living-donor nephrectomy.

## Liver Transplantation

The liver transplantation operation is simple in concept, but serious complications can develop at any time.<sup>30</sup> In the pre-anhepatic first stage, the vascular and biliary connections of the liver are dissected and exposed—portal vein, bile duct, hepatic artery, and inferior vena cava. The liver is separated from the diaphragm and the retroperitoneum, often exposing a raw, bare surface prone to bleeding. In the typical procedure, the major vessels are clamped, the vascular and bile duct connections are transected, and the liver is removed. The first stage usually takes 4 to 8 hours. In the anhepatic second stage, the graft and recipient suprahepatic and infrahepatic vena cava and portal vein are anastomosed end to end. The liver is flushed to remove most of its preservative solution. This second stage usually takes 1 to 1.5 hours. At the beginning of the third stage, the post-anhepatic stage, the large vessels are unclamped to restore portal inflow, and the hepatic artery and bile duct are connected. If all goes well, the third stage is completed in 2 to 4 hours.

Liver transplantation presents a unique set of challenges for transfusion and hemostasis needs. Patients with acute liver failure have low levels of clotting factors. Patients with cirrhosis also usually have thrombocytopenia caused by splenomegaly and low levels of thrombopoietin, much of which is made by the liver. Platelet function may be reduced by liver failure, uremia in hepatorenal syndrome, or anemia. Conversely, some patients have a hypercoagulability syndrome because of high levels of Factor VIII and decreased levels of fibrinolytic proteins.

During the operation, certain problems can arise in each stage. During dissection, portal hypertension can contribute to venous bleeding from the areas around the liver. Before and during the anhepatic stage, fibrinolysis sometimes develops from imbalance of its inhibitors and promoters. The graft is flushed, but when the new liver is unclamped, the patient often is partially anticoagulated by heparin present from the donor's anticoagulation and by heparin-like substances from injured endothelium released into the circulation.

To counteract all the possible problems, the liver transplantation, anesthesia, and laboratory team uses an array of tactics to meet the transfusion and hemostasis needs of the patient. Surgeons use an argon-beam laser to coagulate bleeding surfaces. Two surgical techniques are used in the care of selected patients to improve hemodynamics. If the anatomic features of the graft

are favorable, the liver can be sewn on to the inferior vena cava in a so-called “piggyback” manner to maintain partial blood flow through the vena cava during the operation. Some surgeons use venovenous bypass during the anhepatic stage, either routinely or if interruption of vena caval flow causes too much hypotension. This perfusion technique shunts venous return from the inferior vena cava and the portal vein up to the subclavian vein and improves cardiac output if needed.

To monitor coagulation status and to anticipate transfusion needs, hemoglobin, platelet count, prothrombin time, activated partial thromboplastin time, and fibrinogen are measured regularly. Many programs use thromboelastography (TEG) to supplement routine clotting tests.<sup>31</sup> The TEG instrument measures the initiation, rate, and strength of whole-blood clotting, and displays the results in the operating room as they develop over 20 to 60 minutes. TEG also has the following three functions not available in routine coagulation testing: 1) fibrinolysis can be readily detected; 2) the patient's blood can be tested *in vitro* with protamine or  $\epsilon$ -aminocaproic acid to assess whether these medications would help correct heparinization or fibrinolysis; and 3) hypercoagulability is also observed in some TEG results, but is not well correlated with clinical evidence of thrombosis. TEG testing can be employed in an algorithm for transfusion decision-making.<sup>32</sup>

To meet the patient's transfusion needs, intraoperative blood recovery and reinfusion is helpful.<sup>33</sup> One-third or more of the patient's total RBC transfusions can be provided by recovering shed blood during the operation. The anesthesiologist can give large volumes of warmed blood and fluids through a rapid-infusion pump that delivers more than 1 L per minute if necessary.

Plasma usage usually closely parallels RBC use in operations with large transfusion needs, in effect reconstituting whole blood for the transfusions. If available, whole blood is suitable for the first blood volume or so, because these patients usually have normal levels of Factor VIII. Solvent/detergent-treated (SD) plasma has been used successfully, although it may be deficient in some antifibrinolytic proteins.<sup>34</sup> The SD plasma product in the United States, which is no longer available, was associated with thrombotic or hemorrhagic problems during liver transplant. However, a European product has been used successfully in this setting.

Several programs have reported a range of factors correlating with perioperative transfusion needs. The laboratory variables that appear most often in their conclusions are preoperative anemia, platelet count, prothrombin time (or international normalized ratio), and creatinine.<sup>35</sup> The latter two values, along with bilirubin, are the elements for calculating the model of end-stage liver disease (MELD) score for predicting mortality risk and prioritizing adult transplant candidates in the United States. Higher MELD scores have also been associated with more blood use.<sup>32</sup>

Published blood component usage varies greatly among programs, with recent examples of mean RBC usage ranging from 3 units to 11 to 16 units (Table 40-3). Although there may be some publication bias toward favorable results, patient populations and intraoperative transfusion and surgical practices

account for some of the reported variance. In one study, the anesthesiologist was a major determinant. In France the main variable in a national comparison was the institution. Two European centers compared their practices to determine why one had higher blood usage and lower graft and patient survival. They found, as did previous workers, that more bleeding and higher RBC usage correlated with higher mortality. The center with less blood use took more time during surgery for hemostasis, and was more likely to do “piggyback” transplants or venovenous bypass, both of which preserve circulatory hemodynamics when needed. Jehovah’s Witnesses have undergone liver transplantation without blood component transfusions, with careful patient selection and the use of multiple blood conservation strategies.<sup>42</sup>

Liver transplants still require massive transfusion in some cases. Although some of these patients have preoperative coagulopathy, this usually can be corrected with appropriate transfusions in the first stage of the transplantation procedure. The underlying factors in these large hemorrhages usually are intraoperative problems such as unusually severe portal hypertension, cardiopulmonary instability, and anatomic and technical complications causing surgical blood loss. These problems often are not predictable from the patient’s transplantation evaluation, and significant blood use frequently is unexpected.

The role of antifibrinolytic agents in liver transplants has been mixed. When fibrinolysis develops and causes bleeding, tranexamic acid or ε-aminocaproic acid is often utilized. However, opinions vary on whether these drugs or aprotinin should be used as regular prophylaxis, in view of their potential to cause unintended clotting complications. Aprotinin has been used widely in Europe. A meta-analysis of controlled trials concluded that tranexamic acid and aprotinin reduced blood loss without increasing adverse thrombotic events.<sup>43</sup> However, other

reviewers found that aprotinin’s benefits were mainly in patient groups with higher blood loss, and did not recommend routine use.<sup>44,45</sup> Concern has emerged recently about aprotinin and excess mortality after cardiac surgery, and the drug has been suspended by the manufacturer.

Recombinant Factor VIIa was tested in two double-blind randomized trials in liver transplants. In a single-bolus trial, patients received one 20, 40, or 80 µg/kg bolus just before surgery.<sup>46</sup> In the second trial, doses of 60 or 120 µg/kg were repeated every 2 hours.<sup>47</sup> The median transfusion needs were not different from placebo in either study. The role of the drug in selected patients at high risk of bleeding or with refractory coagulopathy is under study.

Even without medications, thrombosis (either systemic or localized to the hepatic artery) is an occasional complication during liver transplant operations. In some patients, this complication is associated with hypercoagulability found during TEG, and moderate heparinization may be advisable. Aggressive correction of coagulopathy should be avoided when clotting would present special difficulties, as during venovenous bypass, or when the hepatic artery is small or not flowing well.

## Special Needs

### Prevention of Cytomegalovirus Infection

Cytomegalovirus infection is a major infectious complication of organ transplantation because of the cellular immunosuppression needed. If a candidate for solid-organ transplantation is anti-CMV-negative, CMV-reduced-risk cellular blood components should be provided (ie, obtained from anti-CMV-negative donors or leukocyte reduced to remove the bulk of CMV viral load).<sup>48</sup> When an anti-CMV-negative transplant recipient

receives an anti-CMV-negative organ, CMV-reduced-risk transfusions are recommended when possible to prevent third-party CMV infection from the blood donor. The growing availability of leukocyte-reduced components has increased the supply of CMV-reduced-risk components for liver transplantation.

For patients who are already anti-CMV-positive or who receive an anti-CMV-positive graft, CMV-reduced-risk transfusions generally are not necessary. The risk of CMV infection comes from the new organ or from reactivation of the original infection. CMV-reduced-risk components do not provide appreciable clinical benefit in these patients (see Chapter 47).

### Leukocyte Reduction

The leukocyte reduction of blood components for organ transplantation presents a paradox. This is one clinical setting in which transfused white cells were historically beneficial.<sup>49</sup> In the 1970s and early 1980s, transfusions were commonly given to candidates for renal transplantation to achieve better graft survival. RBC transfusions leukocyte reduced by means of freezing and thawing did not confer the same advantage. The effect was attributed to immunosuppression by transfused white cells. When immunosuppression improved, the transfusion advantage decreased. However, even with cyclosporine, donor-specific transfusions can impart some benefit for engraftment and survival.<sup>50</sup>

The other side of the paradox is that if the transplant recipient has previous HLA antibodies against the prospective graft kidney, transplantation is contraindicated because rejection of these organs may ensue. Donor-specific transfusions pose a risk of immunization against the donor, preventing the planned transplant. From this perspective, leukocyte reduction of pre-transplant transfusions would be desirable. HLA alloimmunization also adversely affects survival of heart and lung grafts.

The balance of current opinion probably falls on the side of leukocyte reduction to avoid development of HLA antibodies in candidates for nonhepatic organ transplantation. Research continues on transfusion immunomodulation in transplantation (see Chapter 45).

### Blood Irradiation

Graft-vs-host disease (GVHD) has occurred from passenger leukocytes in transplanted organs. However, GVHD from transfusions in these patients is rare.<sup>51</sup> Solid-organ transplantation usually is not included in recommended indications for blood irradiation (see Chapter 54).

### Breaching Immunologic Barriers

#### ABO

Because there are several times more transplant candidates than available annual organ donations, transplant centers have

employed several methods to evade the ABO barrier for selected patients: 1) exchanges of directed organ donors, 2) neonatal tolerance, 3) A<sub>2</sub> organs, and 4) humoral immunosuppression to permit accommodation of fully ABO-incompatible organs.<sup>52,53</sup> Blood bank support is vital to these efforts (Table 40-4).

The majority of kidney transplants are from living donors, but some patients may not have an ABO-compatible donor. In order to obtain ABO-compatible organs, some transplant centers arrange for willing donors to exchange with another patient.<sup>53</sup> Extended chains of such exchanges have been performed. Another strategy is for a donor to contribute a nondirected kidney to the general organ supply, and then the donor's patient of concern receives priority for an ABO-compatible deceased-donor organ.

Infants do not make their own circulating antibodies for several months after birth. This immunologic "loophole" has been successfully exploited for the transplantation of ABO-incompatible hearts in young children.<sup>54</sup> Graft survival is similar to ABO-compatible transplants, and fewer infants die waiting for a heart when ABO is not a limitation. This has been adopted in OPTN/UNOS organ allocation policy, including upper limits on antibody titers in infants 1 to 2 years old (OPTN Policy 3.7.8).<sup>6</sup> The presence of the incompatible ABO antigen at a very young age leads to long-term suppression of antibody production, with absence of donor-specific anti-A or anti-B peripheral B lymphocytes, and low or no anti-A or anti-B against the heart's antigens.

The tissues of persons with the A<sub>2</sub> blood group have weaker group A expression than in persons with the A<sub>1</sub> blood group, about 20% of the normal quantity. Kidneys from group A<sub>2</sub> donors have been successfully transplanted to group O and group B patients, as have group A<sub>2</sub>B kidneys to group B patients.<sup>55,56</sup> In some centers, candidates' anti-A titers are prescreened, and those with high titers are excluded from receiving a group A<sub>2</sub> or A<sub>2</sub>B kidney. However, transplants to eligible low-titer patients have been performed with regular immunosuppression, and results are similar to ABO-compatible grafts.

Fully ABO-incompatible kidney transplants have been performed using protocols with extra immunosuppression, removal of preexisting ABO antibodies by plasmapheresis, blockage of antibody production, and frequent monitoring of ABO antibody levels. These programs are most often established in living-donor transplants, when the date of transplant can be scheduled in advance, in contrast to unscheduled deceased-donor organ

**Table 40-4.** Roles for the Blood Bank in ABO-Incompatible Organ Transplant Protocols

- Seek A<sub>2</sub> organ donors with A<sub>1</sub> lectin or *ABH* gene typing.
- Select or process blood components to avoid giving passive graft ABO antibodies to recipients before and after receipt of transplant.
- Carefully titrate IgM and IgG ABO antibodies.
- Perform plasmapheresis to remove and control ABO antibody levels in pre- and perioperative periods.

transplants, which may not permit extended pretransplant preparations. Japan, which has very few deceased or group A<sub>2</sub> organ donors, has gleaned the most experience. A national registry of 564 ABO-incompatible transplants in 1989-2003 comprised 14% of all living-donor kidneys.<sup>57</sup> With the use of apheresis and splenectomy, the overall 5-year graft survival was 74%, compared to 81% in ABO-compatible controls. Outcomes improved over time, and the most recent 2-year graft survival was 94% for ABO-incompatible transplants.

Recent studies in Japan and other developed countries have sought to replace splenectomy with other means to suppress antibody production, such as rituximab (anti-CD20) and intravenous immune globulin (IVIG) or cytomegalovirus immune globulin (CMVIG) for immunomodulation, and the administration of mycophenolate mofetil to suppress both B and T lymphocytes.<sup>58-60</sup>

In all protocols, plasmapheresis to reduce and control anti-A or -B titers is a central feature. In the current guidelines for therapeutic apheresis from the American Society for Apheresis (ASFA), ABO-incompatible kidney and neonatal heart transplants are Category II indications, generally accepted adjuncts to other treatments, and incompatible liver transplants are in Category III, with suggestion of benefit, but efficacy not established.<sup>61</sup> Several European renal transplant centers have performed plasmapheresis with an in-line column containing A or B antigen to remove ABO antibody by immunoadsorption.<sup>62</sup>

As a corollary to these efforts, recipients or potential recipients of ABO-incompatible organs should not receive transfusions of large quantities of recipient-type plasma containing graft ABO antibody. The transfusion service selects components of appropriate ABO type, or processes them to remove graft antibody before transfusion.

ABO antibody titration is a critical laboratory test for physicians and their patients in these protocols. IgM antibody mediates complement fixation and endothelial damage in acute transplant rejection of ABO-incompatible organs, and IgM is more readily removed by plasmapheresis than IgG. However, many transplant series emphasize IgG titers for patient eligibility, rejection risk, and plasmapheresis guidance. A working group from several US centers recommended reporting both IgM and IgG titers.<sup>63</sup> Antibody titers routinely performed in the blood bank are subject to some degree of imprecision, with a range of  $\pm 1$  dilution (a fourfold difference). However, many transplant protocols set more precise titer targets for eligibility or antibody removal. In Japan, broad inter-institutional variation in titer results on survey specimens was improved with a more standardized method.<sup>64</sup> Future studies may illuminate which titration methods are most clinically useful and reproducible, and determine the role of more quantitative methods for antibody levels.

In the United States, the UNOS registry was examined for the outcomes of ABO-incompatible kidney transplants between 1995 and 2003.<sup>65</sup> With deceased-donor transplants ( $n = 201$ ), the 5-year graft survivals for fully incompatible transplants were the same as ABO-compatible cases (66-67%). For living-donor

kidneys ( $n = 191$ ), the ABO-incompatible grafts had lower overall long-term survival (66% vs 80% at 5 years), although the difference was mainly in the first year.

ABO-incompatible transplants are most vulnerable to rejection in the first month after surgery, and antibody reduction measures focus on this period. However, after the initial risk phase, most grafts survive despite the continuing presence of graft ABO antibody in the plasma and donor-type ABO antigens in the graft endothelium. This survival in the face of humoral immunity has been termed accommodation. Several mediators of rejection might be involved in this phenomenon.<sup>66</sup> Graft ABO antibodies sometimes remain at lower levels than before the transplant procedure, and may change in specificity. In ABO-incompatible kidneys after 3 to 12 months of graft survival, microarray gene expressions of several regulators of inflammation, apoptosis, signal transduction, and cell interaction were significantly altered in ways that suggested injury protection, when compared to ABO-compatible control grafts.<sup>67</sup> Other factors for further investigation include: 1) the effects of graft-derived A and B antigens in plasma, such as those on endothelial-derived von Willebrand factor; 2) complement pathway components and their immunomodulation of the local immune response; and 3) nitric oxide release from ABO-incompatible endothelial cells, which could dampen apoptosis and platelet adhesion.<sup>68</sup>

## HLA

Similar to the ABO blood group, the HLA system poses a significant barrier to transplantation in patients with preexisting antibodies, but immunologic manipulations are making some headway for these patients. Broadly alloimmunized patients are identified by a high percentage of positive lymphocytotoxic crossmatches to Class I antigens on donor or panel T cells. In the United States, 14% of renal transplant candidates have antibodies against  $\geq 80\%$  of potential donors (panel-reactive antibody, PRA).<sup>16</sup> These patients have great difficulty receiving a compatible living or deceased-donor kidney.

Protocols to suppress HLA antibodies have been termed desensitization. The two main alternate strategies currently used are 1) high-dose IVIG, and 2) plasmapheresis and low-dose IVIG or CMVIG.<sup>68</sup> How IVIG works in these protocols is uncertain, but possibilities include receptor blockade, anti-idiotypic antibody content, and inhibition of the activation of lymphocytes and complement.<sup>69</sup>

High-dose IVIG is given at up to four monthly intervals before receipt of living-donor or deceased-donor transplants, until crossmatches are negative, and then once, 1 month after surgery. In-vitro testing to identify candidates in advance has been performed by assessing whether the presence of IVIG inhibits a patient's antibody in lymphocytotoxicity testing. Of 77 sensitized patients passing this prescreening, 87% received living or deceased-donor organs.<sup>69</sup> Rejection episodes occurred in 28%, but the 3-year graft survival was 87%.

Plasmapheresis and low-dose IVIG have been used mainly before living-donor kidney transplants. Multiple plasmapheresis

procedures are performed every other day before and after the transplant procedure (the number of procedures in proportion to the preexisting antibody titer) and IVIG is given after each procedure. The center with the most experience used CMVIG, converted 63% of patients' crossmatches to negative before transplantation, and had approximately 85% 3-year graft survival.<sup>70,71</sup>

A randomized double-blind clinical trial of desensitization compared high-dose IVIG to placebo in 101 renal transplant candidates with PRA  $\geq 50\%$ .<sup>72</sup> The mean PRA was reduced from about 75% to 60% in the treatment group during four monthly infusions, and 35% of treatment patients received a kidney, compared to 17% of controls. For the transplants, the 2-year graft survival rates of 75% to 80% were similar in the two groups.

One center reported comparative data from periods when either high-dose IVIG or plasmapheresis/IVIG plus rituximab were used. The plasmapheresis/IVIG patients were desensitized in 85% of 48 cases, compared to 38% of 13 high-dose IVIG cases.<sup>73</sup>

Antibody-mediated rejection has also been treated with either of these two approaches, as well as rituximab alone.<sup>74</sup> In the ASFA guidelines, plasmapheresis for HLA desensitization and antibody-mediated rejection are both Category II indications, generally accepted adjunctive therapy.<sup>61</sup>

### Other Applications of Therapeutic Apheresis

Photopheresis is under study for the prevention and treatment of heart and lung transplant rejection.<sup>75</sup> Leukocytes are collected, exposed to psoralen and ultraviolet A light *ex vivo*, and then reinfused. This is thought to induce immunomodulation of T cells regulating or mediating organ rejection. ASFA classifies this therapy in Category III (suggestion of benefit, insufficient evidence of efficacy) for treating lung rejection manifesting as bronchiolitis obliterans.<sup>61</sup> Also under Category III is plasmapheresis in acute liver failure, as a supportive therapy until hepatocellular recovery or transplantation.<sup>61</sup>

## Artificial Organs

Several types of cardiac assist devices are in use or under development for the care of patients with severe cardiac failure.<sup>76</sup> Some are for temporary use or as a bridge to cardiac transplantation. Others are intended for permanent implantation. While using these devices, patients often develop coagulopathy from platelet dysfunction or anticoagulation. Transfusions during these treatments can cause HLA alloimmunization, and leukocyte-reduced components should be used if transplantation is planned.

Hepatic assist devices are perfused with the patient's blood or plasma to remove toxins.<sup>77</sup> These systems are in clinical trials to support patients until their liver recovers, as in poisoning, or until a liver transplant is available. One category of these systems passes the blood through various absorbent materials such as charcoal, resins, or albumin. The other type metabolizes toxins in the blood with immobilized porcine or human hepatocytes in a perfused bioreactor.

## Summary

As organ transplant graft and patient survivals continue to gradually improve, the limited supply of organs has stimulated many creative ways to hurdle traditional immunologic barriers of ABO and HLA tissue incompatibility. The role of transfusion medicine has expanded beyond transfusions to include the laboratory and clinical support of therapies to prevent and reverse graft rejection, making transplants more available and more durable. Progress in this field may lead to new advances in other diseases when immune reactions are foe, not friend.

# 41

## Apheresis: Principles and Technology of Hemapheresis

Ronald O. Gilcher<sup>1</sup> & James W. Smith<sup>2</sup>

<sup>1</sup>Medical Director Emeritus, Oklahoma Blood Institute, Oklahoma City, Oklahoma, USA

<sup>2</sup>Medical Director, Oklahoma Blood Institute, Oklahoma City, Oklahoma, USA

*Apheresis*, a word of Greek derivation, means “removal” in its broadest sense. In this chapter, it refers to any procedure during which blood is withdrawn from the donor or patient and separated *ex vivo* into some or all of its components. Some of these components are retained for donation or therapeutic purposes. The others are returned, usually “on line,” to the person. The word *pheresis* once was used synonymously with the word *apheresis*; however, *apheresis* is the preferred word. *Hemapheresis* is frequently used synonymously with *apheresis*.

### Historical Background

The first experimental apheresis procedure was performed in 1660 by Richard Lower of Oxford, England, who performed a manual procedure on dogs. Plasmapheresis (removal of plasma with return of red cells) was first performed in France in 1902 and in Russia in 1914.<sup>1</sup> In 1914 at Johns Hopkins University, Roundtree and Turner used plasmapheresis in artificial kidney research.<sup>1</sup>

In 1960, Soloman and Fahey used manual plasmapheresis therapeutically to reduce elevated globulin levels in a patient with a hyperviscosity syndrome, and thus began the era of therapeutic apheresis.<sup>1,2</sup> Apheresis became a practical reality with technologic advances, which included development of plastic bags, integrally connected tubing, and *ex-vivo* centrifugation. Initially, apheresis involved blood separation as an “off-line” disconnected process in laboratories with freestanding component separation centrifuges. Now, apheresis is routinely performed as an “on-line” procedure with fully automated blood cell separators at the donor’s or patient’s bedside.

Manual donor plasmapheresis with paid plasma donors was the major method of collecting Source Plasma for fractionation into plasma derivatives (albumin, immunoglobulins, Factor VIII,

and Factor IX) between 1950 and 1980. Because the process was “off line,” requiring separation of the donor from the unit of whole blood during plasma separation, the possibility of returning the red cells to the wrong donor existed and occasionally did occur. The long time of 1.5 to 2 hours to collect 500 to 700 mL of plasma led to the use of paid donors and ultimately to the contamination of many plasma derivatives with hepatitis B virus (HBV) and hepatitis C virus (HCV), and human immunodeficiency virus (HIV). In the 1980s, automated on-line cell separation devices were developed by Haemonetics (Braintree, MA), Baxter Fenwal (Deerfield, IL), and Organon Teknika (Boxtel, The Netherlands) for collection of Source Plasma in the United States and Europe. By 1985, an estimated 120,000 to 150,000 automated donor plasmapheresis procedures had been performed in the United States; however, 15 years later that number was more than 12 million a year and now is estimated to exceed 17 million donations per year worldwide.<sup>3</sup>

Granulocytes, platelets, and Fresh Frozen Plasma (FFP) were the original components collected by means of apheresis technology. Today, numerous blood components are collected from a single donor by means of automated apheresis technology, including the following:

1. Platelets.
2. Plasma.
3. Red Blood Cells (RBCs).
4. RBCs plus plasma (RBCP).
5. 2-unit RBCs (2RBCs).
6. Platelets and RBCs.
7. Platelets and plasma.
8. Granulocytes stimulated with steroids or colony-stimulating factors.
9. Hematopoietic progenitor cells (HPCs) stimulated with granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF).

In the past few decades, plateletpheresis procedures have increased dramatically—from 171,200 in 1989 to 1,167,000 in 2006.<sup>4</sup> RBC apheresis procedures, especially 2RBC collections, are rapidly increasing. Nationally, the collection of apheresis RBCs increased from

824,000 in 2004 to 1,619,000 in 2006.<sup>4</sup> Of the 149,763 collections of allogeneic RBCs at the Oklahoma Blood Institute (OBI) in 2000, 13,944 (9.3%) resulted from RBC apheresis procedures. In 2006, the apheresis RBCP or 2RBC procedures at OBI produced 24,685 units (13% of total RBC units).

Therapeutic apheresis procedures (therapeutic plasma exchange and therapeutic cytapheeresis) have increased as well—from an estimated 60,000 to 80,000 in 1985 to more than 112,000 in 2006.<sup>4</sup> One reason for the increase is the use of hemapheresis technology to remove red cells provides a new approach for patients with hemochromatosis. Another reason is the expanding role of photopheresis in managing conditions such as graft-vs-host disease (GVHD) and graft rejection.

## Current Technology Overview

Edwin J. Cohn, originator of plasma fractionation processes to produce plasma derivatives such as albumin and  $\gamma$ -globulin, developed a prototype machine for centrifugal separation of the cellular elements of blood from plasma. Allen “Jack” Latham, cofounder of Haemonetics, working with Cohn’s prototype, developed a disposable polycarbonate plastic bowl with a rotary seal, which was first used to collect platelets in 1971. Concurrently, George Judson, an IBM engineer on loan to the National Cancer Institute, developed another machine to facilitate white cell (granulocyte) collection.<sup>1</sup> Plasmapheresis and eventually therapeutic plasma exchange (TPE) and therapeutic

cytapheeresis were natural developments in the use of these early apheresis devices to manage human diseases known or thought to be mediated by plasma or cellular factors.

The apheresis devices currently approved by the US Food and Drug Administration (FDA) for donor and patient (therapeutic) use are outlined in Table 41-1. These devices are either discontinuous flow (Haemonetics) or modified continuous flow [Fenwal (Lake Zurich, IL), Fresenius (Bad Homburg, Germany), CaridianBCT (Lakewood, CO)] systems that can be used for one- or two-arm venous access for apheresis procedures. The spinning membrane technology used in the Autopheresis-C (Fenwal) and the flexible bowl technology of Transfusion Technologies (acquired by Haemonetics in 2000) are unique. The latter device has an expandable membrane over a flat disk. Fluid pressure controls the shape and volume of the collecting apheresis chamber and offers unique options for future blood component collection and separation. This flexible bowl is being used in an intraoperative and postoperative autotransfusion device (Haemonetics OrthoPAT System) and in the Haemonetics Cymbal Automated Blood Collection System currently approved for 2RBC collection.

### Fenwal Technology

Fenwal uses continuous-flow technology and a sealless system in the CS3000 blood cell separator, originally introduced in the early 1980s. The device is fully automated and computer controlled. The CS3000 concentrates platelets during collection into a final volume of approximately 200 mL. An enhancement of the CS3000 with a platelet-collection chamber called the TNX-6

**Table 41-1.** Apheresis Devices Used in the United States for Donor Collection and Patient Therapeutics

| Manufacturer/Device | Type  | Product/Procedure     | Venous Access | Intended Use     |
|---------------------|-------|-----------------------|---------------|------------------|
| <b>Fenwal</b>       |       |                       |               |                  |
| CS-3000             | C/CF  | PLAP, HPC, TPE        | 1 or 2 arms   | Donor or patient |
| Amicus              | C/CF  | PLAP, AAFP            | 1 or 2 arms   | Donor            |
| ALYX                | C/CF  | 2RBC, RBCP            | 1 arm         | Donor            |
| Autopheresis-C      | SM/DF | AAFP, SP              | 1 arm         | Donor            |
| <b>Fresenius</b>    |       |                       |               |                  |
| AS104               | C/CF  | PLAP, HPC, TPE        | 1 or 2 arms   | Donor or patient |
| <b>CaridianBCT</b>  |       |                       |               |                  |
| Spectra             | C/CF  | PLAP, HPC, TPE        | 1 or 2 arms   | Donor or patient |
| Trima/Trima Accel   | C/CF  | PLAP, AAFP, RBC, 2RBC | 1 arm         | Donor            |
| Optia               | C/CF  | TPE, HPC              | 1 or 2 arms   | Patient          |
| <b>Haemonetics</b>  |       |                       |               |                  |
| MCS+(LN9000)        | C/DF  | PLAP, AAFP, TPE       | 1 or 2 arms   | Donor or patient |
| MCS+(LN8150)        | C/DF  | RBCP, 2RBC            | 1 arm         | Donor            |
| Cymbal              | C/DF  | 2RBC                  | 1 arm         | Donor            |
| PCS-2               | C/DF  | AAFP, SP              | 1 arm         | Donor            |
| <b>Therakos</b>     |       |                       |               |                  |
| UVAR-XTS            | C/DF  | PCWBC                 | 1 arm         | Patient          |

C = centrifugal; CF = continuous flow; DF = discontinuous flow; SM = spinning membrane; PLAP = platelet by apheresis; AAFP = apheresis fresh frozen plasma; RBC = red blood cell; 2RBC = 2-unit red blood cells; TPE = therapeutic plasma exchange; SP = source plasma; HPC = hematopoietic progenitor cells; PCWBC = photochemically modified white blood cells.

separation chamber has decreased the white cell content in the platelet product. The CS3000 Plus can be used to collect granulocyte-platelet concentrates and HPCs. These devices are being slowly removed from the market.

Fenwal has developed a newer cell separator called the Amicus, which operates in a manner similar to the CS3000, but has a smaller footprint and operates as a one-arm venous access device for platelet collection. The high extraction coefficient for platelets allows frequent collection of double products, such as two apheresis platelet products each containing at least  $3.0 \times 10^{11}$  platelets and less than  $1.0 \times 10^6$  residual leukocytes without the use of a leukocyte reduction filter. In donors with platelet counts of  $\geq 250,000/\mu\text{L}$  before donation, double plateletpheresis products are obtained more than 75% of the time.

The ALYX is a relatively new and compact mobile automated blood collection system that was initially developed as a 2RBC apheresis collection device. It has been approved for collection of concurrent plasma. Following collection in the rigid, cylindrical centrifuge chamber, red cells are pumped through an on-line leukocyte reduction filter into the final storage bag(s).

Fenwal also uses a device called the Autopheresis-C with a spinning membrane, thus incorporating both membrane and centrifugation technology to collect plasma. In the United States, this device is commonly used to collect Source Plasma as well as apheresis FFP. This is a discontinuous system in which only a single venipuncture is performed. Fenwal attempted to change the porosity of the membrane to collect platelet-rich plasma,<sup>5</sup> but the procedure has been abandoned.

### Fresenius Technology

Fresenius introduced a cell separator in Europe in 1987 primarily for the collection of platelets. The Fresenius AS104 is currently licensed in the United States for the collection of apheresis platelets and is licensed for TPE and collection of HPCs. It is a continuous-flow, double-venipuncture system. Fresenius has introduced an upgraded version called the AS204 in Europe but not in the United States. Further development led to the COM.TEC, the latest commercialized version in Europe and Canada. It is not yet available in the United States.<sup>6</sup>

### CaridianBCT Technology

CaridianBCT (formerly Gambro and COBE) acquired the IBM biomedical services technology (the IBM-2997 cell separator) and then developed the COBE Spectra as a sealless system based on the original IBM-2997 rotating-channel belt. The Spectra is a continuous-flow system in which one- or two-arm venous access is used for platelet collection. The Spectra uses a leukocyte reduction system to collect leukocyte-reduced platelet units. The Spectra device indicates when units contain excessive numbers of leukocytes and thus when counting is needed to document leukocyte reduction status. The Spectra device also is used to collect HPCs and to perform therapeutic apheresis procedures.

The newest CaridianBCT cell separators are the Elutra Cell Separation System (not currently FDA-approved) and the

Spectra Optia Apheresis System (recently FDA-approved). The Elutra Cell Separation System is an “off-line” system that uses counterflow centrifugal elutriation to separate cell populations. The Spectra Optia Apheresis System is based on the Spectra but uses a Trima platform and is aimed at the therapeutic apheresis and cell therapy markets. This instrument will eventually incorporate the multiple programs from the Spectra, but in the more portable size of the Trima platform. At the present time it is approved only for TPE.

The Trima system has evolved into the Trima Accel Collection System and is also a relatively new device. The original Trima device is fully automated; the technology is similar to that of the Spectra device. The Trima is a one-arm venous access device, has no rotating seal, and has a smaller footprint than does the Spectra. The Trima is capable of collecting double units ( $\geq 6.0 \times 10^{11}$  platelets) that are leukocyte reduced to  $1.0 \times 10^6$  or fewer residual white cells. The Trima has been designed and is FDA approved to collect a single or double RBC unit along with the apheresis platelet product. To date it has not been used for therapeutic procedures. Collection of 1 or 2 RBC units with a platelet unit ( $\geq 3.0 \times 10^{11}$  platelets) that is leukocyte reduced is a novel idea and has the advantage of increasing the RBC supply of a blood center. The disadvantage is the possibility of deferring a donor on the next visit if the donor's hematocrit decreases to less than 38%. Because of the low extracorporeal red cell mass in the Trima device, a donor giving red cells and a plateletpheresis product can return within 72 hours to donate another plateletpheresis product with the Trima device—provided the donor's hematocrit is 38% or higher.<sup>7</sup> For donors with a predonation platelet count of  $\geq 250,000/\mu\text{L}$ , double plateletpheresis products can be collected more than 75% to 80% of the time.

The Trima Accel Collection System collects platelets, red cells, plasma, and combinations of these blood components. It is unique in that it uses the single-channel belt, whereas the original Trima used the dual-channel belt for the collection of platelets. By using the single-channel belt coupled to an internal leukocyte reduction system, the Trima Accel has an increased platelet extraction coefficient and still maintains a low residual white cell count of less than  $10^6$  per component. The advantages of the Trima Accel are 1) it can collect the same number of platelets as the “standard” Trima but in a shorter time, 2) it can collect more platelets in the same time as the “standard” Trima, or 3) it can collect the same number of platelets in the same time as the “standard” Trima, but do it by processing less of the donor's blood, which means delivering less citrate to the donor and reducing citrate-induced donor reactions.

Obsolete CaridianBCT technologies include a continuous-flow device with a flat membrane for blood separation and the COBE/IBM 2997.

### Haemonetics Technology

The discontinuous-flow cell separators (MCS+ LN9000; MCS+ LN8150; PCS-2) produced by Haemonetics operate with a fixed centrifuge speed and a variable centrifugal force to separate a

donor's or patient's blood into components. A disposable hard-shelled rotating bowl separates the incoming blood in such a way that red cells move to the periphery and plasma to the inside of the rotating bowl. The buffy coat, which contains the white cells and platelets, forms a layer between the red cells and plasma. Platelets or mononuclear cells are collected with the aid of optical detectors by means of a fluid-surge elutriation process. The remaining red cells and plasma are returned to the donor, and the platelets are retained until the desired yield is obtained with multiple passes or cycles. This discontinuous technology is amenable to a one- or two-arm protocol, although the one-arm venous access technique is used more often because of donor preference for a single needlestick.<sup>8</sup> The Cymbal Automated Blood Collection System uses the Dynamic Disk, which is a flexible expandable variable volume bowl for the collection of 2RBC as currently FDA approved. It is also a discontinuous flow system.

The Haemonetics plasma collection system-2 (PCS-2), which currently does not have a functionally closed rotating seal, has a disposable bowl specifically designed to collect plasma. This has become the most commonly used automated cell separator for collection of Source Plasma in the United States and the world. The PCS-2 also is used to collect transfusable plasma in clinically useful volumes of 500 to 600 mL (apheresis FFP). The MCS+ cell separators are fairly lightweight [60 to 70 lb (27 to 31.5 kg)], extremely portable and mobile, fully automated, and flexible in terms of blood components collected. The MCS+ LN9000 is used strictly to collect platelets with or without concurrent plasma. Unlike the Fenwal Amicus and Caridian Trima or Spectra leukocyte reduction system, the initial platelet product is not leukocyte reduced to an acceptable level ( $\leq 1.0 \times 10^6$  residual white cells) and must undergo leukocyte reduction via filtration, which is now accomplished with an on-line process that produces a final transfusable product that contains  $\leq 1.0 \times 10^6$  residual white cells in  $3.0 \times 10^{11}$  or more platelets.

The MCS+ LN8150 has been developed for collection of either RBCP or 2RBC.<sup>9-11</sup> Each RBC unit contains approximately 180 to 200 mL of absolute red cell mass with the machine preprogrammed for the desired amount of red cell mass. Both MCS+ devices (LN9000 and LN8150) have a functionally closed rotating seal to maximize product shelf life. The MCS+ LN8150 operates with an anticoagulant to anticoagulated whole blood (AC:ACWB) collection ratio of 1:16 with citrate-phosphate-dextrose-dextrose (CP2D), which further reduces the amount of citrate in the RBCP or 2RBC units but markedly reduces the citrate in the plasma collected. The plasma of the RBCP collection contains one-half the citrate of whole-blood-derived (WBD) FFP. The red cells from the 2RBC procedure can be filtered on line using a single filter to yield 2 leukocyte-reduced RBC units. These systems return saline to minimize the chance of donor hypovolemia.

The newest instrument/system available from Haemonetics is the Cymbal Automated Blood Collection System, a small, lightweight, portable, discontinuous flow device intended for the collection of 2 RBC units. This device uses a variable volume

bowl that expands as blood fills it, with separation occurring based on density in the centrifugal field. The system uses CP2D with AS-3 and filters the red cell on line to achieve leukocyte reduction.

### Therakos (Johnson & Johnson) Technology

The newest photopheresis device (UVAR-XTS system) is a discontinuous-flow cell separator that collects buffy coat containing mononuclear cells from patients with a variety of conditions such as cutaneous T-cell lymphoma, GVHD resulting from marrow transplantation, or solid-organ rejection. Methoxsalen (Uvadex) is injected into the buffy coat product, the cells are incubated and irradiated with ultraviolet light, and the component is transfused back to the patient. Amelioration of the pathologic process through immunologic effects on clones of mononuclear cells is the desired outcome. The older Therakos UVAR photopheresis system used oral administration of methoxypsoralen and is no longer supported.

### Other Technology

Other devices, both centrifugal and membrane based, are used outside the United States. Dideco (Mirandola, Italy) makes an automated blood cell separator (Excel) for the collection of apheresis platelets. Organon Teknika developed a hollow-fiber membrane (Plasmapur) plasma collection system, which was previously used in Europe to collect source plasma. Several Japanese and European manufacturers make hollow-fiber separators and filters for donor and therapeutic use. Immunoabsorption and cellular adsorption technologies continue to be tried for removal of pathologic antibodies and to modify cell-mediated immunity respectively, although most have been withdrawn from, or are not readily available in, the US market.<sup>12</sup> Several methods have been developed for removal of lipid fractions from patients with homozygous type II hypercholesterolemia. These technologies (see Chapter 43) are expensive and for the most part rather complicated, but effective in a select group of patients.<sup>13,14</sup>

---

## Donor Apheresis

### General Information

The key forces driving transfusion medicine in the early 21st century are donor and recipient safety enhancement, improved product quality, error reduction, blood availability, legal and regulatory issues, and cost. The issues of safety, quality, and error reduction with regard to blood components are enhanced with the use of apheresis-derived products. Metered anticoagulation, automation during collection, reduced variables, labeling techniques, and fewer donor exposures all enhance safety, quality, and error reduction. The issues of blood availability (especially RBC units) and increasing cost (especially for testing for infectious and noninfectious agents and additional processes such as leukocyte reduction) have become critical issues. Apheresis components that have been more expensive to produce in the past are now being produced as

double- and triple-yield products or as multiple types of products (RBCP and RBCs plus platelets). This reduces costs while increasing availability. The advantages of apheresis-derived blood components are listed in Table 41-2. Blood components that can be obtained are presented in Table 41-3.

### Donor Care

Donors who undergo automated apheresis must go through routine screening and testing procedures. At minimum, apheresis

**Table 41-2.** Advantages of Apheresis-Derived Blood Components

- Reduced donor exposure: full transfusion dose
- Frequent repeat donor: “pedigreed” donors
- Higher quality products: more quality control per component collected
- Consistent and standardized products (yields)
- Matching donors to patients
- Reduced donor reactions
- High donor acceptance
- Double yield or multiple full-dose blood component collections
- Safety enhancement: for the patient

**Table 41-3.** Apheresis-Derived Blood Components from a Single Procedure

| Procedure          | Instrument                                                     |
|--------------------|----------------------------------------------------------------|
| <b>Primary</b>     |                                                                |

| PLAP + RBC         | Trima/Trima Accel                                              |
| 2RBC               | MCS+(LN8150), Cymbal, ALYX                                     |
| RBCP               | MCS+(LN8150), ALYX                                             |
| Plasma             | PCS-2, Autopheresis-C                                          |
| Granulocytes       | MCS+(LN9000), Spectra, CS3000,                                 |
| HPC                | Spectra, Optia, CS3000, AS104                                  |
| <b>Secondary</b>   |                                                                |
| Cryoprecipitate    | PCS-2, Autopheresis-C                                          |
| Cryoreduced Plasma | PCS-2, Autopheresis-C                                          |

PLAP = plateletpheresis; RBC = red blood cells; 2RBC = 2-unit red blood cells; RBCP = red blood cells plus plasma; HPC = hematopoietic progenitor cells.

component donors must meet all the requirements of whole-blood donors. The main difference is that the “needle in to needle out” time for a 500-mL whole-blood donation is only 8 to 12 minutes, whereas the time for plasmapheresis and red cell apheresis is 35 to 45 minutes, and the time for plateletpheresis is 60 to 120 minutes. The longer total time for apheresis donation requires more precise scheduling and a more dedicated donor. When 2 RBC units are donated, the interval between donations is 112 days, for a maximum of three donations per year. For whole blood donors, the maximum is six donations per year. Plateletpheresis donors can give up to 24 donations per year. Donors of transfusable apheresis plasma can make up to 13 donations per year (every 28 days) if the blood center obtains a variance from the FDA with regard to regulations for Source Plasma donors, who donate more frequently. The blood center plasma donors are known as infrequent donors under this variance.

In the United States, Source Plasma (for fractionation into albumin, intravenous immune globulin, Factor VIII, and Factor IX) is obtained almost exclusively from compensated donors who donate at commercially operated plasma centers. These donors may donate up to 800 mL of absolute plasma per donation as frequently as twice a week, depending on the donor's weight. The donor must be examined at defined intervals by a physician and must have total protein and serum protein electrophoresis determinations made at FDA-required intervals as specified in the *Code of Federal Regulations*.<sup>15</sup>

Apheresis donors tend to have lower reaction rates than do donors of whole blood (Table 41-4).<sup>16</sup> Vasovagal reactions are most common among first-time blood donors; apheresis donors usually are repeat donors.<sup>17</sup> Hypovolemia is less common among apheresis donors than among whole-blood donors for two reasons. First, the total volume removed in apheresis donation procedures is less than that in whole-blood donation because the component has a lower volume, as in plateletpheresis, or volume is returned to the donor as crystalloid solution in the anticoagulant and saline solution. Second, the relatively long time at rest during apheresis donation allows transcapillary refilling of the intravascular compartment from the interstitial space. Allergic reactions to iodine skin preparations—the reaction is to the organic radical attached to the iodine—are very rare. However, a mild citrate

**Table 41-4.** Donor Reactions

| Reaction       | Whole Blood  | Apheresis FFP | Apheresis Platelets | 2RBC, RBCP |
|----------------|--------------|---------------|---------------------|------------|
| Vasovagal      | Occasionally | Rare          | Rare                | Rare       |
| Hypovolemia    | Occasionally | Rare          | Rare                | Rare       |
| Allergic       | Very rare    | Very rare     | Very rare           | Very rare  |
| Citrate effect | None         | Rare          | Frequent            | Rare       |
| toxicity       | None         | Very rare     | Occasional          | Very rare  |

FFP = fresh frozen plasma; 2RBC = 2-unit red blood cells; RBCP = red blood cells plus plasma; Occasional = 0.5% to 2.5%; Rare = <0.5%; Very rare = <0.01%; Frequent = 5% to 20%.

effect (circumoral paresthesia, feelings of vibration or buzzing, tingling, or coldness) is not uncommon for most plateletpheresis donors. More severe citrate toxicity (muscle cramping, total body shivering, nausea, vomiting, and tetany) is uncommon but is potentially serious and necessitates slowing the return rate of citrate-containing plasma.<sup>18,19</sup> The intravenous administration of calcium-containing solutions is generally not recommended, unless the reactions are unusually severe or prolonged.

Hemolysis occurs rarely and when it does, the cause is almost always mechanical, such as occlusion or partial occlusion of red-cell-containing tubing. On rare occasions (1 in 3000 to 5000 donations), hyperlipemic plasma in platelet donors causes elevated and visible free hemoglobin levels in the collected component. The mechanism of this hemolysis remains unclear.

Venous access is an important consideration in donor apheresis procedures because of the need for 1) long “needle in to needle out” time, 2) a prolonged high flow rate, 3) increased frequency of donation, and 4) the occasional need for two venipunctures with continuous-flow equipment. Possible venous access injuries include blood infiltration and bruising and, rarely, venous thrombosis. Cutaneous nerve injuries are rare, and deep nerve injuries (median, ulnar, and radial nerves) are almost nonexistent. The development of smaller-needle technology for venous access will help reduce these problems.

Extracorporeal blood volume (ECBV) in apheresis procedures is greatly reduced with use of newer devices, such as the Amicus and Trima. With the older devices, especially the discontinuous-flow devices, ECBV tends to be greater but generally is not a problem except in therapeutic apheresis involving pediatric patients. The supine position of donors and access to oral fluids during the procedure eliminate most problems. However, when the older, higher ECBV devices are used, malfunction of a machine can lead to loss of ECBV, resulting in a 56-day donor deferral. The low ECBV of the newer devices allows another plateletpheresis procedure within 3 days if necessary. If the ECBV of the apheresis device is 100 mL or less, plateletpheresis may be performed less than 8 weeks after a whole-blood donation.<sup>20(p24)</sup>

In the early years of donor apheresis, lymphocyte depletion with loss of immunologic memory was a concern because of high white cell levels in apheresis components, especially in platelets. This has proved not to be a problem, and with the current focus on leukocyte-reduced apheresis components, it is no longer a concern even for very frequent apheresis donors.<sup>21</sup> Frequent plateletpheresis does not clinically decrease platelet counts in donors.<sup>22</sup>

### Specific Products and Procedures

Plateletpheresis donations are limited to 24 per year by the AABB and the FDA. Plateletpheresis donation can occur every 72 hours but not more than twice a week. If the interval between plateletpheresis donation is 4 weeks or more, a predonation platelet count is not required. If the interval is less than 4 weeks, a predonation platelet count must be obtained and must be  $\geq 150,000/\mu\text{L}$  for the procedure to be performed. If red cell loss during the procedure exceeds 200 mL, the waiting period is 8 weeks before the next

donation. Donors with predonation platelet counts of  $\geq 300,000/\mu\text{L}$  usually can donate a double-dose platelet product ( $\geq 6.0 \times 10^{11}$  platelets). Almost all plateletpheresis products in the United States are produced as leukocyte reduced (meeting AABB standards<sup>20(p37)</sup> for  $5.0 \times 10^6$  or fewer residual leukocytes). However, the European standard is  $1.0 \times 10^6$  or fewer residual leukocytes per product. Prestorage leukocyte reduction can be accomplished “in process” (nonfiltration leukocyte reduction, CaridianBCT and Fenwal) or immediately after (filtration, Haemonetics) for virtually all plateletpheresis procedures. Prestorage leukocyte reduction has clear advantages over poststorage or bedside leukocyte reduction filtration in reducing febrile reactions and other leukocyte-related complications by preventing accumulation of cytokines and leukocyte fragments during storage.<sup>23-25</sup>

The intravascular volume deficit during the procedure should not exceed 10.5 mL/kilogram of the donor’s weight. Plateletpheresis units must contain  $3.0 \times 10^{11}$  or more platelets per unit in at least 75% of the units tested at maximal storage time. The physician in charge of the donor apheresis unit can make a medical decision to accept a donation from someone not eligible at the time if the benefits to the intended recipient outweigh the risks to the donor. This can occur when the donor is an HLA match or is HPA-1a (Pl<sup>A1</sup>) negative and no other donor is available. Use of single venous access and the high platelet extraction coefficients in the newer plateletpheresis devices (Amicus, Trima Accel) allow shorter collection times or higher product yields in normal collection times.

Automated red cell collection with apheresis technology can be performed using the Haemonetics MCS+ LN8150, which can collect 2 units of RBCs (2RBC) or 1 RBC unit and 1 large-volume plasma unit (RBCP), or the Caridian Trima, which can collect 1 plateletpheresis product and 1 or 2 RBC units.<sup>10,11,26</sup> The Fenwal ALYX and Haemonetics Cymbal have also been designed for collection of 2 RBC units. The 2RBC procedure is becoming increasingly popular in the United States to collect group O, Rh-negative RBC units with the intent of increasing RBC availability. The advantages are 1) a standardized red cell mass (180 to 200 mL per unit), 2) metered anticoagulation, which obviates mixing and reduces clot formation, 3) the ability to return fluids to the donor and reduce any risk of hypovolemia, 4) on-line separation of RBCs and plasma as either a 2RBC or RBCP product, eliminating secondary separation procedures, and 5) the use of smaller needles. For the collection of 1 RBC unit along with another component (plasma or platelets) the standard hematocrit criteria apply. However, for 2RBC collection, FDA has imposed specific donor hematocrit, height, and weight requirements.<sup>11</sup> Table 41-5 outlines the current criteria for allogeneic 2RBC collection as defined by the FDA. The use of 2RBC collection from female donors is limited. After 2RBC apheresis donation, donor deferral for any procedure (whole blood or apheresis) is 16 weeks. The RBCP criteria for collection of 1 unit of RBCs and 1 unit of jumbo plasma are outlined in Table 41-6. The anticoagulant used in RBCP and 2RBC procedures with the Haemonetics MCS+ LN8150 is CP2D at an

AC: ACWB ratio of 1:16. This markedly reduces (50%) the citrate returned to the donor during these procedures as well as the citrate in the plasma collected. The absolute volume of plasma collected (about 90%) is higher than that derived from a whole-blood collection (approximately 80% of which is absolute).

Automated collection of plasma can be accomplished with all of the apheresis devices, either as a sole collection product (Fenwal Autopheresis-C and Haemonetics PCS-2) or as a concurrent product with apheresis platelets or as part of an RBC apheresis procedure (RBCP). Table 41-6 shows the volume of plasma that can be

**Table 41-5.** Criteria for Allogeneic Donation of 2-Unit Red Blood Cells by Apheresis

| Donor Weight (lb) | Donor Height (in) | Donor Hematocrit (%) | Maximum Absolute Red Cell Volume (mL) |
|-------------------|-------------------|----------------------|---------------------------------------|
| <b>Men</b>        |                   |                      |                                       |

| 110-129           | ≥38                  | 180                               | 450                             |
| 130-149           | ≥38                  | 190                               | 450                             |
| 150-174           | ≥38                  | 190                               | 500                             |
| ≥175              | ≥38                  | 200                               | 550                             |

collected during the RBCP procedure according to donor weight and hematocrit. Plasma collected with the Autopheresis-C or PCS-2 is collected at a 1:16 AC:ACWB ratio, as is the plasma of the RBCP.

Apheresis FFP is a unique component and differs substantially from WBD FFP (Table 41-7). There is more absolute plasma per milliliter of anticoagulated plasma (90% in apheresis FFP vs 80% in WBD FFP), much less glucose, and only one-half to two-thirds of the citrate. A truly transfusable dose can be obtained that markedly affects the clotting factor status of an adult patient depending on patient size and the severity of the clotting deficiency. This component meets the criteria for a source of FFP espoused at the 1984 National Institutes of Health consensus conference on the use of plasma.<sup>27</sup> The number of residual platelets and white cells in apheresis FFP also is less than in WBD FFP. This may be important in reducing the recipient reactions to plasma transfusion caused by the release of cytokines or leukocyte fragments by passenger leukocytes into the plasma.<sup>23,24</sup>

Apheresis cryoprecipitate can be derived by means of cryoprecipitation of apheresis FFP. This product was not recognized by the FDA and has generally been abandoned. The Oklahoma Blood Institute previously produced apheresis cryoprecipitate from a volume of absolute plasma equivalent to 3 units of WBD FFP. The apheresis cryoprecipitate had a volume of approximately 100 mL (wet cryo) and did not require pooling or dilution but could be simply thawed and infused. This is in contrast to WBD cryoprecipitate, which is prepared as a dry cryo (volume, 15 to 20 mL) and requires dilution and pooling before administration.<sup>11</sup> The plasma remaining after removal of cryoprecipitate had a volume of approximately 400 mL and was used as replacement fluid for plasma exchange in the care of patients with thrombotic thrombocytopenic purpura (TTP).

Granulocyte donations are relatively infrequent because of the development of better antibiotics to prevent and manage the infections associated with granulocytopenia and because of the availability of cytokines such as GM-CSF and G-CSF, which help reduce the duration of the granulocytopenic period in patients with marrow failure. When granulocytes are needed, as in the management of neutropenia with bacterial or fungal sepsis not

**Table 41-7.** Comparison of Plasma Collected by Apheresis and Whole Blood Donation

|                                         | Collection Technique |          |                 |            |                         |
|-----------------------------------------|----------------------|----------|-----------------|------------|-------------------------|
|                                         | MCS+ LN8150          | ALYX     | PCS-2/Auto-C    | Concurrent | WBD FFP                 |
| Total volume (mL)                       | 450-550              | 450-550  | 500-800         | 250-450    | 200-250                 |
| Absolute plasma (%)                     | 90                   | 87       | 90              | 80-87      | 80                      |
| AC (% citrate)                          | CP2D (3%)            | CPD (3%) | Na Citrate (4%) | ACD (3%)   | CPDA-1, CPD, CP2D, (3%) |
| AC:ACWB ratio                           | 1:16                 | 1:12     | 1:16            | 1:8-1:12   | 1:8                     |
| Grams of citrate (per 100 mL of plasma) | 0.3                  | 0.4      | 0.4             | 0.6-0.4    | 0.6                     |

WBD = whole blood derived; FFP = fresh frozen plasma; AC = anticoagulant; CP2D = citrate-phosphate-dextrose-dextrose; ACD = acid-citrate-dextrose; CPDA-1 = citrate-phosphate-dextrose-adenine; CPD = citrate-phosphate-dextrose.

responding to antibiotics, collection of granulocytes poses problems for the donor and the patient. To collect an adequate number of granulocytes (see Chapter 15), the donor must be stimulated before donation with steroids and G-CSF to increase the circulating pool of granulocytes. Then hydroxyethyl starch (HES), available in low- and high-molecular-weight forms, must be infused during collection to increase red cell sedimentation and to facilitate separation and collection of granulocytes.<sup>28,29</sup> The use of G-CSF, steroids, and HES (pharmacomanipulation of the donor) can cause problems such as musculoskeletal pain, weight gain, fluid overload, allergic reaction to the starch, and reactivation of peptic ulcer disease by the steroids. However, only rarely are these problems severe.

HPCs can be collected with a variety of cell separators, but the Spectra, CS3000, and AS-104 are the most commonly used cell separators for HPC collection in the United States.<sup>30-33</sup> Circulating HPCs are collected by harvesting the buffy-coat-rich portion of the blood and specifically extracting the mononuclear-cell-rich portion of the buffy coat, which contains the CD34-positive progenitor or stem cells.<sup>33</sup> The number of CD34+ cells needed to repopulate the marrow varies from 4 to  $10 \times 10^6$ /kg of body weight. The HPCs usually are cryopreserved in autologous plasma with a 10% final concentration of dimethyl sulfoxide and are frozen in a controlled-rate freezer and stored at temperatures colder than  $-135^\circ\text{C}$ .

Collection of autologous HPCs by apheresis declined 26.1% between 2001 and 2004. Allogeneic HPC collections by apheresis decreased by 21.7% in the same period. Probable changes responsible for this decrease in total HPC collections by apheresis include: 1) marrow transplant protocols are no longer recommended for treatment of breast cancer patients, 2) new drugs such as rituximab and imatinib are used as first-line treatment rather than HPCs collected by apheresis, 3) newer nonmyeloablative protocols involve less processing and thus fewer collections, and 4) collection efficiency is increased by improved stem cell mobilization regimens. However, apheresis collection of allogeneic HPCs stimulated with G-CSF or GM-CSF as a replacement for classic allogeneic marrow HPC collection for hematopoietic reconstitution (see Chapter 33) is increasing in frequency. This may account for the rebound of allogeneic HPC apheresis collections in 2006, by an increase of 25.2%.<sup>4</sup> Autologous HPC apheresis collections also increased in 2006 — by 24.9%.<sup>4</sup>

### Adverse Effects on Donors and Recipients

Donor apheresis procedures are as safe or safer than donation of whole blood because of the ability to return fluids to donors and because the longer collection times allow better fluid equilibration and a lower risk of hypovolemia.<sup>34,35</sup> Hematomas with the use of single venous access devices (MCS+, Amicus, Trima) are no more frequent than in donation of whole blood. The major “expected” adverse consequence is related to the effects of the citrate anticoagulant returned to the donor. Donors of lower body weight are more likely to experience citrate symptoms. Almost all plateletpheresis donors and 2RBC donors experience some citrate effects

(circumoral paresthesia, buzzing sensation, and nasal stuffiness). These effects are not worrisome but they should trigger a slowing of the procedure before more serious toxic effects occur, such as muscle tightening, chills, nausea, vomiting, or tetany. Administering oral antacids, warming donors, and slowing the flow rate reduce the citrate effects. Calcium gluconate (10 mL of 10% solution given slowly intravenously) rarely is needed.<sup>36,37</sup> A single plateletpheresis procedure can remove 25% to 50% of circulating platelets, but the release of platelets that normally are sequestered in the spleen almost always prevents significant thrombocytopenia in the donor. In frequent plateletpheresis procedures, it is not uncommon for the donor’s platelet count to decrease and then rebound after 1 to 2 weeks.

Adverse effects in recipients of plateletpheresis products are equal to or less than the reactions that occur with administration of whole-blood-derived platelet products. The use of leukocyte reduction with almost all plateletpheresis products has markedly reduced but not eliminated transfusion-associated febrile reactions and appears to be reducing the incidence of transfusion-associated GVHD and posttransfusion purpura.<sup>38</sup> Transfusion-related acute lung injury (TRALI) is now recognized as one of the greatest noninfectious risks of transfusion. The greatest transfusion-associated infectious disease risk today is bacterial contamination and occurs almost exclusively in platelets. Because plateletpheresis products are from a single donor and a single collection event, the risk of bacterial contamination may be less with plateletpheresis products than with platelets from several whole-blood donations. However, bacterial contamination data from Europe showed no difference between pooled buffy coat whole-blood-derived platelets and apheresis platelet concentrates.<sup>39</sup>

---

## Therapeutic Apheresis Overview

Therapeutic apheresis has been classified traditionally as therapeutic cytapheeresis or TPE, but must now include plasma immunoadsorption and cellular adsorption. Strictly speaking, TPE implies removal of the patient’s plasma with replacement of a crystalloid or colloid solution to maintain a normovolemic state in the patient. Plasmapheresis generally implies removal of an aliquot of plasma without fluid replacement. Because these procedures are discussed completely in Chapters 42 and 43, only basic principles are mentioned here.

Critical factors involved in therapeutic apheresis procedures include the following considerations:

- 1. What is to be removed and how best to remove it.** What is to be removed from the patient depends on the diagnosis. How it is to be removed depends on the equipment available. For patients with disease mediated by a known plasma factor such as an autoantibody, immune complex, a protein-bound drug or toxin, and a high cholesterol or triglyceride level, it is clear what must be removed.

- 2. How much is to be removed with each procedure.** How much plasma is to be removed depends on the plasma factor involved. The removal of one plasma volume results in a net

overall exchange of 62% of the patient's plasma volume because of progressive dilution by replacement solutions to maintain normovolemia during the procedure.<sup>40</sup> This is true whether plasma or red cells are being removed (Table 41-8). The most effective TPEs remove 1.0 to 1.5 plasma volumes (62% to 78% overall exchange). If the plasma factor is an IgG antibody, only about 45% to 50% of the total body IgG is within the intravascular compartment, whereas the remainder is in the extravascular spaces. Because equilibration is rapid, it is difficult to reduce IgG antibodies with only one TPE; daily TPEs are necessary. Conversely, approximately 90% to 92% of IgM antibodies reside in the intravascular compartment and are more easily removed with one large-volume TPE. Some institutions limit TPE to 1.0 to 1.5 calculated plasma volumes per procedure in most instances because of increased efficiency and a lower rate of complications than with larger-volume exchanges (2.0 volumes or greater).

A simple method for estimating the blood volume of adults is shown in Table 41-9. One of the authors (ROG) developed this modified rule of fives to quickly estimate blood and plasma volumes. It agrees with results of recent blood volume studies within  $\pm 15\%$ .<sup>41,42</sup> Plasma volume is calculated by means of multiplying the obverse of the hematocrit (1.0 minus the decimal equivalent of the hematocrit) by the estimated blood volume.

**3. How often the procedure should be performed.** How often a therapeutic apheresis procedure should be performed depends on how ill the patient is and the rate of regeneration or redistribution of the substance being removed. Removal of IgG antibodies generally requires daily TPE because of regeneration and redistribution from the extravascular to the intravascular space.

Therapeutic plasma exchange occasionally must be performed every 12 hours to save a patient with florid liver failure awaiting a liver transplant.

**4. How many procedures should be performed.** The end-point of therapeutic apheresis (TPE or therapeutic cytapheeresis) with regard to the number of procedures needed depends on the patient's clinical response and specific laboratory measurements. In disorders mediated by antibodies, only a limited number of procedures usually are needed. This is because TPE is generally a treatment that "buys time" during the wait for other therapeutic measures, such as immunosuppression, to take effect. Recurrence or exacerbation of some diseases, such as TTP or inflammatory neuropathy, frequently necessitates extending the therapeutic apheresis time frame to achieve durable remissions.

**5. What the replacement solution should be, if any.** Replacement solutions can be crystalloid or colloid (Table 41-10). Although they are less expensive, crystalloid solutions are less useful for large-volume daily plasma exchanges because of the rapid onset of hypoproteinemia and dilutional coagulopathy. In addition, the volume of crystalloid needed is at least two to three times the plasma removed because of the rapid movement of the crystalloid solution into the extravascular space. The most commonly used replacement solution in TPE is 5% albumin, a true natural colloid, which is slightly hyperoncotic. This form of albumin is stripped of its calcium and acts like a calcium sponge by binding calcium ions. It is a safe product, never having been associated with transmission of any known viral infection (HAV, HBV, HCV, or HIV). Because it is slightly hyperoncotic, albumin can be diluted with saline solution to 4.0% to 4.5% for plasma exchange. The other natural colloid is FFP, which

**Table 41-8.** Plasma Volumes Exchanged: Fraction Removed and Remaining

| Plasma Volume Removed | Fraction Removed (%) | Fraction Remaining (%) |
|-----------------------|----------------------|------------------------|
| 0.5                   | 40                   | 60                     |
| 1.0                   | 62                   | 38                     |
| 1.5                   | 78                   | 22                     |
| 2.0                   | 85                   | 15                     |
| 2.5                   | 91                   | 9                      |
| 3.0                   | 94                   | 6                      |

**Table 41-9.** Estimating Blood Volume: Modified Rule of Fives

| Gender | Body Mass and Build |      |        |          |
|--------|---------------------|------|--------|----------|
|        | Fat                 | Thin | Normal | Muscular |
| Men    | 60                  | 65   | 70     | 75       |
| Women  | 55                  | 60   | 65     | 70       |

Values are in milliliters of whole blood per kilogram of body weight.

**Table 41-10.** Replacement Solutions for Plasma Exchange

| Solution                         | Comment                                                                                                                |
|----------------------------------|------------------------------------------------------------------------------------------------------------------------|
| <b>Crystalloid Solutions</b>     |                                                                                                                        |
| Saline 0.9%                      | Least expensive, high Na and Cl                                                                                        |
| Ringer solution                  | Inexpensive, less Na and Cl                                                                                            |
| Lactated Ringer's solution       | Inexpensive, less Na and Cl                                                                                            |
| Balanced electrolyte solution    | Most physiologic but more expensive                                                                                    |
| <b>Colloids (Natural)</b>        |                                                                                                                        |
| Albumin 5%                       | Safe, hyperoncotic, and expensive                                                                                      |
| Plasma protein fraction 5%       | Not available in United States                                                                                         |
| Fresh frozen plasma (FFP)        | Less safe, isooncotic, contains clotting factors                                                                       |
| Donor retested FFP               | Slightly safer than FFP, more costly than FFP                                                                          |
| Solvent/detergent-treated plasma | Not available in United States, risk of non-lipid-enveloped virus transmission, pooled — includes Octaplas and Uniplas |
| <b>Colloids (Artificial)</b>     |                                                                                                                        |
| Hydroxethyl starch (high MW)     | 450,000 average MW                                                                                                     |
| Hydroxethyl starch (low MW)      | 150,000 average MW                                                                                                     |
| Dextran                          | Infrequently used                                                                                                      |
| Modified fluid gelatin           | Not in United States, used in Europe                                                                                   |

MW = molecular weight.

can be derived from whole blood or apheresis donation. As a byproduct of the RBCP procedure, apheresis plasma contains only half of the citrate of WBD FFP and is 90% absolute plasma vs 80% for WBD FFP. This is the replacement fluid of choice for patients with fulminant liver failure who require plasma exchange to save their lives.<sup>43</sup> However, because of an increased incidence of allergic reactions and slightly increased risk of transmission of infectious disease, FFP is generally used only when clotting factors or other proteins must be replaced or in the management of TTP, in which studies have established it as the replacement fluid of choice.<sup>44</sup> The issue of whether cryoprecipitate-reduced plasma, solvent/detergent-treated (SD) plasma, or unaltered FFP is best in the management of TTP is still not resolved. Artificial colloid solutions (HES or dextran) are used relatively infrequently in the United States and offer no medical advantage over 5% albumin. Depletion of immunoglobulins when using nonimmunoglobulin replacement solutions can put the patient at risk of pneumonia if the IgG levels drop too low. Plasma or IVIG can be given to prevent iatrogenic hypogammaglobulinemia from occurring. Two new SD plasma products are available (Octaplas) or in development (Uniplas) both of which contain normal levels of ADAMTS13 and Factor H, which are beneficial in treating TTP and atypical hemolytic uremic syndrome, respectively.<sup>45</sup> In addition, the use of Octaplas has resulted in a lower number of allergic and citrate reactions than the use of cryosupernatant plasma in acute TTP.<sup>46</sup> SD plasma is currently not available in the United States. Solvent/detergent treatment does not inactivate viruses that do not have a lipid envelope, such as hepatitis A or human parvovirus B19. SD plasma is a pooled product and has normal amounts of clotting factors but is deficient in some of the anticoagulating factors (protein C, protein S, and antithrombin) and plasminogen. Another plasma product with reduced infectious disease risk is donor retested plasma, which is rarely used in the United States. The donor is retested at least 110 days after the initial donation. The unit is not transfused until the retest has been performed and the results are negative for all viral markers tested. The development of pathogen-inactivated plasma will further reduce the risk of transmission of infectious agents but will not prevent the risk of prion transmission believed to be the etiologic agent for variant Creutzfeldt-Jakob disease.

**6. What equipment should be used.** The type of equipment used depends on the particular needs of the therapeutic apheresis service. The newest of the therapeutic devices in the United States is the Caridian Optia (see Table 41-1). Each of the different manufacturers' equipment has certain advantages. Most TPE procedures are performed with centrifugal-based machines. Add-on devices such as staphylococcal protein A immunoadsorption columns can be used *ex vivo* to remove IgG selectively and then to return the immunoadsorbed plasma to the patient.<sup>47</sup> Another special type of therapeutic apheresis, called *photopheresis*, is used to manage a hematologic malignant disease with cutaneous lesions called *cutaneous T-cell lymphoma* or *Sézary syndrome*. Photopheresis is the use of extracorporeal photochemotherapy to modify circulating malignant T cells. These

ultraviolet irradiated and altered T cells in some way modulate an antitumor effect when reinfused.<sup>48,49</sup> The new model of the Therakos Photopheresis System (UVAR-XTS) operates with a form of psoralen (methoxsalen) that is injected into the product collected with the device. This technique reduces the risks of systemic exposure to psoralen in the patient, which occurred in the original Therakos Photopheresis System (no longer available or supported).

**7. What type of vascular access should be used.** Vascular access can be through peripheral veins, central veins, or both. If many TPEs are planned, central venous catheters usually are necessary. Double- or triple-lumen dialysis catheters are ideal for central venous access. Strict catheter care is critical to prevent clotting of the catheter and infections at the catheter site. Flushing the catheter with a heparinized solution immediately after exchange is critical to prevent clotting. If catheter clotting should occur, injection of plasminogen-activating drugs into the clotted lumen frequently lyses the clot and restores patency. Placement of central venous catheters is critical so that the catheter tip is not in the heart (right atrium) but in the superior vena cava. Cardiac irritability with premature ventricular beats can occur if the catheter is in the right atrium. The irritation is caused directly by the catheter or indirectly by return of fluids that are cold, hypocalcemic, hypokalemic, or high in citrate ion. A chest radiograph should be obtained after placement of a subclavian central venous catheter, not only to locate the tip of the catheter within the superior vena cava but also to ensure that the catheter did not perforate the subclavian vein and cause a hemothorax or pneumothorax. For some patients, surgical placement of an arteriovenous shunt, such as an expanded polytetrafluoroethylene (Gore-Tex) graft tunneled under the anterior thigh to connect the femoral artery and vein, may be necessary for long-term TPE.

**8. What anticoagulant should be used and how much.** The use of anticoagulants in therapeutic apheresis usually is limited to citrate anticoagulants (ACD-A, ACD-B, or sodium citrate), heparin, or both. Acid-citrate-dextrose A (ACD-A) is a 3% citrate anticoagulant and ACD-B a 2% citrate anticoagulant. Sodium citrate is available as a 4% citrate anticoagulant. The advantage of citrate as an anticoagulant is that any amount returned to the patient during the red cell return in a TPE procedure is usually a small amount and is metabolized rapidly unless the patient is in severe liver failure. Citrate produces only local anticoagulation in the collected blood and never produces systemic anticoagulation. However, this can be a disadvantage when flow is low, because catheter clotting can occur. If the flow rate is low and heparin is not contraindicated, heparin can be used alone or in combination with citrate. Heparin may enhance systemic anticoagulation more than is expected because of the additional effect of dilution of clotting factors by the non-plasma replacement solutions. The half-life of heparin in the body is approximately 90 minutes. When heparin is used to anticoagulate blood in the draw line and is not used systemically, 17,500 U is added to 500 mL of saline solution (35 U of heparin per milliliter of saline solution). With

an AC:ACWB ratio of 1:8, this formula delivers 5 U of heparin per milliliter of whole blood collected. At an AC:WB ratio of 1:10, it delivers 3.9 U of heparin per milliliter of whole blood collected (3.5 U of heparin per milliliter of anticoagulated blood collected).

**9. Where the procedure should be performed, such as at the blood center or in the inpatient or outpatient areas of a hospital.** Therapeutic apheresis procedures should be performed only when emergency care is readily available. If the procedure is performed at the blood center on an outpatient basis, the blood center must have a knowledgeable physician available. The nursing staff performing the procedure must be trained in resuscitation care, and a crash cart with a cardiac monitor and defibrillator must be available. In the hospital, the same requirements apply for outpatient procedures. Critically ill patients, such as those with acute TTP, should be treated in an intensive care setting where emergency care is readily available.

**10. Whether the presence of a physician is needed throughout each procedure.** A physician must be available to the nurses for each procedure, but the severity of the patient's illness determines whether a physician is needed at the bedside for each therapeutic apheresis procedure. At the Oklahoma Blood Institute, a patient services department handles all therapeutic apheresis procedures, and all procedures are performed by knowledgeable registered nurses.

**11. What complications or adverse reactions are to be expected, such as thrombocytopenia, bleeding, thrombosis, arrhythmia, plasma-induced immune reactions.** Complications and adverse reactions can and do occur. Volume overload, venous access problems, bleeding, thrombosis, immunoglobulin depletion, citrate reactions, hypokalemia, hypocalcemia, hypotension, allergic reactions, infection, viral transmission from blood components, thrombocytopenia, anemia, TRALI, and death can occur. The mortality has been estimated at three deaths per 10,000 procedures.<sup>18</sup>

## Summary

Apheresis technology has rapidly advanced and is replacing some of the manual whole-blood collection techniques. Although more expensive and requiring personnel with greater skill levels to operate the equipment, the new techniques make it possible to collect two or more transfusion doses of blood components from a single donor, theoretically making safer and higher-quality blood components available from a smaller donor base and reducing the chances of error. The ability to use smaller needles and to return fluids will make procedures safer for donors as well. Therapeutic apheresis will continue to advance as new agents such as immunoabsorbents are combined with cell and plasma separation devices, whether centrifugal or membrane. The development of HPCs for marrow repopulation, especially when allogeneic donors are routinely stimulated with cytokines (eg, G-CSF), is signaling an even newer era of apheresis advancement. The new era of pathogen inactivation technology

and its application to replacement fluids will improve safety in the use of FFP derivatives for therapeutic apheresis.

**Bruce C. McLeod**

Professor of Medicine and Pathology, Rush Medical College, and Director, Blood Center, Rush University Medical Center, Chicago, Illinois, USA

Therapeutic plasma exchange (TPE) has been compared to the practice of bloodletting to remove evil humors. The notion of therapeutic removal has changed little since medieval times; however, the concept of an evil humor has been discarded in favor of an evidence-based understanding that some blood cells and plasma components can be harmful. Three subtypes that can be distinguished among plasma macromolecules that are candidates for therapeutic removal are as follows: 1) antibodies that are troublesome because of their binding specificity—these are often autoantibodies; 2) molecules that confer abnormal physical properties, such as hyperviscosity or cold insolubility, on plasma and hence on the blood—these, too, are usually antibodies, although they may be bound in immune complexes; and 3) molecules such as low-density lipoproteins (LDLs) that have nonimmune toxicity. From a theoretic point of view, it is easier to envision a significant therapeutic effect when the molecule to be removed is relatively large and has a relatively long half-life in the circulation, with a correspondingly low rate of synthesis. In practice, the majority of successfully treated disorders are caused by pathogenic immunoglobulin G (IgG), which has these properties. It has been suggested from time to time that removal of complement or coagulation proteins, or inflammatory mediators derived from immunocytes, might contribute to a therapeutic effect. Such proposals have seemed unlikely to the author because the candidate molecules are rapidly synthesized and are relatively short lived, and in fact no therapeutic effect involving such molecules has been proven to date.

Therapeutic plasma exchange can be employed in a fourth way, not foreseen by medieval barbers or 18th century physicians, and that is to achieve relatively high levels of a normal plasma constituent that is deficient in patient plasma and is not available in a concentrated form for simple infusion.

### General Principles of Therapeutic Plasma Exchange

#### Mathematic Principles

Patients often compare TPE to an automobile oil change, and it is instructive to consider the factors that make this analogy inapt. A 100%-efficient 5-liter oil change can be accomplished in 10 minutes, because the engine need not operate during the procedure. In TPE, limitations are imposed on rate and efficiency by the need to keep the heart pumping and the bloodstream nearly full, so that only a small portion of the total blood volume can be outside the body at any time. Because TPE must proceed gradually, either continuously or in small increments, an ever-increasing proportion of the material being removed is not patient plasma but rather replacement fluid infused earlier in the procedure.

During this process, the level of an entirely intravascular substance that is absent in the replacement medium can be predicted by the formula:  $y_x = y_0 e^{-x}$ , in which  $y_0$  is the starting concentration of the substance,  $e$  is the base natural logarithm, and  $y_x$  is the concentration of the substance after  $x$  patient plasma volumes have been exchanged. If  $y_0$  is assigned a nominal value of 1.0, the function yields the smooth asymptotic middle curve plotted in Fig 42-1 for a continuous exchange. The flanking curves, describing small incremental discontinuous exchanges, are similar. This formula accurately forecasts the outcome of an exchange for macromolecules such as LDL and IgG that have a substantial extravascular reservoir, provided that equilibration between the intravascular and extravascular compartments is slow relative to the removal rate.<sup>2</sup>

Because the molecule targeted for removal by TPE is often an IgG antibody, which is approximately 50% extravascular,<sup>2</sup> and because removal of accessible (that is, intravascular) IgG becomes progressively less efficient during a TPE procedure, most practitioners limit an exchange to 1 to 1.5 times the patient's estimated plasma volume. An exchange of this magnitude will remove 60% to 75% of intravascular material while limiting side effects from depletion of normal plasma components. The intravascular IgG

### Section III

**Figure 42-1.** Calculated fraction of intravascular substance remaining during a plasma exchange, assuming no equilibration with extravascular material. (Used with permission from Chopek and McCullough.<sup>1</sup>)

**Figure 42-2.** Computer-generated curve estimating amounts of intravascular and extravascular IgG (upper curves), and total IgG (lower curve) during a course of four one-plasma-volume therapeutic plasma exchanges with an IgG-free replacement medium. Published formulas were used for rates of removal during exchanges and reequilibration after exchanges. No correction was made for continuing synthesis.

level will rise during the ensuing 1 to 2 days by equilibration with extravascular sources, and further removal by a subsequent exchange can then be undertaken more efficiently. The effects of a series of TPEs on extravascular, intravascular, and total IgG are shown schematically in Fig 42-2.

Human serum albumin is the most common replacement fluid in TPE, for reasons that are given below. In such exchanges,

all plasma constituents are removed while only albumin is replaced; thus plasma component depletion in an individual exchange is almost completely nonselective.<sup>2</sup> However, because most other plasma constituents are synthesized much more rapidly than IgG, a series of such exchanges will result in a reasonably selective depletion of IgG over the course of treatment. This is shown in Fig 42-3.

**Figure 42-3.** Total protein, albumin, and IgG levels before and after therapeutic plasma exchange with albumin/saline replacement. Exchanges were carried out three times per week for 3 weeks on seven patients. Points and ranges represent means and standard deviations. Note this disproportionate decrease in IgG levels. (Used with permission from McLeod et al.<sup>3</sup>)

### Regulation of IgG Metabolism

Because IgG removal is often the goal of TPE, it is worthwhile to consider certain aspects of IgG metabolism. The subclasses IgG1, IgG2, and IgG4 together constitute about 90% of total IgG. Their catabolic rates are proportional to total IgG level and their half-lives are therefore inversely proportional to concentration. This pattern has been taken to indicate the existence of a saturable receptor that protects IgG from catabolism. A receptor on endothelial cells having this property has been characterized, which appears to be identical to the FcRn receptor on neonatal intestinal epithelial cells that facilitates transport of intact maternal antibody in breast milk.<sup>4</sup>

It is difficult to measure the IgG synthetic rate in humans. Previous animal studies concerning levels of specific antibody were interpreted to show that the synthetic rate for IgG exhibits negative feedback, increasing when IgG or specific antibody levels or both are lower.<sup>5</sup> More recently, Junghans<sup>6</sup> has shown that “knock-out” mice genetically deficient for the FcRn receptor catabolize IgG quite rapidly and maintain very low IgG levels, but they have the same IgG synthetic rate as normal mice. This argues against negative feedback regulation of IgG synthesis and suggests that a reduction in antibody levels induced by TPE would not produce a meaningful “rebound” increase in IgG synthesis.

Intravenous immune globulin (IVIG) has been reported to be effective in some of the same antibody-mediated diseases as TPE. Yu and Lennon<sup>7</sup> recently proposed that exogenous immune globulin competes with endogenous IgG for FcRn receptors and thereby promotes accelerated catabolism of the latter, including any pathogenic antibodies. In this view, the beneficial effects of IVIG and TPE are essentially the same; both lead to lower levels of harmful antibodies. Therapeutic plasma exchange lowers levels quickly but may be followed by slower catabolism, whereas IVIG presumably has a slower onset of action but promotes rapid catabolism. This concept of the effect of IVIG could provide a

TPE = therapeutic plasma exchange; US = United States.

compelling rationale for sequential treatment of autoantibody diseases with TPE followed by IVIG.

### Replacement Fluids

Saline replacement alone can suffice when only 500 to 1000 mL of plasma is removed in a manual plasmapheresis, but colloid replacement must be given in a multiliter plasma exchange.

Available colloid replacement fluids are listed in Table 42-1, which also summarizes their relative advantages and disadvantages. For the majority of indications the standard replacement medium is 5% human serum albumin in normal saline; however, substitution of 25% to 50% of the total with saline has been shown to be well tolerated in certain patient groups. Although it is a pooled product, 5% albumin is preferred over plasma as a source of replacement colloid because 1) it can be pasteurized to inactivate all known blood-borne pathogens, 2) it can be given without regard to blood type, and 3) it does not require thawing or other preparation before use. Adverse reactions to albumin are rare.<sup>8</sup> Exchanges of plasma for albumin produce temporary deficiencies of other plasma proteins, such as coagulation factors; however, these are usually sub-clinical and levels are rapidly restored by ongoing synthesis and reequilibration.<sup>2</sup>

There are a few circumstances in which replacement of patient plasma with donor plasma seems prudent. Prominent among these is the treatment of thrombotic microangiopathies. Affected patients customarily receive exchanges with Fresh Frozen Plasma (FFP) in light of abundant evidence that patients with thrombotic thrombocytopenic purpura (TTP) respond better to plasma than to albumin. Cryoprecipitate-reduced plasma is also effective for this purpose.<sup>9</sup> Some plasma may also be given toward the end of an exchange to patients with preexisting thrombocytopenia or humoral coagulopathy, who are considered to be at increased risk for bleeding complications when the dilutional coagulopathy of an albumin exchange is superimposed, or to patients with ongoing blood loss regardless of pretreatment coagulation status. Plasma replacement carries a higher risk of urticarial and hypocalcemic reactions.<sup>10</sup>

One group reported infusing a solution of hydroxyethyl starch (HES), a less costly volume expander, in the early part of an exchange.<sup>11</sup> They reason that recommended dosage limitations for HES will not actually be exceeded, because much of the infused HES will be removed in exchange for albumin infused later. This group has seen successes, albeit with a higher incidence of side effects. HES is not recommended for patients with renal impairment, underlying coagulopathy, or a history of hypersensitivity to HES.

Selective Extraction of Plasma Components

Practitioners of TPE have long recognized the inherent wastefulness in removing and discarding all plasma components in order to deplete just one. Selective extraction of a pathogenic component from separated plasma, with recovery and reinfusion of normal constituents, has been considered an attractive goal. Several applications and methods for on-line separation have been explored,<sup>12</sup> but commercial availability and widespread acceptance have been slow to be realized.

Obstacles to commercially practical devices include the high cost and limited capacity of truly selective, biocompatible sorbents and the high extracorporeal volume associated with

sorbent modules having a depletion capacity equivalent to TPE. One approach is to use pairs of small, low-capacity sorbent modules with alternating flow cycles such that one module absorbs material from patient plasma while the absorbent capacity of the other is restored by elution of bound material. This approach to selective extraction lowers the volume and cost of sorbent modules but requires an additional instrument to manage the cycling-elution-regeneration process.<sup>12</sup> Selective extraction techniques and their applications are discussed in more detail in Chapter 41.

Indication and Treatment Intensity Categories

To assist practitioners in assessing the value of apheresis in specific circumstances, the American Society for Apheresis (ASFA) has described indication categories for therapeutic apheresis.<sup>13</sup> The definitions can be summarized as follows: Category I denotes diseases for which apheresis therapy is a standard first-line therapy, although it may not always be necessary; Category II denotes diseases in which apheresis is a valuable second-line therapy when first line measures fail or are poorly tolerated; Category III indicates uncertainty due to inadequate data or controversy due to conflicting reports; and Category IV is reserved for diseases in which there is negative data from controlled trials or anecdotal reports. The indication categories assigned by ASFA are provided in tabular form for the diseases in each of the following sections.

In addition, these tables include the author’s perceptions of the customary intensity (frequency and duration) of TPE therapy for most of the diseases. The four categories used are: aggressive (A), which implies daily TPE until remission or improvement; routine (R), which implies five to seven treatments every other day (or three times per week); prolonged (P), which implies one to three treatments per week for 3 to 8 weeks; and chronic (C), which implies one treatment every 1 to 4 weeks, continuing indefinitely. These intensity categories, which need not be mutually exclusive, are summarized in Table 42-2. Note that more than one category may be applicable to a given disease, or even a given patient, depending on extant clinical circumstances.

The references cited in the following discussions are not exhaustive. Readers seeking a more extensive bibliography may consult the chapters on TPE in a recent text devoted to apheresis<sup>2,12,14-16</sup> and articles in recent journal issues devoted to clinical applications of therapeutic apheresis.<sup>13,17-20,21</sup>

Table 42-2. Intensity of Treatment Categories for TPE

| Level          | Schedule         | Duration                   |
|----------------|------------------|----------------------------|
| Aggressive (A) | Daily            | 3 treatments to indefinite |
| Routine (R)    | 3 times a week   | 5-7 treatments             |
| Prolonged (P)  | 1-2 times a week | 3-8 weeks                  |
| Chronic (C)    | Every 1-4 weeks  | Indefinite                 |

TPE = therapeutic plasma exchange.

## Therapeutic Plasma Exchange in Neurologic Disorders

Immune processes, especially formation of circulating antibody to structures in the nervous system, have been implicated in several neurologic diseases, and TPE has become an important therapy for some of them. The diseases to be considered in this section appear in Table 42-3 along with their respective indications and intensity categories.

### Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) affects the peripheral nervous system. It is the most common cause of acute paralysis with areflexia in the developed world, with an incidence of one to two cases per 100,000 population per year. A typical clinical course begins with symmetric distal paresthesias, which are followed by leg and arm weakness. Symptoms spread proximally and reach a peak of severity by 14 to 30 days after onset. About one-fourth of patients with GBS have mild illness and remain ambulatory throughout. The remainder are disabled by paralysis and may have oropharyngeal and respiratory weakness as well. One-fourth will require assisted ventilation at some point, and the worst cases are marked by quadriplegia, ophthalmoplegia, and prolonged ventilator dependence. A nerve conduction defect resulting from demyelination is found in most cases, but there are variants in which axonal damage is evident in motor fibers or both motor and sensory fibers. In another variant (Miller Fisher syndrome) symptoms are limited to ophthalmoplegia, ataxia, and areflexia. The spinal fluid usually contains few cells and only a moderately elevated concentration of protein. A conduction block indicating demyelination is the usual finding in electrophysiologic studies, although inexcitability may also be seen in the axonal variants.<sup>22</sup>

Demyelination is believed to be caused by circulating myelin antibodies. Early experiments showed that sera from patients with GBS produced demyelination in animals. Later studies have found antibodies to myelin glycolipids, such as GM1, GM1b, GD1a, and GD1b, in the sera of many patients. Antibodies to GQ1b and GT1a are relatively specific for the Miller Fisher variant. Guillain-Barré syndrome is often associated with a history of recent infection with *Campylobacter jejuni*, cytomegalovirus, Epstein-Barr virus, *Mycoplasma pneumoniae*, or other organisms. It has been postulated that antibodies are formed in response to a strain-specific lipopolysaccharide that is antigenically similar to one of the myelin gangliosides; eg, GM1 after *C. jejuni* infection.<sup>22</sup> Epidemic Chinese acute motor neuropathy is an illness of rural Chinese children that has epidemiologic characteristics of an infectious disease. It is clinically similar to GBS and is also associated with evidence of *C. jejuni* infection and GM1 antibodies.<sup>23</sup>

Spontaneous recovery is the usual outcome of GBS and may be associated with the decline in antibody levels expected after recovery from infection. Patients with mild illness require no treatment, but more severely affected patients need careful observation so that appropriate supportive therapies, such as mechanical ventilation, can be implemented when needed. Neither oral nor pulse intravenous steroids are helpful in GBS; however, large randomized controlled trials have documented that TPE can shorten recovery time and reduce disability.<sup>24-27</sup>

The North American trial enrolled 245 disabled patients, 142 of whom received TPE.<sup>24</sup> At 4 weeks, 59% of treated patients vs 39% of controls had improved by one grade in a clinical grading scale devised for the study. Mean improvements were 1.1 and 0.4 grades, respectively. The median time to improve one grade was 19 days in treated patients vs 40 days in controls, while median

\*I = standard first-line therapy; II = second-line therapy; III = controversial; IV = no efficacy.

†A = aggressive; R = routine; P = prolonged; C = chronic (see Table 42-2).

TPE = therapeutic plasma exchange; ASFA = American Society for Apheresis; AChR = acetylcholine receptor molecule; NR = not rated; GAD-65 = 65-kD isoform of glutamic acid decarboxylase; Glu R3 = glutamate receptor; PANDAS = pediatric autoimmune neuropsychiatric disorders associated with streptococcal (infection).

times to walk unassisted were 53 and 85 days, respectively. In the subgroup of ventilated patients, the median times to weaning were 24 and 48 days, respectively, and the median times to walk unassisted were 97 vs 169 days. A similar shortening of recovery time in severely affected patients was shown in the French Cooperative Group trial involving 220 patients.<sup>25</sup> In another study of 556 patients, this group showed benefit from TPE in mildly affected patients as well.<sup>26</sup> A typical treatment schedule in these trials consisted of five to six exchanges of 1.0 to 1.5 plasma volumes over 7 to 14 days. Patients with GBS may need careful monitoring, perhaps in an intensive care unit, because they may have autonomic neuropathy and are more prone to hemodynamic instability during TPE.

Later studies have shown that IVIG is also beneficial in GBS. A large multicenter trial compared IVIG, TPE, and TPE followed by IVIG, with 121 to 130 patients in each treatment group.<sup>28</sup> Mean disability grades at 4 weeks improved by 0.8, 0.9, and 1.1 respectively, while the median times to walk unassisted were 51, 49, and 40 days. The trends favored TPE plus IVIG, although none of the differences was statistically significant. Some authorities now favor IVIG for initial treatment, citing its relative simplicity, wider availability, and lower incidence of adverse effects.<sup>22</sup>

### Chronic Inflammatory Demyelinating Polyneuropathy

Chronic inflammatory demyelinating polyneuropathy (CIDP) is an acquired neuropathy that may follow either a continuously progressive or an intermittent, relapsing course. Both weakness and sensory loss are usually present, and both distal and proximal sites may be affected. Proximal weakness can help to differentiate CIDP from other chronic neuropathies, while progression for more than 2 months helps to distinguish it from GBS. Nerve conduction studies should suggest demyelination, which may be apparent in nerve biopsy tissue if this is obtained. Patchy inflammatory infiltrates may be seen in nerve root biopsies. The cerebrospinal fluid usually has a moderately elevated protein concentration and a cell count less than  $10/\mu\text{L}$ .<sup>29</sup> If certain exclusionary criteria are met, the diagnosis of CIDP is deemed "typical" or "atypical" on the basis of clinical findings and "definite," "probable," or "possible" based on electrophysiologic studies in one recent classification scheme.<sup>30</sup> Treatment is recommended for all groups, and the results of treatment are similar in all.<sup>31</sup> Although it is usually idiopathic, CIDP may also occur in the context of an associated condition, such as inflammatory bowel disease, chronic active hepatitis, connective tissue disease, Hodgkin disease, human immunodeficiency virus (HIV) infection, or monoclonal gammopathy.<sup>29</sup>

The precise cause of CIDP remains unknown; however, the disease associations, the clinical similarities to GBS, and the histopathology suggest an immune process. The presence of a monoclonal protein in some cases points to an antibody-mediated disorder, as does the finding that an animal model of CIDP (experimental allergic neuritis) can be passively transferred with serum. Recent studies have demonstrated antibody to myelin protein antigens such as P0, P2, and PMP22 in the sera

of some patients with CIDP, although a definite cause-and-effect relationship has not been established.<sup>32</sup>

Most patients with CIDP will respond to moderately high doses of glucocorticoids.<sup>29</sup> Early trials of TPE were conducted in patients with CIDP who had failed to improve with steroids or were unable to tolerate them. A double-blind, sham-controlled crossover trial reported by Dyck et al<sup>33</sup> showed improvement in five of 15 patients treated with TPE for 3 weeks; after crossover a similar proportion responded in the sham group. However, many patients worsened after TPE was stopped. A similar study in 18 previously untreated patients was reported by Hahn et al.<sup>34</sup> Of the 15 patients who completed the trial, 12 improved during the TPE portion. These patients took prednisone for 6 months after completing TPE and, following recovery from a brief relapse when TPE was stopped, many maintained good function.

IVIG has also been investigated in CIDP. Hahn et al<sup>35</sup> published a double-blind, placebo-controlled crossover trial in 30 patients. Study patients were permitted to take prednisone at stable low doses. Overall 63% (19 patients) responded to IVIG, while 17% (five patients) improved on placebo. Two studies have compared IVIG to TPE. In a retrospective study by Choudhary and Hughes,<sup>36</sup> 21 of 33 patients (64%) improved after TPE treatment, while a response to IVIG was seen in 14 of 21 patients (67%) treated at the same institution. A prospective observer-blinded crossover study of 20 patients at the Mayo Clinic suggested that both therapies were able to produce rapid, statistically significant improvement; the authors concluded that either was appropriate as a primary treatment.<sup>37</sup> Some authorities recommend using IVIG first, based on its relative simplicity, wide availability, and lower incidence of adverse effects.<sup>30</sup> The TPE protocols used in CIDP have tended to specify relatively prolonged treatment.<sup>21(p121)</sup> A proposed schedule is three one-plasma-volume exchanges each week for 2 weeks, followed by two exchanges each week for another 4 weeks.<sup>33</sup>

### Peripheral Neuropathy and Monoclonal Gammopathy

The background incidence of a circulating monoclonal immunoglobulin is about 1% in adults over 50 and rises to about 3% in adults over 70, whereas about 10% of patients with polyneuropathy have such a protein.<sup>38</sup> Thus, principles of epidemiology suggest a causal relationship in at least some cases. This idea is supported by studies showing that myelin antibody activity is expressed by the monoclonal proteins of many patients with neuropathy. Specificity for a carbohydrate epitope on myelin-associated glycoprotein (MAG) can be identified in a majority of IgM-associated neuropathies. The same epitope is found on myelin glycoprotein P<sub>0</sub> and on other gangliosides in nerve cell membranes. Injection of anti-MAG into experimental animals is known to produce demyelination. Additional patients have antibody activity against myelin sheath sulfatides, membrane-associated chondroitin sulfate C moieties, or various myelin gangliosides.<sup>20,39</sup>

Most clinical features of neuropathies associated with a monoclonal gammopathy are similar to CIDP<sup>29</sup>; however, sensory

abnormalities tend to be more prominent and, while progression may be slower overall, it is also more relentless, so that instances of spontaneous improvement are uncommon. The prevalence of neuropathy is higher in patients with IgM paraproteins than in those with IgG or IgA except in osteosclerotic myeloma, where the prevalence of neuropathy with IgG or IgA proteins is quite high, sometimes as a part of the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes). Nerve biopsies show demyelination, and immunofluorescence may demonstrate IgM and complement in IgM-associated cases.<sup>38,39</sup>

Patients with multiple myeloma or Waldenström's macroglobulinemia should be treated with appropriate chemotherapy and may experience improvement in the neuropathy as a result. However, many patients have neuropathy in addition to a monoclonal gammopathy of undetermined significance (MGUS) and are usually treated with immunosuppressive regimens similar to those used in CIDP.<sup>38</sup>

Therapeutic plasma exchange can be helpful in MGUS-associated neuropathy. In a sham-controlled trial in 39 patients, twice-weekly exchange led to improvement in disability scores, weakness scores, and electrodiagnostic parameters in the blinded portion of the trial. Scores also improved in sham-treated patients who received true TPE in an open follow-up study.<sup>40</sup> In this and other studies, a response was noted more frequently in patients with IgG and IgA paraproteins than in those with IgM.<sup>14,21(p146)</sup>

### Myasthenia Gravis

Myasthenia gravis is a disease of the neuromuscular junction that is characterized clinically by fatigability, with or without weakness in skeletal muscle. Ocular myasthenia, with diplopia and ptosis, may be the initial presentation, but other muscles are eventually affected in most patients. Involvement of muscles innervated by lower cranial nerves leads to the most serious symptoms, including dysphagia and respiratory insufficiency.<sup>41</sup>

About 85% of patients with myasthenia have circulating antibody to a portion of the  $\alpha$ -subunit of the acetylcholine (ACh) receptor molecule (AChR) on the motor end plate of muscle cells. Up to 41% of those lacking anti-AChR have circulating antibody to a muscle-specific kinase (MuSK) that is also found in the motor end plate. A few others have antibody to the muscle cytoplasmic proteins titin or RyR.<sup>41</sup>

There are two kinds of drug therapy for myasthenia. Acetylcholinesterase inhibitors, such as neostigmine and pyridostigmine, slow the degradation of ACh at the neuromuscular junction, enhancing its action on remaining receptors. Immunosuppressive drugs, such as prednisone and azathioprine, are also useful. These agents reduce damage to receptors through general antiinflammatory properties or decreased antibody synthesis or both.<sup>42</sup>

Surgical treatment is also employed. Malignant thymoma is sometimes associated with myasthenia in younger patients. Strength may improve in such patients after surgical resection of the thymus. This observation led to trials of thymectomy in younger patients without tumors, who may also experience disease remission.<sup>41,42</sup>

Because of the relationships between circulating antibody, pathology, and symptoms, TPE has seemed a very reasonable approach to treatment for myasthenia. Although a controlled trial has never been published, numerous open trials have suggested that TPE can lead to rapid symptomatic improvement in concert with lower levels of circulating AChR antibody. Therapeutic plasma exchange has also been effective in patients who test negative for antibody, suggesting that some pathogenic antibodies may not be detected by current assays.<sup>20,41</sup>

As a result of favorable experience, TPE is a widely accepted therapy for myasthenia; however, it is not recommended for all patients. It is instead reserved for those with severe disease and those who are intolerant of, or unresponsive to, other therapies. Patients whose breathing, swallowing or walking is inadequate are good candidates for the rapid improvement brought about by TPE, even as an initial treatment.<sup>42</sup> Therapeutic plasma exchange can also be useful to optimize muscle function before thymectomy or other surgery. An occasional patient will need regular TPE at 2- to 4-week intervals in addition to maintenance drug therapy for optimal function.

Myasthenia may respond to IVIG. No randomized trials have been conducted to prove efficacy; however, in a controlled study comparing IVIG to TPE in 87 patients, either three or five infusions of 0.4g/kg IVIG were equivalent to three TPE treatments. The median time to response was shorter for TPE-treated patients (9 days vs 15 days), but not significantly so ( $p = 0.14$ ).<sup>43</sup> A multicenter retrospective chart review found that ventilatory status at 2 weeks and functional status at 1 month were significantly better in patients treated with TPE.<sup>44</sup>

### Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome (LEMS) is also characterized by weakness and fatigue. Neither bulbar nor oculomotor symptoms are likely to be prominent in LEMS, but signs of dysautonomia, such as dry mucous membranes and orthostatic hypotension, are common. The syndrome is most often seen in patients with cancer, with almost half of cases being in patients with small cell lung cancer. Neuromuscular symptoms may precede any other sign of tumor.<sup>45</sup>

The pathophysiology of LEMS also involves the neuromuscular junction, but the defect is in the nerve cell ending instead of the muscle cell. Symptoms are caused by circulating antibody against "active zones" in the nerve terminus, which house the voltage-gated calcium channels that mediate electrical events in neuromuscular impulse transmission. These antibodies reduce the amount of ACh released during depolarization events, causing weakness in affected skeletal muscles as well as dysfunction in autonomic nerves.<sup>45</sup>

Curiously, cholinesterase inhibitors are not as effective in LEMS as they are in myasthenia gravis.<sup>46</sup> More useful are agents that prolong nerve action potentials by blocking voltage-gated potassium channels (VGKCs). These drugs may improve muscle strength in patients with LEMS, presumably by enhancing ACh release; 3,4-diaminopyridine is the most useful agent of this type.

Immunosuppressive drugs such as prednisone and azathioprine may also be beneficial in LEMS, and paraneoplastic cases may respond to specific antitumor therapy.<sup>45,46</sup>

Therapeutic plasma exchange has been helpful in LEMS. Responses are usually less dramatic than those seen in myasthenia gravis, perhaps suggesting that a damaged nerve ending needs more time to heal than a motor end plate. IVIG has also been reported to be active in both the short and long term.<sup>45,46</sup>

### Neuromyotonia and Limbic Encephalitis

Neuromyotonia is characterized by muscle cramps, involuntary contractions, fibrillations, and fasciculations. There is evidence to suggest that some cases are caused by the presence of antibodies to VGKC in nerve fibers. VGKC have a role in terminating action potentials, such that their blockage prolongs action potentials and enhances ACh release. Therapeutic plasma exchange has been followed by clinical improvement in individual cases.<sup>47</sup> VGKC antibodies have also been found in some patients with limbic encephalitis characterized by memory impairment, often with preservation of general intelligence. Therapeutic plasma exchange has led to improvement in individual non-paraneoplastic cases, in concert with diminution in antibody levels.<sup>48</sup>

### Stiff-Person Syndrome

Stiff-person syndrome (SPS), originally known as stiff-man syndrome, is characterized by progressive rigidity and/or spasms of trunk and proximal limb muscles. About 60% of patients have high titers or circulating antibody to the 65-kD isoform of glutamic acid decarboxylase (GAD-65), which is the rate-limiting enzyme in the synthesis of  $\gamma$ -amino butyric acid (GABA), the neurotransmitter at many inhibitory central nervous system (CNS) synapses. When present, anti-GAD-65 is believed to have a pathogenic role, even though neuronal GAD is a cytoplasmic enzyme. CNS histology is normal in SPS, suggesting that anti-GAD causes functional rather than structural changes. Pathogenesis is more uncertain in patients who lack antibody to GAD. About 5% of cases are associated with cancer, usually breast cancer. Instead of anti-GAD, most such patients have antibody to amphiphysine, a 128-kD presynaptic vesicle protein. A few have antibody to a postsynaptic protein called gephyrin that is associated with receptors for GABA and for glycine, another inhibitory neurotransmitter. Symptoms often respond to diazepam or other agents that increase CNS GABA levels. Immunomodulatory therapies such as prednisone, TPE, and IVIG have also seemed beneficial in individual cases, but no controlled trials of TPE have been performed. In paraneoplastic cases improvement may follow removal of the malignancy.<sup>21(p156),49</sup>

### Paraneoplastic Neurologic Syndromes

In addition to LEMS, several other neurologic syndromes associated with malignant tumors are characterized by circulating antibody to structures in the nervous system. Paraneoplastic encephalomyelitis includes seizures, mental changes, and cerebellar and autonomic dysfunction. It is often associated with

anti-Hu (also called ANNA-1), an antibody to a 38- to 40-kD antigen in the nuclei of neurons and of small cell lung cancer cells. Paraneoplastic cerebellar degeneration is characterized by ataxia, dysarthria, and down-beating nystagmus. It may be associated with ovarian, breast, and small cell lung cancers, as well as with Hodgkin disease. About 40% of these patients have an antibody to 34- and 62-kD antigens in Purkinje cells (anti-Yo). Paraneoplastic opsoclonus-myoclonus syndrome produces both vertical and horizontal dysrhythmic conjugated eye movements. It may occur in children with neuroblastoma and in adults with lung, breast, or other tumors. Cases seen with breast or gynecologic cancers may have circulating anti-Ri (also called ANNA-2), an antibody to 55- and 80-kD antigens in neuronal nuclei. Paraneoplastic SPS is characterized by stiffness and spasm in axial muscles. It is associated with antibody to amphiphysin, a 128-kD synaptic vesicle protein. Cancer-associated retinopathy produces photosensitivity and gradual vision loss. It is associated with anti-CAR, an antibody to antigens shared by retinal neurons and small cell lung cancer cells.<sup>50</sup>

Treatment of these syndromes is uniformly difficult. They seldom respond well to immunosuppressive drugs or to antitumor measures, even when these are otherwise effective. Therapeutic plasma exchange has been tried in these syndromes, usually with disappointing results.<sup>21(p142),50</sup>

### Nonneoplastic Disorders with Central Nervous System Antibodies

Rasmussen's encephalitis is a rare, acquired disorder that begins in childhood, often following a viral infection. Seizures are a prominent feature; however, unlike patients with idiopathic epilepsy, those with Rasmussen's encephalitis develop progressive, predominantly unilateral neurologic deficits including hemiparesis and mental retardation. The histopathology includes inflammation and atrophy of brain tissue, usually confined to one hemisphere.<sup>51</sup> Recent studies have revealed circulating IgG antibody to the Glu R3 receptor for the CNS neurotransmitter glutamate, which may arise in response to a cross-reactive microbial antigen. Treatment with either TPE or IVIG has been followed by temporary improvement.<sup>20</sup> Sydenham chorea is a movement disorder that may follow a group A streptococcal infection in children. Patients with Sydenham chorea may also exhibit obsessive-compulsive symptoms, while children who develop obsessive-compulsive behaviors, tics, and other neurologic symptoms in the absence of chorea may also have evidence of streptococcal infection (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection; PANDAS).<sup>52</sup> A cross-reactive antibody response to streptococcal antigens could mediate symptoms in some of these patients, and small controlled trials have indicated that both TPE and IVIG can be beneficial in either Sydenham chorea or PANDAS.<sup>20,21(p143),53</sup>

### Multiple Sclerosis

Multiple sclerosis (MS) is a disease characterized by localized neurologic dysfunction that is caused by demyelinated

“plaques” in the CNS. Two clinical patterns are observed. About 70% of patients will have acute attacks that resolve fully or partially (relapsing-remitting). The other 30% have slow, continual progression of disease (chronic progressive). The frequency of attacks in relapsing-remitting MS tends to decrease with disease duration, and some patients evolve to a chronic progressive pattern.<sup>54</sup>

Discrete areas or plaques of demyelination in white matter, which are easily visualized with magnetic resonance imaging (MRI), are the hallmarks of MS. Histopathologically these areas are initially inflammatory but progress to fibrosis.<sup>54</sup> The mechanism of their appearance remains unexplained, but most authorities in the field suspect involvement of the immune system.<sup>55</sup> Experimental allergic encephalomyelitis, an animal model of MS, can be induced by immunization with myelin basic protein (MBP) or other myelin proteins. Experimental allergic encephalomyelitis is mediated by T cells and can be passively transferred with T cells from immunized animals. Most evidence suggests a misdirected cellular immune response in MS as well, and it has been difficult to assign a primary pathogenic role to circulating antibody. Antibodies to MBP or myelin oligodendrocyte glycoprotein (MOG) can be found both in CNS lesions<sup>56</sup> and in serum<sup>57</sup> in some MS patients. Although they are predictive of progression to MS in patients with a clinically isolated demyelinating event,<sup>58</sup> such antibodies do not produce MS in experimental animals.<sup>59</sup> Also, anti-MOG does not correlate with histopathologic classification or apparent responsiveness to TPE.<sup>60</sup>

The study of treatments for MS is complicated by the natural history of the disease, particularly the tendencies for acute attacks to subside and for attack frequency to decline, but also by other spontaneous fluctuations in disease activity. Clinical measurement tools such as the Expanded Disability Status Scale are used to quantify improvement or progression of disability. Although these bring some degree of objectivity to clinical studies, they are subject to interrater variability.<sup>61,62</sup>

Immunosuppressive and immunomodulatory agents have been the mainstays of drug therapy in MS. Resolution of acute attacks is thought to be hastened by brief courses of either glucocorticoids or adrenocorticotrophic hormone, both of which may promote faster restoration of normal nerve conduction by decreasing edema and inflammation in and around new plaques. The relentless progression of disability is probably not halted by these measures, although aggressive treatment of optic neuritis with intravenous steroids may delay the onset of frank MS that often follows. Cyclosporine, total lymphoid irradiation, and cytotoxic immunosuppressants such as azathioprine and cyclophosphamide have only modest benefits that may not warrant the risks such drugs entail. Mycophenolate mofetil and low dose methotrexate have also been tried. Mitoxantrone and interferon- $\beta$  have shown promise in recent studies, as has glatiramer acetate, a mixture of synthetic polypeptides that may modulate immune responses to MBP. These agents reduce the frequency of acute attacks and the appearance of new lesions seen with MRI. Immunomodulatory

monoclonal antibodies, such as alemtuzumab, daclizumab, natalizumab, and rituximab are also being investigated.<sup>62-64</sup>

Prophylactic administration of IVIG to patients with MS is reported to reduce the frequency of attacks and may slow clinical deterioration in relapsing-remitting patients. It has not as yet been shown to mediate improvement in chronic visual impairment or motor symptoms.<sup>64</sup>

The rationale for TPE in MS is uncertain, given the paucity of evidence that any circulating factor has a role in the etiology of acute attacks or chronic progression. Therapeutic plasma exchange has nevertheless been used, and encouraging results have been reported from uncontrolled studies. In controlled trials, however, it has been difficult to discern benefit, even with vigorous TPE regimens.<sup>14</sup> The first randomized, double-blind, sham-controlled study in chronic progressive MS was reported to show significant benefit for patients receiving TPE in addition to cyclophosphamide and prednisone.<sup>65</sup> The study was subsequently questioned because of anomalies in statistical analysis, and because dramatic recoveries in several of the TPE patients, not seen in subsequent trials, suggested that some relapsing-remitting patients were misclassified and entered into the trial during attacks that would have improved spontaneously.<sup>61</sup> Two later sham-controlled trials have not shown convincing benefit.<sup>66,67</sup> A single trial suggested that TPE could be useful in a subset of patients with MS with prolonged severe demyelination<sup>68</sup>; however, that study combined results of MS patients with those of patients having neuromyelitis optica. The Therapeutics and Technology Assessment subcommittee of the American Academy of Neurology and the MS Council for Clinical Practice Guidelines have classified TPE as “of little or no value” in progressive MS and of uncertain value in acute severe demyelination in previously non-disabled individuals.<sup>69</sup>

---

## Therapeutic Plasma Exchange in Hematologic and Oncologic Disorders

Therapeutic plasma exchange has been tried in a variety of hematologic and oncologic conditions. These are listed in Table 42-4 along with their respective indications and intensity categories.

### Monoclonal Proteins

In addition to peripheral neuropathy (discussed above), four other syndromes associated with monoclonal immunoglobulins are regarded as clinical indications for TPE. Hyperviscosity, coagulopathy, and renal failure, which almost always occur in the setting of a malignant B-cell disorder, are discussed below; cryoglobulinemia is covered in a later section.

Hyperviscosity was the first condition to be treated successfully with manual plasmapheresis, the precursor to TPE. The full-blown syndrome consists of neurologic symptoms, a bleeding diathesis, a peculiar retinopathy marked by alternating dilated and constricted segments in retinal veins, and hypervolemia caused by expansion of plasma volume. Symptoms are uncommon if the

**Table 42-4.** Indication and Intensity of Treatment Categories for TPE in Hematologic and Oncologic Disorders

| Disorders                                       | Antibody Specificities | ASFA Indication Category* | Intensity Category† |
|-------------------------------------------------|------------------------|---------------------------|---------------------|
| Hyperviscosity syndrome                         | Not applicable         | I                         | P, C                |

†A = aggressive; R = routine; P = prolonged; C = chronic (see Table 42-2).

TPE = therapeutic plasma exchange; ASFA = American Society for Apheresis; vWF = von Willebrand factor; HPA = human platelet antigen; IA = protein A-silica immunoadsorption; NR = not rated.

relative serum viscosity is below 4 and become more likely when it exceeds 6. The hyperviscosity syndrome is most often seen in patients with Waldenström's macroglobulinemia, who have IgM paraproteins, but it may also occur in multiple myeloma.<sup>70</sup>

At higher paraprotein levels a relatively large change in viscosity may follow a relatively small change in concentration. It is this nonlinear relationship that allowed the 2-unit manual plasmapheresis technique available in the 1950s to lower viscosity enough to relieve symptoms. Because most IgM paraproteins are roughly 80% intravascular, the same relationship also predicts that a one-plasma-volume automated exchange will provide a wide margin of safety and can therefore be repeated less frequently for hyperviscosity than is necessary for many other conditions. Viscosity measurements should guide therapy, of course, but treatment every 1 to 2 weeks may be adequate.<sup>70</sup>

Paraproteins may interfere in platelet and clotting factor interactions in the absence of hyperviscosity. Such coagulopathies are found in 60% of patients with macroglobulinemia, 40% of patients with IgA myeloma, and 15% of patients with IgG myeloma.<sup>71</sup> In instances that are clinically significant, TPE therapy can help restore adequate hemostasis.

Renal failure develops in 3% to 9% of patients with myeloma and confers a poor prognosis. In many cases, renal biopsy demonstrates accumulation of free light chains in renal tubules. Urinary excretion of light chains will greatly exceed the amount that could be removed by TPE if renal function is normal. The reverse may be true in renal failure; however, light chain levels return to baseline within hours after TPE.<sup>72</sup> Three controlled studies have examined rates of recovery of renal function in myeloma patients who received TPE therapy. In one study, three of seven dialysis-dependent patients who received TPE recovered renal function, while none

of five control patients did.<sup>73</sup> In another, 13 of 15 patients in the treatment group recovered renal function compared with only two of 14 controls.<sup>74</sup> A more recent controlled study enrolled 104 patients and assessed a composite outcome comprising death, dialysis, or a low glomerular filtration rate. Outcomes were not improved in the patients randomly assigned to receive TPE treatment.<sup>75</sup> Thus, the value of TPE in this circumstance is questionable.

### Alloantibodies to Blood Cells

Alloantibodies to red cells and platelets may be problematic in a number of disease processes. Treatment by antibody removal has been tried in several of these.

Hemolytic disease of the fetus and newborn was one of the first problems to be approached with automated apheresis instruments. In the hope of slowing fetal hemolysis, sensitized D-negative mothers carrying D-positive fetuses underwent TPE to lower anti-D titers. Since the original reports, the number of sensitized mothers has declined as prophylaxis with Rh Immune Globulin has become more widespread. Furthermore, intrauterine transfusion with D-negative red cells has proven to be a better treatment for affected fetuses. For these reasons, TPE is seldom called for now, but it may still be useful in an occasional pregnancy when there is very early evidence of fetal involvement, because intrauterine transfusion is not feasible before about 18 weeks of gestation.<sup>76</sup> Prompt, early institution of TPE was followed by successful delivery after multiple prior abortions in compelling case reports involving mothers with anti-M and anti-P.<sup>18</sup>

Therapeutic plasma exchange has also been used to remove isoagglutinins in the setting of hematopoietic stem cell transplantation. Allogeneic transplantation across a major ABO barrier (eg, group A donor to group O recipient) is feasible if a

hemolytic transfusion reaction to red cells in the transplant can be avoided. This was first accomplished in marrow transplants by exhaustive pretransplant TPE of the recipient; however, most centers have preferred to simply remove most of the red cells (eg, <20 mL remaining) from an incompatible marrow graft before transplantation.<sup>77</sup> Peripheral blood stem cell collections include far fewer red cells (usually <10 mL). Such grafts can be infused safely without any manipulation. Red cell engraftment may be delayed in this situation. Therapeutic plasma exchange has been used, both before transplant to avoid delayed engraftment and after transplant to correct it, with uncertain results in both cases.<sup>78</sup> Transplantation of a solid organ, such as a liver or kidney, across a major ABO barrier can result in hyperacute rejection and is usually avoided for this reason. When organ availability is limited, however, clinical circumstances have sometimes led to transplantation of an ABO-incompatible liver or kidney after extensive TPE of the recipient, often with a satisfactory outcome.<sup>19,79</sup>

Organ transplantation across a minor ABO barrier (eg, group O donor to group A recipient) does not carry an increased risk of rejection. Some patients, however, develop hemolytic anemia caused by isoagglutinins derived from B lymphocytes in the transplant. Red cell destruction mediated by these “passenger lymphocytes” is most often seen in heart-lung or liver transplantation, in which the volume of lymphoid tissue transplanted is relatively high, and is usually evident by 1 to 3 weeks after transplantation.<sup>80</sup> Severe hemolysis may improve after TPE and compatible (eg, group O) red cell transfusion.<sup>81</sup>

Alloimmunization to HLA or platelet antigens can cause refractoriness to platelet transfusions. To restore responsiveness, antibody removal by means of TPE or a protein A-silica column has been attempted. Intravenous immune globulin has also been tried.<sup>18</sup> However, the results have been inconclusive and the best option for alloimmunized patients is transfusion of compatible platelets.

## Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

### Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura is characterized by microangiopathic hemolytic anemia and thrombocytopenia, often severe. Central nervous system changes, fever, and renal abnormalities may be seen in advanced cases, although frank renal failure is unusual. A rare relapsing form begins in childhood, but the majority of cases in adults are sporadic, with women accounting for 70%. Thrombotic thrombocytopenic purpura is most often idiopathic but may be seen in association with other illnesses, such as systemic lupus erythematosus (SLE) and HIV infection, as well as with certain drugs. Idiopathic TTP was formerly assigned a mortality rate of 90%, but empiric studies in the 1970s and 1980s demonstrated much improved survival in patients receiving daily TPE with plasma replacement. Some patients, including children with the relapsing form of the disease, will respond to simple plasma infusion.<sup>82</sup>

A convincing account of the pathogenesis of TTP has been offered. It involves a plasma enzyme (a metalloproteinase called ADAMTS13 on the basis of structural features) that cleaves ultralarge von Willebrand factor (ULvWF) multimers secreted by endothelial cells, yielding the smaller vWF polymers found in normal plasma. Children with relapsing TTP have an inherited deficiency of ADAMTS13,<sup>83</sup> while in idiopathic adult cases an “acquired deficiency” arises because of the formation of an autoantibody inhibitor to the enzyme.<sup>84,85</sup> In either case, persistence of ULvWF in the circulation promotes inappropriate adherence of platelets to endothelial cells and to each other, leading to consumptive thrombocytopenia and to microvascular obstructions that cause mechanical trauma to red cells and varying degrees of end-organ ischemia. Periodic plasma infusion may abort or prevent attacks in congenitally deficient patients by supplying active enzyme.<sup>83</sup> Idiopathic cases respond better to TPE (78% response rate vs 63% for plasma infusion in the Canadian study),<sup>86</sup> presumably because exchanges remove inhibitory antibody as well as replacing the deficient enzyme. Exchanges are usually carried out daily until the platelet count and LDH (as a marker of hemolysis) have normalized.

Various immunosuppressive maneuvers, including glucocorticoid therapy, vincristine, rituximab, and splenectomy have been advocated as adjunctive treatments. Discovery of a causative autoantibody provides support for their use in idiopathic, but not in congenital, cases.<sup>18,21(p159)</sup>

A syndrome resembling TTP has been identified in some patients taking the antiplatelet drugs ticlopidine<sup>87</sup> and clopidogrel.<sup>88</sup> Antibody to ADAMTS13 has been detected in such cases,<sup>89</sup> and TPE has been reported to improve outcome (76% survival vs 50% for unexchanged patients in a retrospective study of ticlopidine recipients).<sup>87</sup> ADAMTS13 deficiency is generally not found in TTP-like syndromes associated with other drugs such as quinine or cyclosporine.<sup>90</sup>

### Hemolytic Uremic Syndrome

The hemolytic uremic syndrome (HUS) usually involves microangiopathic hemolysis, renal insufficiency, and mild-to-moderate thrombocytopenia. It occurs in children in a self-limited form that follows infection with a verotoxin-producing *Escherichia coli* (diarrhea positive); however, not all pediatric cases have this association (diarrhea negative). Both a familial and a nonfamilial form may be seen in adults. Some nonfamilial cases are associated with prior chemotherapy or stem cell transplantation.

Because of the striking overlap in clinical manifestations, it was long supposed that the pathogenesis of HUS was the same as, or similar to, that of TTP. Largely on this basis, TPE and protein A-column therapy have been recommended for diarrhea-negative childhood HUS and for adult HUS. Responses have generally been less favorable than in TTP, especially in HUS associated with chemotherapy or hematopoietic stem cell transplantation.<sup>82,91,92</sup>

Studies of ADAMTS13 in adult patients with familial and nonfamilial forms of HUS have revealed neither severe deficiency nor inhibitory activity.<sup>84</sup> Thus, the hypothesis that HUS has the same pathogenic mechanism as TTP would seem to be in error. Deficiency of complement factor H has been identified in some patients with familial HUS.<sup>93</sup> This might provide some rationale for plasma replacement therapy; however, for most cases of HUS the role of TPE is unclear at this time. This is also true for the role of TPE in the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) in pregnant women,<sup>94</sup> which shares clinical features with TTP, HUS, and preeclampsia.

### Posttransfusion Purpura

Posttransfusion purpura (PTP) is a rare syndrome in which the platelet count falls to dangerously low levels about 1 week after an allogeneic transfusion. Patients who develop the syndrome lack the common allele for one of the platelet-specific glycoprotein antigens, most often the HPA-1a antigen on glycoprotein IIIa. Most patients have had multiple prior transfusions or pregnancies, and have been immunized thereby to the platelet-specific antigen coded by the prevalent allele. The transfusion that precedes the illness appears to stimulate an anamnestic increase in the titer of IgG platelet-specific alloantibody, most often anti-HPA-1a. Posttransfusion purpura is self-limited and should resolve without treatment after a few weeks; however, bleeding complications, including fatal CNS hemorrhage, may occur in the interim.<sup>95</sup>

Although it is somehow linked to a platelet-specific alloantibody response, the mechanism of extensive destruction of antigen-negative autologous platelets in PTP remains uncertain. The following four possibilities have been proposed: 1) immune complexes consisting of platelet antigen and platelet antibody bind to autologous platelets and mediate their destruction, 2) soluble platelet-specific alloantigen derived from the transfusion is adsorbed by autologous platelets, 3) a simultaneous platelet autoantibody response occurs, or 4) a broad polyclonal alloimmune response produces some antibodies that cross-react with autologous platelets.

Treatment of PTP is recommended, because many patients will have bleeding complications. High-dose glucocorticoids are usually given empirically and pulse methylprednisolone at 1 g/day has been reported effective. Platelet transfusions, even those from antigen-negative donors, seldom raise the platelet count but are likely to cause severe reactions. Daily TPE usually promotes a rise in platelet count within several days and is thought to be an effective treatment for this reason, even though no controlled trials have been conducted.<sup>96</sup> Exchanges usually include FFP replacement to avoid a superimposed humoral coagulopathy. Intravenous immune globulin produces a similarly rapid increase in platelet count and has become the favored treatment modality for this group of patients.<sup>97</sup>

### Idiopathic Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura (ITP) is an autoimmune illness affecting platelets. Most patients have an autoantibody of

the IgG class directed against a platelet-membrane glycoprotein antigen. Idiopathic thrombocytopenic purpura is sometimes accompanied by warm autoimmune hemolytic anemia (WAIHA; Evans syndrome). In pediatric patients, ITP is acute and self-limited; recovery is the rule regardless of treatment. Adults with ITP, most of whom are women, seldom recover without treatment and their disease often progresses to a chronic form. An ITP syndrome may also be seen in patients with SLE or HIV.<sup>98,99</sup>

The goal of treatment in ITP is to prevent bleeding. Fortunately most of the circulating platelets in patients with ITP are relatively young and have above-average hemostatic activity, so that a normal platelet count is not needed to avoid hemorrhage. Glucocorticoids, splenectomy, and IVIG are the mainstays of therapy.<sup>98,99</sup> Large intravenous doses of anti-D will often raise the platelet count in Rh(D) positive patients because excessive red cell destruction occupies phagocytic cells and inhibits platelet destruction. A few favorable anecdotal reports of TPE in ITP appeared in the 1970s, and one small trial suggested a lower rate of splenectomy in exchanged patients but a later study found no long-term benefit associated with such therapy.<sup>99</sup> Given this experience, enthusiasm for this approach has waned.<sup>21(p134)</sup>

Favorable responses to protein A-silica column treatment have been reported in ITP associated with HIV infection,<sup>100</sup> as well as in patients with chronic ITP without HIV.<sup>101</sup> The mechanism of action of protein A in this effect is unknown. A purely subtractive mechanism (ie, removal of platelet antibody) seems unlikely, because responses have been reported when as little as 250 mL plasma per week was treated. Bearing this uncertainty in mind, the protein A-silica column remains an option for chronic ITP refractory to more standard therapies,<sup>21(p134)</sup> and is discussed in greater detail in Chapter 41.

### Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia (AIHA) is caused by autoantibodies to red cells. Such antibodies are classified as either “cold” or “warm” agglutinins, depending on the temperature of maximal activity. Cold agglutinins are usually IgM antibodies directed against the I/i antigens; they bind most strongly at low temperatures and may produce a syndrome of complement-mediated intravascular hemolysis (cold agglutinin disease; CAD). Warm agglutinins are usually IgG and are often directed against an antigen that does not appear on Rh<sub>null</sub> cells; they bind better at body temperature and produce a predominantly extravascular hemolytic syndrome, WAIHA. Autoimmune hemolytic anemia can be idiopathic but can also be associated with infections, lymphoproliferative disorders, or other autoimmune diseases.<sup>102</sup>

Most patients need treatment. Standard therapy is aimed at lowering antibody production and inhibiting destruction of sensitized cells. Glucocorticoids, IVIG, and splenectomy are often effective in WAIHA, and other immunosuppressive drugs may be tried if these measures fail. All of these approaches are less successful in CAD.<sup>102</sup>

Therapeutic plasma exchange to deplete circulating antibody has been tried in both WAIHA and CAD when conventional

treatments have failed. Because the IgM antibodies in CAD are predominantly intravascular and only loosely bound to cells, their removal by TPE should be relatively efficient. Such therapy, when added to conventional drug treatment, has been reported to lower antibody titers and transfusion requirements, albeit only temporarily. In WAIHA much of the circulating antibody is bound to red cells; TPE has been tried in this disorder also, but it is less likely to be helpful.<sup>21(p118)</sup> A nonrandomized study compared responses to red cell transfusions in five AIHA patients who underwent TPE before some transfusions and four other patients who did not. Responses were significantly better in the patients who did *not* receive TPE and were not improved by TPE in the patients who did, suggesting that TPE is not effective for this purpose.<sup>103</sup>

### Pure Red Cell Aplasia and Aplastic Anemia

Pure Red Cell Aplasia and Aplastic Anemia are marrow disorders. In the former there is reticulocytopenic anemia, while the latter leads to pancytopenia. At least some cases of both conditions likely have an immunologic basis. Allogeneic marrow transplantation is the preferred treatment for severe aplastic anemia if a suitable donor is available, but immunosuppressive therapies, such as glucocorticoids, cytotoxic drugs, cyclosporine, and antithymocyte globulin may be effective, especially in milder cases.

In the serum of a minority of patients it is possible to demonstrate a factor, probably antibody, that inhibits the growth of marrow-derived precursor cells in culture.<sup>104</sup> This provides a rationale for TPE, which has been reported in both disorders in a few cases. Results in aplastic anemia have been mixed; responses appear to be more likely in patients with serum inhibitory activity. All reported instances of TPE treatment for pure red cell aplasia have led to improvement, which is sometimes quite dramatic in patients with serum inhibitory activity. Thus, although TPE is not a primary therapy for either disorder, it can be offered to patients who have failed to improve after receiving conventional treatment, especially those found to have serum inhibitory factors.<sup>21(p117)</sup>

### Coagulation Factor Inhibitors

Coagulation factor inhibitors are IgG antibodies to components of the clotting cascade. They interfere with clotting by inactivating the targeted factor. Inhibitors may be autoantibodies that arise in individuals with no prior bleeding. Alternatively they may be alloantibodies that form in genetically deficient patients after exposure to “foreign protein” in the course of factor replacement therapy. Factor VIII is the clotting protein most often affected by antibodies of either type, and most of the following concerns Factor VIII inhibitors.

The two goals of treatment for a patient with an inhibitor are control of individual bleeding episodes and suppression of inhibitor synthesis. Depending on inhibitor titer, the first goal can sometimes be achieved by infusion of high doses of human Factor VIII. Porcine Factor VIII, which cross-reacts

only partially with human Factor VIII antibodies, can be effective in the face of somewhat higher inhibitor titers, but its availability in recent years has been uncertain. For patients with the highest titers, Factor VIII-bypassing products such as recombinant Factor VIIa are needed. Therapeutic plasma exchange or selective immunoadsorption of IgG during a bleeding episode may reduce inhibitor titers enough to allow infused Factor VIII to bring about hemostasis. Suppression of inhibitor synthesis is approached with immunosuppressive measures, including high-dose glucocorticoids, cytotoxic agents, cyclosporine, IVIG, and rituximab.<sup>15,105,106</sup> Tolerance-inducing protocols that include regular infusion of exogenous Factor VIII have been devised for patients with alloimmune inhibitors. In the so-called Malmö protocol, extensive TPE or IgG depletion with protein A-sepharose column procedures is used to reduce the inhibitor level at the onset of treatment so that infused “tolerizing” factor can circulate.<sup>107</sup> Frequent, large (two to three plasma volume) exchanges with FFP replacement are recommended for patients with inhibitor. Central venous access is often required; placement of a catheter in a patient with a refractory bleeding diathesis is a challenge for all concerned and often mandates infusion of a Factor VIII-bypassing product for wound hemostasis.<sup>108</sup>

Therapeutic plasma exchange has also been reported for treatment of patients with antiphospholipid antibodies, which may interfere with in-vitro assays of coagulation, such as the partial thromboplastin time. In contrast to the inhibitory antibodies described above, however, they usually promote inappropriate coagulation in vivo and cause thrombotic events. Patients suffering thrombotic events in three or more organ systems are said to have catastrophic antiphospholipid antibody syndrome.<sup>109</sup>

---

## Therapeutic Plasma Exchange in Rheumatic and Other Immunologic Disorders

Therapeutic plasma exchange has been tried in a number of rheumatic diseases and other diseases that are considered to have an immune or autoimmune etiology. These are listed in Table 42-5 along with the author's intensity guidelines and the indication categories assigned by ASFA.

### Cryoglobulinemia

Cryoglobulins are abnormal serum proteins that precipitate reversibly at 4°C; some will precipitate at higher temperatures. Such precipitates always contain immunoglobulin, and immunoelectrophoretic or immunofixation analysis allows distinction of three types. Type I cryoglobulins consist of a single species of monoclonal immunoglobulin. These are usually found in B-cell lymphoproliferative disorders such as myeloma or Waldenström's macroglobulinemia. Cryoglobulin levels are often quite high (>500 mg/dL) and may cause Raynaud phenomenon or acral necrosis due to microvascular obstruction, as well as other symptoms. Type II cryoglobulins contain both monoclonal and polyclonal immunoglobulins. The former is usually an IgMκ

**Table 42-5.** Indication and Intensity of Treatment Categories for TPE in Rheumatic and Other Immunologic Disorders

| Disorders                              | Antibody Specificities | ASFA Indication Category* | Intensity Category† |
|----------------------------------------|------------------------|---------------------------|---------------------|
| Cryoglobulinemia                       | IgG                    | II                        | A, R, P, C          |
| Rheumatoid arthritis                   | IgG                    | NR (II for IA)            | R ?                 |
| Systemic lupus erythematosus           | dsDNA and others       | III (IV for nephritis)    | R, P                |
| Systemic vasculitis                    | ANCA                   | NR                        | R ?                 |
| Polymyositis and dermatomyositis       | Unknown                | IV                        | R?                  |
| Goodpasture syndrome                   | Type IV collagen       | I                         | A                   |
| Rapidly progressive glomerulonephritis | ANCA                   | II                        | R                   |
| Renal transplantation                  |                        |                           |                     |
| Humoral rejection                      | HLA antigen            | II                        | A, R                |
| Presensitization                       | HLA antigen            | II                        | R                   |
| Recurrent focal glomerulosclerosis     | Unknown                | III                       | R                   |
| Heart transplant rejection             | HLA antigen            | III                       | R                   |

\*I = standard first-line therapy; II = second-line therapy; III = controversial; IV = no efficacy; IA = protein A-silica immunoadsorption, NR = not ranked.

†A = aggressive; R = routine; P = prolonged; C = chronic (see Table 42-2).

TPE = therapeutic plasma exchange; ASFA = American Society for Apheresis; IgG = immunoglobulin G; dsDNA = double-stranded DNA; ANCA = antineutrophil cytoplasmic antibodies; NR = not rated.

with anti-IgG specificity, while the latter is polyclonal IgG bound to the IgMκ in an immune complex. Most cases occur in the context of chronic hepatitis C infection. They typically manifest a cutaneous vasculitis on the lower extremities and may have visceral manifestations of immune complex disease as well.<sup>110</sup> Type III cryoglobulins are mixed polyclonal, often with IgM anti-IgG that binds IgG in immune complexes. These may arise in acute infections, such as hepatitis B, or in chronic inflammatory states such as severe rheumatoid arthritis. Clinical manifestations resemble serum sickness.

If there is an underlying condition, cryoglobulin levels and related symptoms may decrease with treatment of this primary disorder, for example, chemotherapy for myeloma or interferon for hepatitis C virus infection. For idiopathic and secondary cases of mixed cryoglobulinemia, prednisone therapy often relieves symptoms, while alkylating agents may be useful in patients with severe symptoms resistant to prednisone.

Therapeutic plasma exchange will reduce cryoglobulin levels and control symptoms, even in the absence of other treatments,<sup>111,112</sup> but inconvenience and expense mitigate against such use. It should be started promptly for patients who seek treatment for severe acral ischemia or visceral manifestations of vasculitis, in whom it can help achieve control of symptoms until aggressive drug therapy takes hold.<sup>113</sup> Patients with chronic vasculitic skin ulcers may also benefit.<sup>114</sup> In all cases replacement fluids should be warmed to body temperature before infusion.

### Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a disease of unknown cause that is more prevalent in women. It is the most common chronic inflammatory joint disease and a leading cause of disability. Most patients have rheumatoid factor, an IgM autoantibody to IgG; however, because this antibody is absent in many clinically typical

cases, and because it is also found in patients who do not have arthritis, it is not likely to be directly involved in pathogenesis.

Conservative treatment includes nonsteroidal antiinflammatory agents, oral glucocorticoids in low doses, and intraarticular steroids. More severely affected patients eventually receive slow-acting “disease-modifying antirheumatic drugs” that are probably immunomodulatory, such as antimalarials, gold compounds, and methotrexate. Tumor necrosis factor and IL-1 inhibitors are also approved for treatment of RA.

Therapeutic plasma exchange was tried for RA in the 1970s and 1980s, but controlled trials did not show benefit. There were subsequent reports of lymphapheresis, with or without accompanying TPE. Some controlled trials investigating this approach showed significant but short-lived benefit, while others did not. In practice, the prospect of only a modest chance of modest benefit from a costly, inconvenient therapy has discouraged treatment with therapeutic apheresis.<sup>17</sup>

A sham-controlled trial of 12 weekly protein A-silica column treatments produced improvement in 33% of 48 treated patients vs only 9% of 43 controls. Benefit persisted for about 8 months on average, and a subsequent course was again beneficial in seven of nine initial responders.<sup>115</sup> Although its mechanism of action is unclear, this device has gained Food and Drug Administration approval for use in RA.

### Systemic Lupus Erythematosus

Systemic lupus erythematosus has long been regarded as the prototypic autoimmune disease. The most important diagnostic criterion, circulating antibodies to DNA, especially double-stranded DNA (anti-dsDNA), identifies patients who may have a variety of other autoantibodies and a disparate array of clinical syndromes in which skin disease, joint disease, cytopenias, or nephritis may be the sole or dominant problem.

Immunosuppressive measures are the cornerstone of therapy for SLE. Most patients are given prednisone in varying doses, and those with severe disease may also receive azathioprine or cyclophosphamide. The plethora of autoantibodies that seem relevant to clinical signs made SLE an obvious target for TPE. It was one of the first illnesses to be treated with automated TPE in the early 1970s, and early case reports and uncontrolled series suggested a favorable effect.<sup>17</sup>

Lupus nephritis is a particularly devastating manifestation in which glomerular deposition of immune complexes and anti-dsDNA is believed to have a prominent role in pathogenesis. Thus it seemed an attractive setting for randomized trials of TPE. A controlled trial with only eight patients suggested benefit.<sup>116</sup> However, in a multicenter randomized controlled trial comparing oral cyclophosphamide plus TPE to oral cyclophosphamide alone, there was no advantage for the patients receiving TPE.<sup>117</sup> A later international trial, which enrolled patients with a variety of severe manifestations, was structured to exploit enhanced sensitivity to a properly timed pulse dose of intravenous cyclophosphamide that was believed to follow pathogenic antibody removal by TPE.<sup>118</sup> As mentioned above, subsequent work with knock-out mice deficient for the FcRn receptor suggests that enhanced susceptibility would not occur.<sup>4</sup> In any case, this trial also failed to show any advantage for all patients treated with TPE<sup>119</sup> or for a subgroup with nephritis.<sup>120</sup> Thus large controlled studies have failed to confirm any worthwhile effect of TPE in SLE.

### Systemic Vasculitis

The term *systemic vasculitis* encompasses a group of disorders that cause inflammation in blood vessel walls and ischemic tissue damage. Vasculitis syndromes are conveniently classified on the basis of the size of vessels typically involved, but most are of unknown etiology. Immune complexes are found in patients with some syndromes, and autoantibodies such as antineutrophil cytoplasmic antibodies (ANCA) in Wegener's granulomatosis (c-ANCA) and polyarteritis (p-ANCA), can be demonstrated in others. This has lent credence to the notion that humoral immune factors are somehow involved.<sup>121</sup>

Prednisone is the first-line therapy for most vasculitic syndromes and cyclophosphamide is often added in more severe cases. Randomized controlled trials in renal vasculitis,<sup>122</sup> as well as in a group of patients with polyarteritis or Churg-Strauss angiitis,<sup>123</sup> have shown little evidence that addition of TPE to drug therapy confers long-term benefit. Nevertheless, it may be requested for patients who are not responding to maximal drug therapy.

### Polymyositis and Dermatomyositis

Polymyositis and dermatomyositis are inflammatory diseases affecting skeletal muscle. A characteristic dermatitis involving the eyelids, knuckles, neck, and shoulders is also part of the latter condition. The usual clinical picture includes proximal weakness with biochemical evidence of muscle cell enzyme leakage; the diagnosis is confirmed by muscle biopsy. The natural

history is progressive fiber loss, eventually leading to profound, irreversible weakness. An autoimmune etiology is suspected, but circulating antibody specific for skeletal muscle has not been implicated. Initial treatment is high-dose prednisone, which can often be tapered to maintenance levels. Resistant disease is treated with azathioprine, methotrexate, an alkylating agent, or a combination. Controlled trials have also shown that IVIG infusion reduces muscle enzyme levels and improves strength temporarily.<sup>20</sup>

Several uncontrolled series were interpreted to show that TPE was beneficial, but they were unfortunately confounded by concurrent escalations in immunosuppressive drug therapy.<sup>20</sup> A randomized controlled trial in which 12 patients received TPE, 12 received lymphapheresis, and 12 received sham apheresis, with no changes in drug therapy, showed no difference in the response rate among the three groups.<sup>124</sup> Thus despite the successes with IVIG, there appears to be no role for TPE in the treatment of polymyositis.

### Goodpasture Syndrome

Goodpasture syndrome (GPS) is characterized clinically by pulmonary hemorrhage and rapidly progressive glomerulonephritis. Light microscopy of renal biopsies shows crescent formation in many glomeruli, while immunofluorescent and electron microscopy reveal linear subendothelial immune deposits that may also be evident in a lung biopsy. In 95% of cases there is a circulating antibody that binds to glomerular basement membrane (anti-GBM). Such antibodies are specific for a noncollagenous sequence near the carboxy terminus of the  $\alpha 3$  chain of type IV collagen, which is found in appreciable quantities only in renal and pulmonary basement membranes. Untreated GPS progresses quickly and relentlessly, and most patients die of uremia or complications of lung hemorrhage.<sup>125</sup> The preferred treatment for GPS is high-dose prednisone and cyclophosphamide, combined with aggressive TPE, to quickly reduce anti-GBM levels and minimize progression of tissue damage.<sup>19</sup> Exchanges are usually carried out daily and may be continued for up to 2 weeks. It is prudent to give some FFP replacement in the latter part of each exchange to avoid a dilutional coagulopathy that might cause exacerbation of lung bleeding.

A single controlled trial failed to show an advantage for GPS patients who received TPE; however, this study has been largely discounted because the TPE schedule (every 3 days) was not sufficiently aggressive and because the extent of renal damage at entry was worse in the TPE group than in controls.<sup>126</sup> Early treatment is recommended because patients who are already dialysis-dependent at the onset of TPE are unlikely to recover renal function.<sup>127</sup> It follows that the subset of patients whose renal biopsies show irreversible lesions are not likely to benefit from TPE unless they also have pulmonary hemorrhage.

### Other Rapidly Progressive Glomerulonephritis

In addition to GPS, there are two other categories of rapidly progressive glomerulonephritis (RPGN)—those with an immune

complex disease, who have granular subendothelial immune deposits, and those with pauci-immune RPGN, who have scant immune deposits, if any. Light microscopic findings in both are similar to those found in GPS, with severe glomerular inflammation and crescent formation. Some cases also have associated lung hemorrhage. Patients in either group may have isolated renal disease or may have accompanying features that suggest a diagnosis of systemic vasculitis, mixed cryoglobulinemia, or Henoch-Schönlein purpura for granular-immune complex RPGN, or microscopic polyangiitis or Wegener's granulomatosis for pauci-immune RPGN patients, most of whom test positive for ANCA.<sup>128</sup>

Therapies are similar for these two categories of RPGN, and some trials and series have included patients with both types. Virtually all patients receive prednisone and most receive either oral or intravenous cyclophosphamide. Therapeutic plasma exchange has been used extensively in patients with both types of disease. Two controlled trials, one published in 1988<sup>129</sup> and the other in 1992,<sup>130</sup> showed no advantage for patients who received TPE in addition to immunosuppressive drugs. However, a subgroup analysis in the second study suggested that patients who have dialysis-dependent renal failure are more likely to recover renal function if they receive TPE. No such trend was noticed in the more recent trial conducted by Guillevin and colleagues.<sup>123</sup> A prospective, randomized trial by Stegmayr et al<sup>131</sup> compared TPE with immunoadsorption. Among 38 patients with non-GPS RPGN, 87% of whom had ANCA, 70% avoided long-term dialysis. Therapeutic plasma exchange and immunoadsorption were equally effective. In another study of ANCA-positive patients with an elevated creatinine, 54% of dialysis dependent patients randomly assigned to receive TPE became dialysis independent compared to only 32% of those who received pulse methylprednisolone instead of TPE.<sup>132</sup> Thus, while the role of TPE is not clearly defined in all types of RPGN, current evidence suggests efficacy in ANCA-positive patients who are dialysis dependent.

### Solid Organ Transplantation

In organ transplant recipients TPE has been used both to treat and to prevent rejection, as well as for recurrence of certain diseases in a transplanted organ. Photopheresis, which has also been tried for the same purposes, primarily in heart transplantation, is covered in Chapter 43.

### Rejection

Cellular immune mechanisms mediate most organ allograft rejection episodes; however, antibody-mediated rejection may occur rapidly in patients who have preexisting antibodies to ABO or HLA antigens expressed by the graft. Such "hyperacute" rejection is characterized histologically by neutrophil infiltration, fibrin deposition, and endothelial damage in small blood vessels; failure of the graft is mainly caused by ischemic damage. All treatments have been futile in hyperacute rejection, including TPE. So-called "vascular changes," which may be seen microscopically in later rejection episodes, were formerly taken to indicate

antibody-mediated rejection, even when immunofluorescence microscopy and tests for circulating antibody were negative.<sup>133</sup>

Standard posttransplant management for kidney and heart transplantation consists of prophylactic immunosuppression with glucocorticoids, a calcineurin inhibitor (cyclosporine or tacrolimus) and an antimetabolite such as azathioprine or mycophenolate mofetil. High-risk recipients and those who have rejection episodes in spite of these standard measures are treated with pulse steroids or T-cell antibody preparations or both.<sup>134,135</sup>

Case reports and uncontrolled series published in the late 1970s and early 1980s suggested TPE was beneficial in renal transplant rejection. Then five controlled trials<sup>19</sup> were reported in the mid- and late 1980s. Four showed no significant benefit for patients receiving TPE in addition to standard drug therapy, even in the subgroups whose transplant biopsies showed "vascular" histologic changes. In the one study suggesting benefit, the mean treatment time was 10 to 11 months after transplant, when antibody-mediated rejection is less likely. The last and largest study concluded that TPE therapy for renal transplant rejection could no longer be recommended.<sup>136</sup> Nevertheless, use of TPE for this purpose continued to be reported.<sup>19</sup>

In the more recent past, a new wave of enthusiasm for TPE has focused on patients with clinical and histologic evidence of acute rejection who also have circulating donor-specific antibody and/or deposition of complement component C4d in transplant biopsy tissue, suggesting a humoral mechanism. The antibody can be shown by a positive crossmatch with donor cells or by flow cytometric reactions with donor antigens. C4d deposition is demonstrated by immunofluorescence microscopy.<sup>133,137</sup>

Uncontrolled studies have been encouraging. Observations in the pretransplant period have shown that antibody titers can be reduced by TPE.<sup>138</sup> Furthermore, in open trials, patients with refractory acute rejection who demonstrate donor-specific antibody and/or C4d have relatively good long-term graft survival ( $\geq 80\%$ ) after treatment regimens that include TPE and IVIG.<sup>139,140</sup> A recent conference on antibody-mediated rejection recommended that demonstration of circulating antibody be considered an essential criterion for diagnosis of humoral rejection and that the effectiveness of TPE and IVIG in this entity be studied in "rigorous prospective, multicenter" trials.<sup>141</sup>

TPE has also been employed in cases of cardiac allograft rejection. Favorable outcomes have been reported in individual patients who were also receiving other therapies, but no controlled trials have been conducted. The criteria for a diagnosis of humoral rejection in this setting continue to evolve.<sup>137</sup> "Vascular" histology is more difficult to detect or exclude in the endomyocardial biopsies performed to monitor cardiac allografts because few blood vessels are found in this part of the heart muscle. Immunofluorescence microscopy for IgG had been considered a reasonable criterion for humoral rejection; however, it has been suggested more recently that this diagnosis be made, and TPE employed, in patients with deteriorating cardiac function whose biopsies lack cellular infiltrates.<sup>142</sup> In some such biopsies it has been possible to demonstrate capillary endothelial swelling, macrophage influx, and C4d

deposition.<sup>143</sup> Controlled data to support the TPE recommendation are lacking, as are any published data correlating this clinical syndrome with circulating donor-specific antibody.

Pretransplant TPE has been tried in organ transplant candidates who are presensitized to HLA antigens. Those whose sera react with lymphocytes from a large fraction of the population are less likely to have a compatible crossmatch with a cadaveric donor and hence have a lower likelihood of receiving a transplant. Prospective immunosuppression, combined with antibody removal by TPE or protein A-sepharose immunoadsorption, has been explored as a means to achieve a compatible crossmatch before transplantation and thereby prevent hyperacute rejection. Several centers have reported groups of patients who received kidney transplants after being prepared in this way and achieved quite respectable graft survival rates. Similar protocols have facilitated successful transplantation of ABO-incompatible kidneys and livers.<sup>19</sup> In more recent studies, pretransplant TPE has facilitated elective living donor transplantation of HLA-crossmatch positive as well as ABO-incompatible organs.<sup>79,138,144</sup>

In summary, evidence from controlled trials has not shown global efficacy for TPE in reversing established rejection episodes in renal allografts. Anecdotal experience focusing on patients with circulating antibody and immunopathologic evidence of humoral rejection seems more promising, but controlled trials in such patients have yet to be published. Pretransplant antibody removal can make transplantation feasible for otherwise ineligible candidates. It can also facilitate transplantation of kidneys from living donors across ABO and donor-specific crossmatch barriers. Clarification of the role of TPE in cardiac transplantation awaits controlled studies targeting patients with documented humoral rejection and circulating donor-specific antibody.

### Recurrence of Disease

Focal glomerulosclerosis (FGS) is a disease that causes nephrosis and renal failure, predominantly in children. It recurs in about 30% of allograft recipients, which suggests that a humoral factor may have a role in its pathogenesis. A 50-kD plasma factor that binds to protein A has been implicated but has not been further characterized.<sup>145</sup> Reduced proteinuria and improved renal function have been reported when recurrence in an allograft is treated with stepped-up immunosuppression and TPE.<sup>146,147</sup>

Goodpasture syndrome may occasionally recur in a transplanted kidney; however, this can usually be avoided by delaying transplantation until the anti-GBM response has subsided spontaneously. If the syndrome recurs in spite of this precaution, it should be treated promptly with TPE and cyclophosphamide.<sup>147</sup>

Allograft vasculopathy, a diffuse coronary artery disease that sometimes develops in transplanted hearts, is the leading cause of morbidity and mortality in heart transplant recipients who survive beyond 1 year. It may be related either to continuing hyperlipidemia or to chronic rejection. Selective depletion of LDLs, which is discussed in greater detail in the section on hypercholesterolemia, has been reported helpful in a few such patients with persistent lipoprotein abnormalities.<sup>148</sup>

## Therapeutic Plasma Exchange in Toxic and Metabolic Disorders

This section covers conditions in which removal of plasma constituents other than immunoglobulin is potentially beneficial. These are listed in Table 42-6 along with indication and intensity categories.

### Hypercholesterolemia

Familial hypercholesterolemia (FH) is a genetically determined deficiency of cell surface LDL receptors that interferes with cholesterol off-loading from LDL into cells and with the normal negative-feedback regulation of LDL synthesis, leading to highly elevated levels of circulating LDL, cholesterol (650 to 1000 mg/dL), and lipoprotein(a) [Lp(a)]. Skin xanthomas and coronary atheromas develop in the first decade of life in homozygotes, and death from myocardial infarction before age 20 is common. Heterozygotes also have elevated LDL, cholesterol (350 to 500 mg/dL), and Lp(a) levels; they may develop xanthomas by age 20 and coronary atherosclerosis by age 30.<sup>149,150</sup>

Milder forms of hypercholesterolemia can be influenced by dietary modifications and are amenable to drug treatment with agents such as HMG-CoA reductase inhibitors, bile acid-binding resins, nicotinic acid, and ezetimibe, a new agent that inhibits gut absorption of both dietary and biliary cholesterol.<sup>150,151</sup> However, FH homozygotes and some FH heterozygotes respond only modestly to these measures and remain at risk for premature death. Drastic surgical measures, such as ileal bypass, portacaval shunt, and liver transplantation may be recommended for such patients if they have evidence of coronary artery disease.<sup>149,150</sup> Alternatively, removal of LDL and its associated cholesterol from the blood can be accomplished repeatedly by various modalities of therapeutic apheresis.<sup>150</sup>

A standard TPE will lower LDL and cholesterol levels by 50% or more, and long-term treatment every 1 to 2 weeks can lead to shrinkage of cutaneous xanthomas and regression of coronary artery deposits. Although TPE removes both LDL and Lp(a), it also depletes high-density lipoproteins (HDL), which

**Table 42-6.** Indication and Intensity of Treatment Categories for TPE in Metabolic Disorders

| Disorders                                | ASFA Indication Category* | Intensity Category† |
|------------------------------------------|---------------------------|---------------------|
| Homozygous familial hypercholesterolemia | II (I for LDL-P)          | C                   |
| Refsum's disease                         | II                        | A, R, P             |
| Overdose or poisoning                    | III                       | A                   |
| Acute hepatic failure                    | III                       | A                   |

\*I = standard first-line therapy; II = second-line therapy; III = controversial; IV = no efficacy; LDL-P = LDL-apheresis, ie, selective depletion of LDL.

†A = aggressive; R = routine; P = prolonged; C = chronic (see Table 42-2).

TPE = therapeutic plasma exchange; ASFA = American Society for Apheresis.

are believed to have an antiatherogenic action. This disadvantage has stimulated efforts to deplete LDL semiselectively and on-line from patient plasma separated by an apheresis device, and then return the LDL-depleted plasma to the patient.<sup>150</sup> Several systems designed to accomplish this goal are described in Chapter 43.

### Refsum's Disease

Refsum's disease results from deficiency of the peroxisomal enzyme phytanoyl-CoA hydroxylase, which participates in degradation of phytanic acid by  $\alpha$ -oxidation. Accumulation of diet-derived phytanic acid in plasma lipoproteins and in tissue lipid stores leads to symptoms, which may include peripheral neuropathy, cerebellar ataxia, retinitis pigmentosa, anosmia, deafness, ichthyosis, renal failure, and arrhythmias. Slow progression is the usual course, but rapid deterioration and even sudden death may follow a marked increase in plasma phytanic acid.<sup>152</sup>

Restriction of dietary intake of phytanic acid via dairy products, meats, and ruminant fats is the mainstay of treatment. It leads to gradual clearing of phytanate stores by slow  $\omega$ -oxidation and gradual symptomatic improvement in most patients. Nutrition must be maintained, however, because mobilization of calories from endogenous fat can increase plasma phytanic acid levels acutely and cause clinical exacerbations. Therapeutic plasma exchange will remove large quantities of phytanic acid incorporated into plasma lipids.<sup>153</sup> Selective lipoprotein depletion is also effective.<sup>154</sup> Apheresis therapy is most appropriate for patients who have very high plasma phytanate levels and an associated exacerbation of symptoms. Skin disease, neuropathic symptoms, and ataxia usually improve as plasma levels drop. Cranial nerve defects usually do not.<sup>152</sup>

### Drug Overdose and Poisoning

Toxic effects may occur after exposure to excessive doses of pharmacologic agents or to harmful agents in the environment. Management techniques for both types of event are similar and may include removal of toxin still in the gastrointestinal tract, enhancement of renal elimination, and direct removal from blood by hemodialysis, hemoperfusion (eg, over charcoal columns), or TPE.<sup>155</sup> Specific antidotes may also be given if available. Serious events are usually treated with multiple measures.

Therapeutic plasma exchange has been reported to be beneficial, when combined with other therapies, in cases involving substances, such as methyl parathion, vincristine, and cisplatin, that bind tightly to plasma proteins. It has also been reported for severe hyperthyroidism, either endogenous or exogenous, in which its effectiveness may be limited by extensive binding of L-thyroxine to tissue proteins. Therapeutic plasma exchange has been reported in poisonings due to ingestion of the *Amanita phalloides* mushroom; however, diuresis clears more *Amanita* toxin.<sup>19</sup>

Unfortunately, the literature on this topic is older and entirely anecdotal. Furthermore, TPE has always been used in combination with other therapies that are presumably effective. This complicates formulation of firm, rational guidelines. Nevertheless it

seems reasonable to offer TPE to a severely affected patient with an overdose or poisoning who has a high blood level of a toxic agent that binds to plasma proteins. It should also be noted that TPE has shown minimal or no beneficial effect in overdosage of drugs known to bind to tissue proteins and lipids, including barbiturates, chlordecone, aluminum, tricyclic antidepressants, benzodiazepines, quinine, phenytoin, digoxin, digitoxin, prednisone, prednisolone, tobramycin, and propranolol.<sup>19</sup>

### Acute Hepatic Failure

Acute hepatic failure may develop after a severe liver insult, such as overwhelming hepatitis B infection or acetaminophen overdosage. Cases may also be caused by drug reactions, Wilson's disease, vascular anomalies, acute fatty liver of pregnancy, and a variety of toxins. Acute hepatic failure results in many metabolic imbalances and synthetic defects. Clinical symptoms include jaundice, coagulopathy, encephalopathy, and renal failure. The treatment of choice is liver transplantation, which leads to 60% to 80% long-term survival vs >60% mortality for untransplanted patients. Cerebral edema accounts for fatal outcomes.<sup>156</sup>

Conservative treatment is basically supportive. Fluid, electrolyte, and nutritional supplements are adjusted in response to metabolic abnormalities. Bowel sterilization with enteral antibiotics minimizes production of ammonia by intestinal bacteria. Pressors are infused if needed for hemodynamic support. Osmotic diuretics, sedatives, hyperventilation, and proper positioning are all employed to reduce intracranial pressure. Platelets and plasma products are infused to improve coagulation.<sup>156</sup>

Therapeutic plasma exchange with plasma replacement has seemed appealing as a means to restore metabolic homeostasis, remove toxic metabolites that may cause cerebral edema, and supply coagulation factors and other deficient plasma proteins in quantity without causing volume overload. Practical evaluations of this approach have produced mixed results.<sup>156</sup> Some investigators have found TPE helpful in stabilizing and maintaining patients until an organ for transplant becomes available. Improvements in blood pressure, cerebral blood flow, and neurologic status were attributed to TPE in one study<sup>157</sup>; however, intracranial pressure, a key prognostic indicator, did not decrease. Hemoperfusion over activated charcoal, which will lower plasma ammonia levels, has also shown no advantage over intensive supportive care alone.

Potential problems with extensive TPE arise from the diminished ability of patients with acute hepatic failure to metabolize the citrate in infused plasma. Accumulation of citrate leads to ionized hypocalcemia and to alterations in arterial ketone body ratios that may interfere with regeneration of hepatocytes.<sup>158</sup> Thus, although TPE can partially reverse coagulopathy and other synthetic deficits in these patients, a favorable net impact on outcome has been difficult to demonstrate.

Other methods for extracorporeal support of patients with liver failure have been investigated. Several devices place patient plasma in "metabolic contact" with hepatocyte suspensions of either human or porcine origin. One contains a suspension of

pig liver cells in the exterior space surrounding the hollow fibers in a filter cartridge. Patient plasma separated by an apheresis device and passed through a charcoal column to remove ammonia, flows through the hollow fibers before being returned to the patient. It is proposed that such devices could provide both detoxification and synthetic functions; however, evidence for the latter has been disappointing. Other devices aim to remove toxins via binding to various extracorporeal sorbents, such as activated charcoal or albumin molecules. None of these approaches has yet been shown to improve outcomes for acute liver failure patients in a large controlled trial, but research is ongoing.<sup>159</sup>

## Conclusion

Therapeutic plasma exchange is an effective therapy for a number of diseases, especially those mediated by paraproteins or autoreactive antibodies. Improvements in apheresis instruments that are outside the scope of this chapter have made it a very safe treatment as well. Thus, it should continue to have an important role in the management of selected diseases.

# Specialized Therapeutic Hemapheresis and Phlebotomy

## Robert Weinstein

Professor of Medicine and Pathology, University of Massachusetts Medical School, and Chief, Division of Transfusion Medicine, UMass Memorial Medical Center, Worcester, Massachusetts, USA

A comprehensive, evidence-based analysis of apheresis therapies by the American Society for Apheresis (ASFA) recorded 40 disease states as Category I (apheresis as first-line therapy) or Category II (apheresis as adjunctive therapy) indications for therapeutic apheresis.<sup>1</sup> Among these, 24 (60%) were indications for plasma exchange, consistent with prior surveys that found plasma exchange to be the predominant form of apheresis therapy in North America.<sup>2,3</sup> At the same time, ASFA created a new category P (“pending”) to take into account potential treatment indications that are under investigation, in particular those that are in pivotal Phase III trials that may lead to approval by the US Food and Drug Administration (FDA).<sup>1,4</sup> All of the potential indications in this category are specialized forms of apheresis that target specific fractions of the plasma or cellular compartments of the blood for processing or removal.<sup>1</sup>

Whereas specialized apheresis procedures have been in wide use for decades,<sup>5</sup> some as a result of clinical trials and some on the basis of accumulated experience,<sup>6</sup> the approval of new therapeutic indications, devices, and drugs is increasingly dependent on the presentation of carefully acquired supportive evidence.<sup>7-9</sup> This applies to apheresis therapies as well.<sup>1,10,11</sup> Accordingly, this chapter (which reviews therapeutic apheresis procedures that target, for processing, specific fractions of the plasma or cellular compartment of the blood) emphasizes those procedures that are supported by evidence.

## Therapeutic Red Cell Apheresis

John J. Abel of the Johns Hopkins University used the term “plasmapheresis” to describe a method for removing large quantities of plasma from experimental animals.<sup>12</sup> The first reported series of cases in which the manual removal of plasma was employed for clinical purposes (treatment of Waldenström’s macroglobulinemia) was described as plasmapheresis.<sup>13</sup> Thus, the

removal of red cells for therapeutic purposes can be referred to as erythrocytapheresis. This term particularly applies to the removal of red cells using automated blood processing instruments that are capable of selectively removing erythrocytes while returning the plasma, buffy coat cells, and additional isotonic saline to the patient.<sup>14-17</sup> The use of automated blood processing equipment to exchange patient red cells for donor red cells is referred to as red cell exchange,<sup>18-21</sup> although the term erythrocytapheresis is frequently used in reference to red cell exchange.<sup>1,22</sup>

## Red Cell Exchange

Therapeutic red cell exchange can be performed by manual exchange transfusion<sup>21,23(pp153-160)</sup> or with programmable automated blood processing (apheresis) instruments.<sup>18-20,22</sup> This discussion focuses on automated red cell exchange.

Basic features of automated blood processors that perform apheresis using centrifugation technology are detailed in Chapter 41. The machine operator enters the patient’s gender, height, and weight into the instrument’s computer and total blood volume is calculated.<sup>24,25</sup> The programming functions of these instruments also accept input regarding the starting and desired ending hematocrit of the patient, the average hematocrit of red cell replacement units to be used, and the desired fluid balance (a default of 100% may be offered by the instrument). Finally, the operator enters the desired fraction of the patient’s own red cells (fraction cells remaining or FCR) that should remain in the patient’s circulation at the end of the procedure. The instrument calculates the volume of replacement fluid (eg, red cells of average hematocrit as programmed into the instrument’s computer) needed for the procedure.<sup>24</sup>

Calculation of the desired FCR is predicated on the targeted therapeutic endpoint of the red cell exchange.<sup>21,23,26-30</sup> Thus (Formula 1):

$$\text{FCR (as \%)} = 100 \times \left( \frac{\text{starting hematocrit}}{\text{desired ending hematocrit}} \times \frac{\text{endpoint parameter}}{\text{starting parameter}} \right)$$

where the specified parameter may be the % hemoglobin S, the % parasitized red cells seen on the peripheral blood film, etc.

According to ASFA, red cell exchange is indicated (Category I or II) for treatment of severe manifestations of the protozoal infections *Plasmodium falciparum* and *Babesia microti* and for the management of sickle cell disease (SCD).<sup>1,6</sup> Therefore, if a patient with sickle cell anemia whose hematocrit is 27% and whose starting hemoglobin S level is 100% is to undergo red cell exchange, and if the targeted endpoint hemoglobin S level is 30% and the desired ending hematocrit is 30%, then the FCR is calculated accordingly:

$$\text{FCR (as \%)} = 100 \times \left( \frac{27\%}{30\%} \times \frac{30\%}{100\%} \right) = 27\%$$

At the end of the procedure, the patient's own red cells will amount to 27% of the circulating red cell mass.

### Sickle Cell Disease

Sickled erythrocytes were first described in 1910 by Dr. JB Herrick, who noted the abnormally shaped red cells in the peripheral blood film of a dental student from the Caribbean island of Grenada,<sup>31</sup> but the malady known now as sickle cell anemia was familiar to the people of central and west Africa.<sup>32,33</sup> Caused by homozygosity for the mutant  $\beta^S$  gene on chromosome 11,<sup>34-36</sup> the disease likely resulted in a survival disadvantage in Africa.<sup>37</sup> However, the gene frequency remained high because of the protection from *P. falciparum* malaria afforded to heterozygote children<sup>38</sup> and because of social factors.<sup>39</sup>

The substitution of valine for glutamic acid as the sixth amino acid residue from the amino terminus of the hemoglobin  $\beta$  chain results in hydrophobic interactions between nearby hemoglobin S molecules such that hemoglobin S aggregates into large polymers when deoxygenated.<sup>40</sup> The polymerization of hemoglobin S in vivo is the underlying basis for the hemolytic and vaso-occlusive morbidity of SCD,<sup>26,40,41</sup> and the exquisite dependence of polymerization on the concentration of hemoglobin S<sup>42,43</sup> has provided a scientific basis, in concert with the strong clinical basis,<sup>44</sup> for transfusion therapy in sickle cell anemia.

For the most part, clinical studies related to transfusion management of SCD have focused on simple transfusion or manual exchange transfusion.<sup>23,26,27,44-50</sup> The efficacy of manual vs automated red cell exchange in the treatment of SCD has not been directly studied in a clinical trial; however, red cell exchange can be completed more efficiently and quickly by automated than by manual methods.<sup>21</sup> Automated red cell exchange has been shown to mitigate iron overload, while maintaining a low hemoglobin S level, in SCD patients receiving chronic treatment.<sup>51-53</sup> Thus, it has entered into routine use in centers where therapeutic apheresis is available. Its role in the aspects of SCD for which it is indicated<sup>1,6</sup> is discussed below (see Table 43-1). Manual exchange transfusion, or automated red cell exchange using discontinuous flow equipment, may be performed using isotonic saline, rather than red cells, as the replacement fluid in the early phases of the procedure in order to maximize the removal of hemoglobin-S-containing red cells and avoid the gratuitous removal of normal red cells.<sup>23,51,53</sup>

### Life- or Organ-Threatening Complications

Red cell exchange is standard therapy for children with acute vaso-occlusive stroke (see below for discussion of stroke prevention) and should be performed shortly following documentation of thrombotic (rather than hemorrhagic) stroke by non-contrast computed tomography.<sup>21,23,44,54</sup> The treatment goal should be a hemoglobin concentration between 9 and 10 g/dL and less than 30% hemoglobin S. Acute intervention, followed by chronic maintenance transfusion therapy, may limit early morbidity and mortality and prevent recurrence (see below).<sup>23,27,44,46</sup>

Acute multiorgan failure syndrome is a complication of severe pain episodes of sickle cell disease.<sup>21,54,55</sup> It may present as an unusually severe pain episode in patients with sickle cell anemia or hemoglobin SC disease and is characterized by fever, accelerated hemolysis with a rapid decrease in hemoglobin and platelet count, nonfocal encephalopathy, and rhabdomyolysis.<sup>55</sup> Beside the central nervous system, other organs, including liver and kidney, may be involved.<sup>55</sup> Although standard red cell transfusion therapy may be effective if severe anemia is present, red cell exchange should be considered with higher hemoglobin levels.<sup>54</sup> This syndrome may be less likely in patients who are on aggressive chronic transfusion regimens in whom the frequency of episodes of pain or acute chest syndrome has been observed to be reduced.<sup>50</sup>

In its 2000 report<sup>49</sup> the National Acute Chest Syndrome Study Group (NACSSG) defined acute chest syndrome, the leading cause of death and hospitalization of patients with SCD,<sup>56,57</sup> on the basis of presentation with a new alveolar infiltrate involving one or more complete lung segments (atelectasis excluded) and accompanied by chest pain, a fever  $>38.5^\circ\text{C}$ , tachypnea, wheezing, or cough. Although the NACSSG report did not describe a particular advantage of red cell exchange over simple transfusion, the trial was not randomized for the purpose of detecting such a difference.<sup>21,49</sup> Many experienced practitioners recommend exchange transfusion for patients who present with diffuse pulmonary involvement or progressive respiratory decline despite simple transfusion, the goal being a hemoglobin no higher than 10 g/dL and less than 30% hemoglobin S.<sup>21,44,54</sup>

Although priapism has not been evaluated by ASFA as an indication for automated red cell exchange,<sup>1</sup> it occurs in approximately 30% to 90% of males with SCD<sup>58-60</sup> and thus may result in consultation requests to the apheresis service. Early claims of success in applying red cell exchange therapy to priapism after 12 to 24 hours of unresponsiveness to conventional treatments were unconvincing in that detumescence was rarely noted sooner than 24 to 48 hours after red cell exchange,

**Table 43-1.** Red Cell Exchange in Sickle Cell Disease

|                   |                                                                                                                                           |
|-------------------|-------------------------------------------------------------------------------------------------------------------------------------------|
| Acute or emergent | Acute vaso-occlusive stroke<br>Multiorgan failure syndrome<br>Acute chest syndrome refractory to standard management                      |

and often not until 2 to 7 days after treatment, and there were no controlled studies.<sup>44,61</sup> A cautionary note regarding red cell exchange for the treatment of priapism was introduced with the description of acute, severe neurologic abnormalities in six boys with sickle cell anemia 1 to 11 days following partial exchange transfusion for priapism unresponsive to conservative therapy.<sup>62</sup> The syndrome was characterized by severe headache at the onset, often associated with increased intracranial pressure, and further neurologic events ranging from seizure activity to obtundation requiring ventilatory support.<sup>62,63</sup> The mean posttreatment hemoglobin of the affected children was 12.1 g/dL, and the syndrome, termed ASPEN (association of sickle cell disease, priapism, exchange transfusion and neurologic events), was attributed to cerebral ischemia after an acute rise in hemoglobin, concomitant decrease in hemoglobin S and release of vasoactive mediators during detumescence.<sup>62,63</sup> A recent series<sup>64</sup> described six adult men and one child with sickle cell anemia, six of whom received automated red cell exchange 28 to 48 hours after onset of an episode of priapism (one was treated 7 days after onset of priapism). All of them ultimately required surgical decompression procedures. Finally, a comprehensive review of 42 well-documented case reports of transfusion therapy in SCD-associated priapism evaluated the effectiveness of transfusion therapy vs conventional therapies in terms of time to detumescence.<sup>65</sup> The mean time to detumescence with transfusion therapies was 10.8 days (26 cases) vs 8.0 days with conventional therapies (16 cases). Neurologic complications with transfusion therapy were described in nine cases, some with persistent long-term deficits.

### Primary and Secondary Prevention of Stroke

Approximately 5% to 10% of untransfused children with SCD will have a cerebral infarction by age 20.<sup>45,66</sup> Chronic transfusion therapy, given every 3 to 4 weeks, to maintain the level of hemoglobin S below 30% can improve the arteriographic appearance of affected cerebral vessels and reduce the risk of recurrent stroke from 66% to 90% to approximately 10%.<sup>45,46,54</sup> Chronic automated red cell exchange can be substituted for simple transfusion.<sup>51-53</sup> Some authors argue in favor of discontinuation of chronic transfusion therapy after 3 or more years<sup>67</sup>; however, reports of recurrent stroke rates of 50% or greater after discontinuation of transfusion therapy have led most sickle cell treatment programs to recommend indefinite prophylactic transfusion regimens.<sup>27,54,68,69</sup>

The utility of chronic transfusion therapy to decrease the risk of recurrent stroke in children with SCD<sup>27,45,46,54</sup> and the demonstration that transcranial Doppler ultrasound was highly predictive of stroke risk in such children,<sup>70,71</sup> led to the Stroke Prevention Trial in Sickle Cell Anemia (STOP trial), which sought to study the ability of transfusion therapy to prevent a first stroke in high-risk children with SCD.<sup>48</sup> Time-averaged mean blood-flow velocity of at least 200 cm/sec in the internal carotid or middle cerebral artery<sup>70,71</sup> and a stroke-free history were required for study entry.<sup>48</sup> Over a period of approximately 2 to 3 years, transfusion therapy to maintain hemoglobin S below 30% without exceeding a hemoglobin concentration of 12 g/dL

reduced the occurrence of stroke in the treatment group by 90% compared to the control group.<sup>48</sup> A follow-up study (STOP 2)<sup>72</sup> examined the effect of discontinuation of transfusion therapy after 30 months in children from the first STOP trial whose transcranial Doppler readings had reverted to normal. The study was ended prematurely after 79 of an intended 100 subjects had been enrolled. An interim analysis revealed that among 41 children who had been randomly assigned to discontinue transfusions, 14 had reverted to high-risk transcranial Doppler findings 4 to 9 months after stopping transfusions and two had had ischemic strokes. No neurologic events or high-risk Doppler findings were noted in the subjects randomly assigned to continue transfusion therapy. The National Heart, Lung, and Blood Institute recommends continuing transfusion therapy beyond 30 months.<sup>73</sup>

### Transfusional Iron Overload

There are no randomized, prospective comparisons of simple transfusion vs automated red cell exchange in the prevention of iron overload in children with SCD who require chronic transfusion therapy. However, four case series of 8 to 14 subjects<sup>51-53,74</sup> have been reported in which children were either converted from a simple transfusion program to monthly red cell exchange or begun on red cell exchange early on. In addition, some in each series were on chelation therapy with desferrioxamine<sup>23</sup> and some were not. In general, red cell exchange resulted in a 25% to 100% increase in red cell usage and a corresponding variable increase in donor exposures. However, serum ferritin tended to stabilize in those who were not on chelation therapy and significantly decrease in those who continued on chelation therapy. Some children who were begun on red cell exchange before development of iron overload did not accumulate iron as a result of their red cell exchange treatments.

### Protozoan Disease

Severe manifestations of malaria and babesiosis are ranked as Category II indications by ASFA, largely on the basis of anecdotal evidence.<sup>1,2</sup>

### Malaria

Severe malaria is caused by infection with *P. falciparum*.<sup>75</sup> The infection results from injection of sporozoites into the bloodstream by the bite of a female *Anopheles* mosquito, the division of the malarial sporozoites into merozoites in the liver, and the development of the merozoites into ring-form trophozoites, and then schizonts, within invaded erythrocytes in the circulation.<sup>75</sup> These asexual blood stages of *P. falciparum* are responsible for the symptoms of severe malaria that occur when infection is complicated by serious organ failure or metabolic dysfunction (see Table 43-2).<sup>75-79</sup>

The manifestations of severe *P. falciparum* malaria appear to derive from the adherence of infected erythrocytes to glycosylated molecules on endothelium and to platelet CD36 via *P. falciparum* erythrocyte membrane protein-1 (PfEMP-1), an adhesive protein encoded by the parasite genome and expressed on the surface of infected erythrocytes.<sup>80,81</sup> The sequestration of parasitized

| Renal failure           | Creatinine $> 3.0$ mg/dL<br>Urine output $< 400$ mL/24 hours in adults                                                                         |
| Pulmonary abnormalities | Pulmonary edema<br>Acute respiratory distress syndrome<br>Hypoxemia                                                                            |
| Hypoglycemia            | Blood glucose $< 40$ mg/dL                                                                                                                     |
| Shock                   | Systolic blood pressure 70 mm Hg                                                                                                               |
| Hemostatic defects      | Clinical and/or laboratory evidence of disseminated intravascular coagulation                                                                  |
| Metabolic acidosis      | Arterial pH $< 7.25$<br>Plasma bicarbonate $< 15$ mmol/L                                                                                       |
| Hyperparasitemia        | $> 5\%$ of erythrocytes parasitized                                                                                                            |

erythrocytes in endothelium in the brain and other organs results in vascular obstruction and elaboration of proinflammatory cytokines such as tumor necrosis factor- $\alpha$  and interferon- $\gamma$  that, in addition to other factors, may result in the severe manifestations of the disease.<sup>80,81</sup> Thus, the use of exchange transfusion and automated red cell exchange in the treatment of severe malaria is based on an ability to rapidly reduce the burden of parasitemia and the potential to thereby improve the rheologic properties of the blood and reduce the level of toxic mediators such as cytokines.<sup>29</sup> Red cell exchange followed by plasma exchange, or automated whole blood exchange, has been described as an approach to the removal of both parasitized red cells and inflammatory mediators in the treatment of severe *P. falciparum* malaria. However, the evidence to support this approach is anecdotal at best.<sup>29</sup>

A meta-analysis of eight case-control studies did not find a survival advantage in using exchange transfusion as an adjunct to the treatment of severe *P. falciparum* malaria<sup>82</sup>; however, the authors speculated that automated red cell exchange might be a promising alternative (the studies analyzed employed manual whole blood exchange transfusion). Five case series (16 patients total) and one case report describe lowering of parasitemia by 80% to 90% using automated red cell exchange of 1.0 to 1.5 red cell volumes in approximately 2 hours, followed by rapid clinical recovery, in cases of severe *P. falciparum* malaria, including cerebral malaria.<sup>82-87</sup> The United States Centers for Disease

Control and Prevention (CDC) recommends strong consideration of exchange transfusion or automated red cell exchange if parasite density is  $> 10\%$  or in case of complications such as cerebral malaria, acute respiratory distress syndrome (ARDS), or renal failure.<sup>88</sup> Treatment may be repeated until parasitemia involves  $< 1\%$  of circulating red cells.<sup>29,88</sup>

### Babesiosis

Babesiosis in humans is a zoonotic disease and is spread to humans primarily through ticks of the genus *Ixodes*.<sup>89</sup> In the Northeastern United States, where most cases of human babesiosis occur, the predominant organism is *Babesia microti*, the reservoir hosts are wild rodents, and the vector for transferring the protozoa from host to humans is the deer tick *Ixodes dammini*, the same tick that transmits *Borrelia burgdorferi*, causative agent of Lyme disease.<sup>89,90</sup> The first two reported cases of human babesiosis, one from Europe<sup>91</sup> and one from California,<sup>92</sup> occurred in splenectomized individuals. The first case in a patient with an intact spleen was reported in Nantucket.<sup>93</sup>

When injected into the human bloodstream, the sporozoites of babesia are presumed to complex with C3 in the circulation and then enter erythrocytes by attaching to the C3b receptor.<sup>30</sup> After asexual budding into four merozoites the parasite perforates the erythrocyte membrane, resulting in hemolysis. They are then free to infect other erythrocytes, and transform into dividing trophozoites (ring forms and tetrads visible on peripheral blood films).<sup>30</sup>

After an incubation period of 1 to 6 weeks following inoculation, infected patients develop a flu-like syndrome characterized by fever, fatigue, and malaise.<sup>30,90</sup> Headache, chills, sweats, myalgia, and arthralgia are frequent complaints. Physical findings may include fever and splenomegaly, and jaundice and pallor may accompany marked extravascular hemolysis.<sup>94</sup> Although most cases are subclinical or mild,<sup>94,95</sup> severe manifestations, including disseminated intravascular coagulation, respiratory failure, and renal failure may occur.<sup>28</sup> Immunocompromised or asplenic individuals are typically more severely affected.<sup>96</sup>

Although clinical trials are lacking, several case reports and case series suggest that, given the absence of an exoerythrocytic phase of infection, red cell exchange, whole blood exchange or red cell exchange followed by plasma exchange, combined with antibiotic therapy, can be beneficial in severe cases of babesiosis with  $> 5\%$  parasitemia.<sup>6,28,29,97</sup> A single one- to two-volume red cell exchange can reduce the circulating population of parasitized erythrocytes by 85% to 90%.<sup>6</sup>

### Erythrocytapheresis and Therapeutic Phlebotomy (Venesection)

According to ASFA, symptomatic erythrocytosis and polycythemia vera, clinical entities that are characterized by an elevated circulating total red cell volume,<sup>98,99</sup> are Category II indications for red cell volume reduction by erythrocytapheresis.<sup>1,6</sup> In clinical practice, therapeutic phlebotomy, rather than automated erythrocytapheresis, is a mainstay of management.<sup>100,101</sup> The International Council for Standardization in

RCV = red cell volume ("red cell mass"); LAP = leukocyte alkaline phosphatase; EPO = erythropoietin; BFU-E = burst-forming unit erythroid, a marrow-derived erythroid colony in culture.

Haematology recognizes absolute erythrocytosis in an individual whose measured total red cell volume (often referred to as "red cell mass"<sup>102</sup>) is more than 25% above the mean predicted value for a person of the same body surface area.<sup>98</sup> This will be the case in men with a hematocrit of 60% or higher and women with a hematocrit of 56% or higher.<sup>98</sup>

### Polycythemia Vera

Polycythemia vera has been acknowledged as a distinct clinical disorder for more than a century.<sup>103,104</sup> Classified as a bcr/abl-negative myeloproliferative disorder, polycythemia vera is characterized by panmyelosis in the marrow and peripheral blood, splenomegaly, hyperviscosity of the blood, thrombosis and a tendency to evolve into either acute myeloid leukemia or myelofibrosis.<sup>99,101,105,106</sup> Over 95% of cases are now known to be associated with an acquired point mutation, V617F, in exon 14 of the protein tyrosine kinase Janus kinase 2 (JAK2).<sup>107-111</sup> The remaining 5% of patients appear to have mutations in exon 12 of JAK2, including some who may have a more benign phenotype (idiopathic erythrocytosis).<sup>112,113</sup> Popular

diagnostic systems for polycythemia vera are presented in Table 43-3.<sup>102,114,115</sup> A revised diagnostic system that recognizes the predominance of JAK2 mutations in polycythemia vera has been proposed.<sup>116</sup>

### Therapeutic Phlebotomy in Polycythemia Vera

The increased whole blood viscosity that results from the expansion of total red cell volume in patients with polycythemia vera is the underlying basis of the life-threatening prothrombotic state and the headache, fatigue, dyspnea, cyanosis, and other signs and symptoms that characterize the disorder.<sup>101,105</sup> Aggressive phlebotomy to a hematocrit below 45% in males of European ancestry and below 42% in females of European ancestry and in both genders of African ancestry is indicated for prevention of life-threatening thrombotic complications of polycythemia vera.<sup>101,105,117</sup> High-risk patients (age  $>65$  years or history of cardiovascular risk factors such as hypertension, diabetes, hypercholesterolemia, congestive heart failure, smoking, or thrombosis) should also be treated with cytoreductive chemotherapy (eg, hydroxyurea, busulfan, interferon- $\gamma$ ).<sup>101,117</sup> Low-risk patients (age

<60 years, no cardiovascular risk, platelet count <1,500,000/ $\mu$ L) may initially be managed with phlebotomy alone.<sup>101,117</sup> Low-dose aspirin (100 mg/day) is recommended for all patients without specific contraindications to its use.<sup>117,118</sup> The pharmaceutical development of JAK2-selective kinase inhibiting agents may influence future management of polycythemia vera.<sup>119</sup>

### Erythrocytapheresis in Polycythemia Vera

A retrospective case series<sup>120</sup> of 69 patients with polycythemia vera who underwent 206 isovolemic erythrocytapheresis procedures using 4% albumin as replacement fluid<sup>121</sup> reported reduction of hematocrit from  $56.8 \pm 5.6\%$  to  $41.9 \pm 6.6\%$  after removal of  $1410 \pm 418$  mL of red cells with a hematocrit of  $79.7 \pm 9.3\%$ .<sup>120</sup> A subset of 21 patients for whom close follow-up data were available, and whose hematocrit was reduced from  $58 \pm 5.7\%$  to  $41.5 \pm 4.9\%$  by a single erythrocytapheresis procedure maintained a hematocrit of <50% for a median of 6 months.<sup>120</sup> The durability of response to a single procedure was associated with a median 70% inhibition of in-vitro erythropoietin-independent erythroid burst-forming unit growth that the authors attributed to iron removal during the apheresis procedure.<sup>122</sup> This claim has not been confirmed. Automated erythrocytapheresis may be useful in polycythemia vera for the rapid induction of hematocrit lowering, followed by maintenance therapeutic phlebotomy, for emergent isovolemic hematocrit lowering in patients with acute thrombotic or microvascular complications, or to avoid perioperative thrombohemorrhagic complications in a patient with an uncontrolled hematocrit who requires urgent surgery.<sup>6,121</sup>

The volume of red cells to be removed (VR) during an erythrocytapheresis in order to achieve a desired hematocrit can be calculated as (Formula 2)<sup>121</sup>:

$$VR = \left[ \frac{(\text{starting hematocrit} - \text{desired hematocrit})}{79} \right] \times [\text{blood volume (mL/kg)}] \times [\text{body weight (kg)}]$$

Thus, for a 70-kg person with a blood volume of 70 mL/kg whose hematocrit is to be lowered from 68% to 55%, the volume of red cells to be removed is calculated as:

$$VR = [(68 - 55) \div 79] \times 70 \times 70 = 910 \text{ mL of red cells.}$$

Formula 2 can be used to estimate the volume of replacement fluid (crystalloid or colloid) needed to maintain fluid balance.<sup>121</sup> An easy alternative is to program an automated apheresis instrument to perform a “red cell exchange” using replacement fluid with hematocrit of 0%, a target FCR of 100%, and a target hematocrit as desired (see Formula 1).

### Secondary Erythrocytosis

Secondary erythrocytosis refers to conditions that result in an elevated total red cell volume but are not clonal disorders of the marrow.<sup>98,99,101,102,123</sup> Congenital and acquired causes have been

**Table 43-4.** Secondary Erythrocytosis

| Type       | Underlying Cause                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |

described, and predominantly involve the regulation or aberrant expression of erythropoietin or abnormalities of the erythropoietin receptor (see Table 43-4).<sup>98,99,101,102,123-129</sup> A diagnostic investigation of a patient with suspected erythrocytosis is performed in order to 1) establish that a true state of erythrocytosis exists (eg, an elevated total red cell volume), 2) distinguish secondary erythrocytosis from polycythemia vera, and 3) determine the cause of secondary erythrocytosis, thereby guiding the approach to clinical management.<sup>101,102,116,123,130,131</sup>

### Therapeutic Phlebotomy in Secondary Erythrocytosis

The role of phlebotomy is less certain in secondary erythrocytosis than in polycythemia vera.<sup>123</sup> As suggested by Table 43-4, secondary erythrocytosis is generally an adaptation to the disordered regulation of erythropoietin or to hypoxemia. In some cases the underlying cause can be treated medically or surgically, and in others the erythrocytosis represents a physiologic adaptation to a chronic condition. For example, adults with cyanotic congenital heart disease are not considered to be at heightened risk for thrombotic stroke despite mean hematocrits of  $57.5\% \pm 7.2\%$ <sup>132</sup> and do not exhibit symptoms of hyperviscosity at hematocrits below 65% in the absence of dehydration or iron deficiency.<sup>133</sup> In fact, microcytosis or a history of phlebotomy are significant risk factors for stroke in this population, as are atrial fibrillation and hypertension.<sup>134</sup>

Isovolemic phlebotomy, with saline replacement, should be reserved for patients with moderate symptoms of hyperviscosity (ie, headache, slow mentation, visual disturbance, tinnitus, dizziness, etc), and who are neither dehydrated nor iron deficient.<sup>133</sup> A program of therapeutic phlebotomy should not be undertaken purely for the sake of achieving a target hematocrit in an asymptomatic individual. Withdrawal of up to a unit of whole blood, replaced by 750 to 1000 mL of isotonic saline, has been recommended for relief of symptoms.<sup>133</sup> Preoperative autologous blood donation if the hematocrit is above 65% may also be considered.<sup>133</sup> Similar recommendations may refer to patients with high oxygen-affinity hemoglobin levels who have symptoms such as dizziness, dyspnea, or angina, which are believed to result, in part, from an expanded total red cell volume.<sup>101,123</sup> There is no formal evidence that phlebotomy is beneficial, and a modest target (ie, a hematocrit <60% achieved by partial exchange transfusion) has been recommended.<sup>101,123</sup> Patients with chronic hypoxic lung disease and erythrocytosis or with smoker's erythrocytosis are best managed using medical therapy to deal with their underlying pulmonary disorder. Non-controlled studies suggest that phlebotomy to a hematocrit of 50% to 52% may improve exercise tolerance, alleviate headache and confusion, and otherwise ameliorate symptoms of hyperviscosity.<sup>101,123</sup>

Postrenal transplant erythrocytosis, defined as a hematocrit above 51% to 55%, occurs spontaneously in 15% to 20% of kidney transplant recipients in the first 8 to 24 months after engraftment.<sup>129,135-137</sup> One fourth of cases remit spontaneously within 2 years of onset, the balance persisting for up to several years until chronic graft rejection supervenes.<sup>123</sup> Male gender, retention of native kidneys, smoking, a rejection-free course with a well-functioning graft, and limited or no need for erythropoietin during the period of pretransplant hemodialysis have been listed as risk factors for postrenal transplant erythrocytosis.<sup>129,135</sup> Hyperviscosity symptoms such as malaise, headache, plethora, lethargy, and dizziness are described as common among patients with this condition, and 10% to 30% develop significant thromboembolic complications.<sup>129,135</sup> The pathogenesis appears to be multifactorial, and likely involves an interplay between endogenous erythropoietin production by the retained native kidney, the renin-angiotensin system, androgen secretion, insulin-like growth factors, and cytokines.<sup>129,136,137</sup> One retrospective series reported 11 thromboembolic events including transient ischemic attacks and strokes, and venous thromboembolism in 10 of 53 (19%) patients with postrenal transplant erythrocytosis but in none of 49 control cases ( $p < 0.001$ ).<sup>135</sup> This sort of experience has led to an appreciation of the need to control the red cell volume in these patients.<sup>129,135-137</sup> The mainstay of treatment is angiotensin-converting enzyme inhibition or angiotensin-converting enzyme receptor blockade, sometimes in combination with theophylline, which lowers hemoglobin and hematocrit within 8 weeks with peak effect seen after up to 12 months.<sup>138-142</sup> Cautious phlebotomy may be used initially to lower the hematocrit to 45% to 50%; however, using

phlebotomy to maintain a target hematocrit over time results in iron deficiency.<sup>129,142</sup>

### ***Erythrocytapheresis in Secondary Erythrocytosis***

Although automated erythrocytapheresis is seldom recommended for management of secondary erythrocytosis,<sup>121</sup> it may be useful in circumstances where isovolemic procedures are called for, such as in cyanotic heart disease.<sup>133</sup>

One retrospective series reported 208 erythrocytapheresis procedures involving 61 patients, most of whom appeared to have chronic pulmonary insufficiency or cyanotic congenital heart disease (details were not provided).<sup>143</sup> The volume of whole blood processed was  $1322 \pm 446$  mL in two to four cycles (discontinuous flow equipment) at a whole blood flow rate of 60 mL/minute, a mean of 576 mL (range 426-800 mL) of red cells was removed per procedure, mean hematocrit was reduced from  $58.4\% \pm 4.5\%$  to  $42.7\% \pm 5.3\%$ , and patients were maintained with a hematocrit below 50% for an average of 6.5 months after every procedure.<sup>143</sup> Another descriptive case series claimed that hemoglobin, hematocrit, and blood viscosity could be lowered "drastically" for as long as 11 months by a single erythrocytapheresis procedure.<sup>14</sup> Apheresis has not been reported in the management of posttransplant erythrocytosis.

### ***Hereditary Hemochromatosis***

Although not covered in the 2007 ASFA review of indications for therapeutic apheresis,<sup>1,6</sup> hereditary hemochromatosis is an important indication for therapeutic phlebotomy<sup>144</sup> and erythrocytapheresis has been described as an alternative to phlebotomy in its management.<sup>145</sup> This is an inherited disorder that, untreated, results in iron deposition in, and damage to, the liver, heart, pancreas, and other organs.<sup>144,146,147</sup> Its prevalence is approximately 1:200 among those of European ancestry.<sup>148-150</sup> The most common genetic mutation, accounting for >90% of cases (and almost all cases in persons of Northern European ancestry) is homozygosity for a single missense mutation (G to A) at nucleotide 845 in the HFE gene on chromosome 6p21.<sup>149-153</sup> This mutation results in substitution of cysteine with tyrosine at amino acid 282 and is referred to as the C282Y mutation.<sup>154</sup> Abnormalities of the HFE gene may result in a defect in iron sensing in the deep crypt cells of gut epithelium and thus inappropriate iron uptake despite abundant iron stores in the body.<sup>149</sup> The accumulation of iron in the liver and other organs slowly results in liver failure (cirrhosis, hepatocellular carcinoma), diabetes, hypogonadism, hypopituitarism, arthropathy, cardiomyopathy and heart failure, and skin pigmentation.<sup>149,152</sup> A presenting syndrome of asthenia, arthralgia, and abnormal liver function has been described as classic for the clinical disease.<sup>147</sup> Because of the central importance of iron loading in the pathogenesis of hereditary hemochromatosis, iron removal by therapeutic phlebotomy is the mainstay of treatment.<sup>155</sup> Additional genetic associations with hereditary hemochromatosis, and diagnostic elements of the condition, are provided in Tables 43-5 and 43-6.

**Therapeutic Phlebotomy in Hereditary Hemochromatosis**

Therapeutic phlebotomy has been the primary mode of iron reduction in hereditary hemochromatosis for over a half century.<sup>144,155,160</sup> Phlebotomy therapy should be started in all patients whose serum ferritin level is elevated (see Table 43-6) and should not be withheld from the elderly on the basis of age or from iron-loaded patients who have not developed clinical symptoms.<sup>144,155</sup> A common treatment approach is to perform one phlebotomy per week (1 unit or 7 mL/kg of whole blood not to exceed 550 mL per phlebotomy) until the serum ferritin is  $\leq 50$  ng/mL.<sup>144,155</sup> Thereafter, it is usually necessary to annually remove 3 to 4 units of blood to maintain the ferritin at that level. Malaise, weakness, fatigability, and liver transaminase elevations often improve during the first several weeks of treatment, but joint symptoms may initially worsen before eventually improving (if at all).<sup>144,155</sup> Cardiomyopathy and cardiac arrhythmias may resolve with phlebotomy, but insulin-dependent diabetes generally will not. The risk of hepatocellular carcinoma will persist if cirrhosis was present before the onset of phlebotomy therapy.<sup>144,155</sup> Hypogonadotropic hypogonadism and thyroid dysfunction do not usually improve with phlebotomy; however, pituitary and gonadal function may improve if they were of recent onset at the time phlebotomy therapy was started.<sup>144</sup>

**Erythrocytapheresis in Hereditary Hemochromatosis**

Early reports from Europe<sup>14,15,17,161</sup> suggested that automated erythrocytapheresis could efficiently remove red cells and deplete iron in patients with hemochromatosis. A German group from Munich reported successful lowering of iron in 14 patients with hemochromatosis, with intervals of 2 to 11 months between procedures.<sup>14</sup> An Italian group<sup>15</sup> treated 14 patients with a mean of 93 (range 21-203) erythrocytapheresis procedures over a mean (median) of 9.6 (24) months. A mean of 19 (range 4.2-40.6) grams of iron were removed, transferrin saturation was reduced from  $90 \pm 8.7\%$  to  $17 \pm 10.6\%$ , serum ferritin decreased from  $3164 \pm 1488$  ng/mL to  $60.5 \pm 77.5$  ng/mL, and hepatic iron was said to have normalized in all cases. A follow-up study from Munich<sup>17</sup> described prospective observations on eight patients with hereditary hemochromatosis who were treated with isovolemic erythrocytapheresis (1000 mL removed) every 4 weeks until serum ferritin fell below 300 ng/mL. Iron depletion, thus defined, was achieved after a mean of 8.5 months during which a mean of 9.4 liters of red cells were removed in a mean of 8.9 procedures. Serum ferritin levels decreased from  $2596 \pm 399$  ng/mL to  $168 \pm 83$  ng/mL and transferrin saturation fell from  $91 \pm 6\%$  to  $19 \pm 10\%$ . Maintenance erythrocytapheresis every 5 to 6 months prevented iron reaccumulation during 18 to 36 months of follow-up.<sup>17</sup> A group from Zaragoza, Spain<sup>162</sup> compared data from nine patients with hemochromatosis who were treated with erythrocytapheresis over a period of 2 years to nine similar patients who were treated with conventional phlebotomy therapy. The erythrocytapheresis procedures were performed using a discontinuous-flow blood processor via single-needle access. A mean of 275 mL of red cells were removed with each procedure. The median serum ferritin reduction with each erythrocytapheresis was 55 ng/mL compared to 17 ng/mL

**Table 43-6.** Some Diagnostic Considerations in Hereditary Hemochromatosis (absent a cause of secondary iron overload)<sup>147,148,155,158,159</sup>

with phlebotomy. Patients treated with erythrocytapheresis achieved their iron depletion goal in one third the time required for those treated with phlebotomy.<sup>162</sup>

A prospective evaluation of erythrocytapheresis in 13 patients with hereditary hemochromatosis was reported from Palma de Mallorca, Spain.<sup>145</sup> The volume of red cells to remove was calculated according to the patient's blood volume and preprocedure hematocrit (as noted in Formula 2 above), and the goal of each procedure was to remove a maximum of 800 mL of red cells and reduce the patient's hematocrit to 30%. Procedures were scheduled every 2 weeks, but the treatment interval would be extended for another 2 weeks if the starting hematocrit was found to be <36%. Starting serum ferritin was (mean ± SD) 1517 ± 1329 ng/mL, and was reduced to 20 ± 6.5 ng/mL after 6.7 ± 2.9 months and 13.5 ± 7.2 apheresis sessions. A mean of 565.5 ± 152 mL of red cells was removed with each procedure; this translated into removal of 878 ± 315 mg of iron per month. Four of the 13 patients underwent a maintenance erythrocytapheresis procedure after 6, 14, 16, and 16.5 months.<sup>145</sup>

A report from Buenos Aires<sup>163</sup> described a curious regimen of isovolemic erythrocytapheresis in combination with recombinant human erythropoietin, 4000 units subcutaneously three times per week (approximately 150 µg/kg/week) and folic acid 10 mg daily by mouth, in nonanemic patients with hereditary hemochromatosis. Ten men with hereditary hemochromatosis were subjected to erythrocytapheresis when their hematocrit reached 30% (or hemoglobin 10 g/dL), and the volume of red cells collected was calculated using Formula 2 as described above but in no case was greater than 30% of the circulating red cell mass. Procedures were performed with both continuous- and discontinuous-flow equipment using a three-phase apheresis protocol: collection of the red cell product, infusion of isotonic saline to replace the removed red cell volume, return of autologous plasma and buffy coat cells. A median of 3.1 erythrocytapheresis procedures (range 2.4-4.4) were performed each month during which a median of 2098 mL (1648-3677) of red cells were collected. It took a median of 9 (3-14) days for the hematocrit to reach 34% (or hemoglobin to rise to 10 g/dL) between procedures. Serum ferritin was reduced from a mean (range) of 2960 (1057-7200) ng/mL to 270 (184-398) ng/mL in a median of 3.25 (1.0-7.5) months.<sup>163</sup>

More recently, a pilot study from the Netherlands<sup>164</sup> reported results from six patients with hereditary hemochromatosis who received a mean (range) of 9.8 (5-18) erythrocytapheresis procedures over 4.8 (2-9) months using discontinuous-flow equipment. An estimated mean (range) of 465.2 (360-579) mg of iron were removed per procedure and a mean total of 4.38 (2.69-7.97) grams of iron were removed. Initial serum ferritin was 1419 (798-2541) ng/mL and final ferritin was 54 (39-90) ng/mL.<sup>163a</sup>

In summary, erythrocytapheresis in the treatment of hereditary hemochromatosis is supported by Type II-3 evidence<sup>1</sup> and may be an acceptable alternative to conventional schedules of

whole blood phlebotomy in selected patients. This indication has not yet been reviewed by ASFA and thus has not been assigned an indication category as of this writing.<sup>1</sup>

Therapeutic Platelet Apheresis

Thrombocytapheresis is a term that describes the selective removal of platelets from a patient for therapeutic purposes, using a blood processing (apheresis) device.<sup>1</sup> The 2007 ASFA review of indications for apheresis therapy lists *symptomatic thrombocytosis* as a Category II indication for thrombocytapheresis.<sup>1,6</sup> Although not made clear without a careful reading of the text,<sup>6</sup> this designation refers to primary thrombocytosis, as results from a clonal (myeloproliferative) disorder of the marrow.<sup>164</sup> Thrombocytapheresis for prophylaxis in asymptomatic patients or to lower the platelet count in cases of secondary or reactive thrombocytosis<sup>164</sup> is listed as a Category III (ie, unproven) indication because data either conflict or are insufficient to demonstrate benefit in these circumstances.<sup>1,6</sup> Some prominent causes of primary and secondary thrombocytosis are listed in Table 43-7.<sup>164-166</sup>

Secondary thrombocytosis per se does not convey a risk of thromboembolic morbidity absent confounding factors such as malignancy or major surgery.<sup>165,167</sup> Even then, antiplatelet agents should be the first option for treatment.<sup>166</sup> In any case, treatment of the underlying cause is the prime factor in the resolution of secondary thrombocytosis.<sup>164</sup> In fact, given the absence of risk posed by the platelet count in secondary thrombocytosis, the platelet count may be considered a laboratory sign of an underlying condition that should be investigated.<sup>164</sup>

Table 43-7. Some Causes of Primary (Clonal) and Secondary (Reactive) Thrombocytosis<sup>164-166</sup>

| Type                     | Possible Causes                                                                                                                                                                                                                                                        |

### Consequences of Thrombocytosis in Primary Thrombocytosis (Essential Thrombocythemia)

Thrombocytosis with thromboembolic complications is a feature common to all of the chronic myeloproliferative disorders,<sup>168,169</sup> but essential thrombocythemia is the one most likely to be diagnosed in a patient who presents with thrombocytosis.<sup>165</sup> Thus, the remainder of this discussion will focus on essential thrombocythemia. Both thrombotic and hemorrhagic complications result in patients with essential thrombocythemia.<sup>164,170</sup> Factors that increase risk of thrombosis by threefold or more include age greater than 60 years and cardiovascular risk factors such as hypertension, hypercholesterolemia, and a prior thrombotic event.<sup>171-173</sup> There is no evidence in favor of prophylactic treatment of low-risk, asymptomatic patients, regardless of platelet count, but high-risk and symptomatic patients are treated to lower their platelet count to below 400,000/ $\mu$ L. In a cohort of 126 subjects with a median age of 31 years (range 5-40) smoking appeared to neutralize the protective effect of age less than 60 years.<sup>174</sup> The United Kingdom Medical Research Council Primary Thrombocythemia 1 Study has established hydroxyurea plus low-dose aspirin as the treatment of choice.<sup>175</sup> Whereas the actuarial rate of first thrombosis in an untreated high-risk population is approximately 26% at 2 years, the rate decreases to about 4% at 2 years with hydroxyurea and aspirin.<sup>175,176</sup> As the platelet count rises above 1.0 to 1.5 million/ $\mu$ L, there is increasing evidence of platelet dysfunction that may result in a risk of mucocutaneous hemorrhage in 35% or more of patients with essential thrombocythemia. This platelet count is an indication for cytoreductive therapy.<sup>164,170,177,178</sup> While several in-vitro platelet function abnormalities can be demonstrated,<sup>170</sup> the most significant functional consequence of hyperthrombocytosis is an acquired von Willebrand syndrome that results from the accelerated clearance of hemostatically competent large multimers of von Willebrand factor from the circulation.<sup>179-184</sup> Hemostatic function appears to improve with reduction of the platelet count.<sup>179,181,183,184</sup>

### Therapeutic Thrombocytapheresis in Primary Thrombocytosis

Rapid lowering of an elevated platelet count, using apheresis and/or chemotherapy, is indicated for patients with myeloproliferative disorders who present with clinical syndromes of microvascular thrombosis such as digital or cerebral ischemia.<sup>170</sup> Several case series and case reports have reported successful, rapid lowering of the platelet count in symptomatic patients in whom chemotherapy was either not an immediate option or was judged to have an insufficiently rapid effect.<sup>168,185-189</sup> Procedures in which 1.5 to 2.0 blood volumes are processed, and crystalloid replacement fluids are used to manage fluid balance, can lower the platelet count by 30% to 60%.<sup>6,185,189,190</sup> However, thrombocytapheresis without concomitant chemotherapy is not a practical means for controlling the platelet count beyond the acute setting.<sup>185,187,189</sup> Thus, symptomatic thrombocytosis is a Category II indication for thrombocytapheresis.<sup>1</sup> Weekly thrombocytapheresis, beginning in the 5th gestational week, has

been used in the management of a high-risk pregnant patient with essential thrombocythemia.<sup>190</sup>

### Therapeutic White Cell Apheresis

Hyperleukocytosis (white cell count  $>100,000/\mu$ L) with leukostasis is a Category I indication for therapeutic leukocytapheresis performed by centrifugation using discontinuous- or continuous-flow equipment.<sup>1,6,191-195</sup> Leukocytapheresis by selective adsorption techniques is currently under study in the United States and elsewhere for the treatment of inflammatory bowel disease, which ASFA has designated a Category P (pending) indication.<sup>1,6,196</sup>

### Leukocytapheresis for Hyperleukocytosis

Hyperleukocytosis is a risk factor for early mortality, often from pulmonary and/or central nervous system hemorrhage, in adults and children with acute myeloblastic leukemia.<sup>191,197</sup> It occurs in 5% to 13% of newly presenting cases of adult acute myelogenous leukemia and 12% to 25% of pediatric acute myelogenous leukemia.<sup>192,198</sup> The reported incidence in acute lymphoblastic leukemia ranges from 10% to 30%.<sup>198</sup> Mortality rates of 20% to 40% have been reported.<sup>198</sup> Children with acute lymphoblastic lymphoma are less susceptible to intracerebral hemorrhage if the white cell count is below 400,000/ $\mu$ L.<sup>191,199</sup> Clinical features of hyperleukocytosis with leukostasis include respiratory distress, hypoxemia, diffuse interstitial or alveolar infiltrates on chest x-ray, confusion, somnolence, stupor or coma, headache, dizziness, tinnitus, gait instability, or visual disturbances.<sup>198</sup> Physical examination may demonstrate papilledema, dilated retinal veins and/or retinal hemorrhages, cranial nerve defects, or meningeal signs.<sup>198</sup> Metabolic derangements caused by tumor lysis may include hyperkalemia, hyperuricemia, hypocalcemia, and hyperphosphatemia and may result in renal failure and early death.<sup>191,192,197</sup> Pulmonary, central nervous system, cardiac, and other organ morbidity results from obstruction of small vessels by aggregates of leukemic blasts with resulting infarction and hemorrhage.<sup>200</sup> Coagulopathy results from release of lysosomal enzymes from myeloid blasts, disseminated intravascular coagulation, and thrombocytopenia resulting from marrow failure.<sup>198-200</sup>

A standard treatment approach to hyperleukocytosis includes intravenous hydration, lowering of plasma uric acid using allopurinol or urate oxidase and, if urate oxidase is not used, administering intravenous sodium bicarbonate to alkalinize the urine.<sup>199</sup> Hydroxyurea may be prescribed to rapidly lower the total circulating nucleated cell count without precipitating a tumor lysis syndrome.<sup>198</sup> Induction chemotherapy may be used for this purpose but may precipitate tumor lysis syndrome and hemorrhage.<sup>200</sup> The processing of 1.5 to 2.0 blood volumes, using crystalloid or colloid fluids to maintain fluid balance, with or without a sedimenting agent such as 6% hydroxyethyl starch to enhance the separation of white cells from red cells, can reduce the circulating white cell count by up to 60%.<sup>6,193,194,201</sup> Leukocytapheresis before

initiation of definitive induction chemotherapy has been reported to lower the leukemic blast count to  $<100,000/\mu\text{L}$  in approximately 60% of patients, and to lower the incidence of early death (Day 21 after admission) by half, but does not affect long-term survival and may not prevent death from leukostasis in patients who present with severe symptoms of pulmonary or cerebral leukostasis before initiation of apheresis.<sup>191,193,195,201</sup> In any case, leukocytapheresis is not initiated without the above-mentioned measures (eg, hydration, uric acid lowering, and hydroxyurea) and should not be considered primary therapy in patients who present with high blast counts but without symptoms of leukostasis. Thus, leukostasis is appropriately classified as a Category II indication for leukocytapheresis.<sup>1,194,199,201</sup>

### Leukocytapheresis for Inflammatory Bowel Disease

Idiopathic inflammatory bowel disease principally refers to ulcerative colitis and Crohn's disease, similar but distinct disorders of intestinal inflammation.<sup>202-204</sup> Both may present with fever, diarrhea, rectal bleeding, weight loss, and abdominal pain.<sup>203</sup> Whereas perianal disease and anal strictures and fistulas are common in Crohn's disease, they are not features of ulcerative colitis. Also, ulcerative colitis is exclusive to the colon, while Crohn's disease involves the ileum in two-thirds of patients.<sup>203</sup> The majority of patients with ulcerative colitis exhibit positive serology for perinuclear-staining antineutrophil cytoplasmic antibodies but few are positive for anti-*Saccharomyces cerevisiae*.<sup>203-204</sup> Medical therapy for both disorders includes oral aminosalicylates, oral or parenteral steroids, immunomodulators (including azathioprine or mercaptopurine), and biological agents such as the anti-tumor necrosis factor agent infliximab.<sup>205-208</sup>

Interest in leukocytapheresis in the treatment of severe inflammatory bowel disease derives from the observed infiltration of the intestinal mucosa in these disorders by granulocytes and macrophages that produce marked mucosal tissue injury through the release of reactive oxide compounds, matrix metalloproteinases, and proinflammatory cytokines.<sup>203,208,209</sup> Two leukocyte adsorption columns are currently in use in Europe and Japan: a column of cylindrical nonwoven polyester fibers that preferentially binds granulocytes and lymphocytes (Celsorba, Asahi Kasei Kuraray, Tokyo, Japan) and a column of cellulose acetate beads that binds primarily granulocytes and monocytes (Adacolumn, JIMRO, Takasaki, Japan).<sup>196</sup> Reports of case series and small randomized (but not blinded) trials have claimed clinical benefit for both devices.<sup>1,196</sup> The Adacolumn is currently in Phase III pivotal trials in the United States; thus, inflammatory bowel disease is listed as a Category P (pending) indication for adsorption leukocytapheresis (designated "adoptive cytappheresis" by ASFA<sup>1,6</sup>) until the outcome of the trial is known.<sup>210</sup>

### Extracorporeal Photochemotherapy

Extracorporeal photochemotherapy (ECP, also referred to as "photopheresis") describes a procedure in which circulating

mononuclear cells are collected by centrifugal apheresis, exposed to 8-methoxypsoralen (8-MOP, a photoactivating agent), and then exposed to ultraviolet A (UVA) light. The treated cells are then reinfused into the patient. The only commercially available closed system is UVAR-XTS (Therakos, Exton, PA). A typical procedure, using single-needle access, consists of six cycles of processing 125 mL of blood or three cycles of processing 225 mL of blood to collect a buffy coat volume of approximately 240 mL. The instrument mixes the collected buffy coat cells with saline and 8-MOP (17  $\mu\text{L}$  per mL of buffy coat) and then pumps the cells through a 1-mm plastic film between two banks of fluorescent UVA lamps (352 nm, 1-2 J/cm<sup>2</sup>) to affect photoactivation. Whereas red cells and plasma are returned to the patient at the end of each collection cycle, the treated buffy coat product is returned following the last cycle. A full procedure is completed in approximately 3 hours.<sup>211,212</sup>

The precise mechanism of action of ECP is unknown,<sup>211,213</sup> but available evidence suggests that it works through a process of immunomodulation.<sup>212-214</sup> Photoactivated 8-MOP intercalates within nuclear DNA of normal and malignant T lymphocytes and causes apoptosis of treated T cells, but not treated monocytes, within 24 hours after ECP.<sup>215,216</sup> The two main immunologic consequences of phagocytosis of apoptotic cells appear to be induction of major histocompatibility Class I-restricted CD8+ cytotoxic T lymphocytes through the antigen-presenting activity of human dendritic cells and the elaboration by monocytes and macrophages of immunosuppressive cytokines including interleukin (IL)-10 and IL-1 receptor antagonist.<sup>213</sup> Further, ECP results in an increase in CD83+, CD86+ plasmacytoid (DC2) dendritic cells with a concordant diminution in CD80+, CD123+ monocytoïd (DC1) dendritic cells. The DC2 cells stimulate Th2 T-helper cells to secrete inhibitory cytokines (eg, IL-4, IL-10, IL-13) while inhibiting stimulation of Th1 T-helper cells that secrete proinflammatory cytokines (eg, IL-2, interferon- $\gamma$ ) and thus inhibiting Th1-mediated alloreactivity.<sup>214</sup> ECP also appears to result in an increase in a population of circulating CD4+, CD25+, CD69-CTLA-4+ regulatory T cells that are immunosuppressive and are involved in transplant tolerance.<sup>217</sup> Such induced immunologic responses to ECP are presumed to explain observed clinical benefit in diverse conditions such as cutaneous T-cell lymphoma, chronic graft-vs-host disease (GVHD), and cardiac transplant rejection.<sup>211-216,218</sup>

In 1998 the United States Centers for Medicare and Medicaid Services (CMS) approved Medicare reimbursement for ECP in the palliative treatment of skin manifestations of cutaneous T-cell lymphoma (CTCL) not responsive to other therapy. In 2006 CMS further determined that ECP is "reasonable and necessary" for treatment of acute cardiac allograft rejection and chronic GVHD refractory to standard immunosuppressive drug treatment.<sup>219</sup> ASFA has listed treatment of heart transplant rejection and cutaneous manifestations of GVHD as Category II indications for ECP, and erythrodermic CTCL and prophylaxis of heart transplant rejection as Category I indications for ECP.<sup>1,6</sup> Some

ECP regimens used in the treatment of the Category I and II indications<sup>1,6</sup> are described in Table 43-8.<sup>212,214,221-229</sup>

### Cutaneous T-Cell Lymphoma

ASFA has listed the treatment of erythrodermic CTCL as a Category I indication for ECP.<sup>1,6</sup>

#### Background

The CTCLs are a heterogeneous group of extranodal non-Hodgkin lymphomas of T-cell origin that target the skin.<sup>229,230</sup> Mycosis fungoides, the most common form of CTCL, accounts for almost half of all primary cutaneous lymphomas.<sup>230</sup> It is largely a disease of adults (median age 55-60 years at diagnosis) and typically presents as an indolent disorder that progresses slowly over years from patchy skin involvement to infiltrated plaques, tumors, and widespread disease.<sup>230</sup> Whereas localized (eg, nonerythrodermic) mycosis fungoides is adequately managed with topical therapies, the application of ECP in erythrodermic mycosis fungoides is recommended by ASFA and by the British Photodermatology Group and UK Skin Lymphoma Group.<sup>1,211</sup> Whereas limited-stage mycosis fungoides does not shorten life expectancy, advanced-stage disease may be associated with a 10-year disease-specific survival of 20%.<sup>230</sup> Sézary syndrome is defined as a triad of erythroderma, generalized lymphadenopathy, and the presence of neoplastic T cells (Sézary cells) in the

skin, lymph nodes, and peripheral blood.<sup>230</sup> Diagnostic criteria were recommended by the International Society for Cutaneous Lymphomas for the purpose of identifying patients with a worse prognosis compared to other erythrodermic forms of CTCL (notably erythrodermic mycosis fungoides).<sup>231</sup> These include  $\geq 1$  in 1000 circulating Sézary cells per  $\mu\text{L}$  of blood; a CD4/CD8 ratio  $\geq 10$  caused by expansion of circulating CD4+ T cells and/or aberrant loss or expression of pan-T-cell antigens (CD2, CD3, CD4, CD5) by flow cytometry; demonstration of a circulating T-cell clone by molecular or cytogenetic methods; or a cytogenetically abnormal T-cell clone.<sup>231</sup> The prognosis is poor, with median survival of 2 to 4 years and 5-year survival of approximately 24%.<sup>229</sup> A retrospective cohort study from Stanford of 106 patients with erythrodermic mycosis fungoides and Sézary syndrome identified age  $\geq 65$  years, clinical Stage IV and circulating Sézary cells  $\geq 5\%$  of total lymphocytes as independent negative prognostic factors for survival.<sup>232</sup> Median survivals of patients with none, one, or more than one of these adverse prognostic factors were 122 months ( $n = 36$ ), 44 months ( $n = 39$ ), and 18 months ( $n = 31$ ), respectively ( $p < 0.005$ ).<sup>232</sup>

#### Extracorporeal Photochemotherapy in the Treatment of Cutaneous T-Cell Lymphoma

The 1987 report by Edelson et al<sup>233</sup> of a successful pilot trial of ECP, in which 27 of 37 treatment-resistant patients with CTCL experienced an average 64% decrease in cutaneous involvement after  $22 \pm 10$  weeks, led to FDA approval of ECP for the treatment of advanced CTCL later that year.<sup>234</sup> Long-term follow-up of the original 29 patients with erythrodermic CTCL from the pilot study of Edelson et al<sup>233</sup> reported that median survival of the treated patients was 60.33 months from diagnosis and 47.9 months from the start of ECP. Four of the six patients who achieved complete responses in the original study remained in complete remission.<sup>235</sup> A retrospective study from London compared survival of patients with Sézary syndrome who had not received ECP to survival of patients who had.<sup>236</sup> Median survival was 39 months (range 1-138) in the ECP group ( $n = 29$ ) and 26.5 months (12-67) in the non-ECP group ( $n = 15$ ), a nonsignificant difference ( $p = 0.12$ ).<sup>236</sup> All patients had been demonstrated to have a circulating T-cell clone by testing based on polymerase chain reaction, whereas this was not the case in Edelson's study.<sup>233</sup>

Between 1987 and 2001, 21 studies were reported in which a total of 485 patients were treated using ECP.<sup>211,212,237</sup> Although most patients in these studies had erythrodermic CTCL, most studies did not report the response rates separately for the erythrodermic subjects.<sup>237</sup> In addition, responses were defined as  $>25\%$  skin clearing in some studies and  $>50\%$  skin clearing in others, and complete responses were defined as either 75% to 100% skin clearing,  $>90\%$  skin clearing, or 100% skin clearing.<sup>212</sup> Nonetheless, overall response rates reported in these studies ranged from 31% to 87.5%, and complete response rates ranged from 0% to 54% (20%-30% in most studies).<sup>211,212,237</sup> The variability in response rates has been attributed to

**Table 43-8.** Regimens of Extracorporeal Photochemotherapy (ECP)

| Indication                    | Treatment                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
|-------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

differences in entry criteria, prior or concurrent therapy, duration between diagnosis and application of ECP, the ECP protocol followed, and definition of response.<sup>211</sup> In one analysis of 23 patients with Sézary syndrome treated with ECP as the sole therapy for up to 1 year,<sup>237</sup> improvement in skin score was positively associated with a reduction in circulating Sézary cells as a percentage of total white cell count ( $p = 0.03$ ). Neither the absolute change in total white cell count, lymphocyte count, CD34 count, CD8 count, nor the Sézary count distinguished the 13 patients who responded to treatment from the nonresponders. Nor were age, gender or prior treatment with chemotherapy associated with responder status. Baseline lymphocyte count was associated with change in skin score at 6 months ( $p = 0.046$ ) but not at 12 months. Sézary cell count as a percentage of total white cell count was the only baseline variable that was a significant predictor of responder status at 6 months: a 1% increase in % Sézary cells at baseline was associated with an odds ratio of 1.07 of becoming a responder ( $p = 0.021$ ) at 6 months but not at 12 months.<sup>238</sup>

Cardiac Allograft Rejection

ASFA has listed prophylaxis of heart transplant rejection as a Category I indication for ECP and treatment of heart transplant rejection as a Category II indication for ECP.<sup>1,6</sup> The Category I designation for heart transplant rejection prophylaxis is apparently determined on the basis of two small randomized pilot studies.<sup>220,221</sup>

Background

Between 1990 and 2006, approximately 3000 to 4500 heart transplant procedures were reported each year to the registry of the International Society for Heart and Lung Transplantation.<sup>239</sup> Between 1 January 2004 and 30 June 2006, 41% of heart transplant procedures were performed for heart failure caused by

coronary disease and 45% for noncoronary cardiomyopathy, with an average recipient age of (mean  $\pm$  SD)  $50.7 \pm 12.5$  years (range 18–77).<sup>239</sup> Treatment for an episode of allograft rejection was associated with a 26% increase in mortality risk before hospital discharge and a 48% increase in mortality risk after discharge but within the first postoperative year.<sup>239</sup> From January 1992 to June 2006, acute allograft rejection accounted for 12% of deaths, and after 5 years allograft vasculopathy and late graft failure (presumed to be the result of chronic rejection and consequent allograft vasculopathy) combined to account for 30% of deaths.<sup>239</sup> Immunosuppressive therapy to prevent allograft rejection has included perioperative lymphocyte antibody (polyclonal antilymphocyte or antithymocyte globulin, OKT3, or IL-2 receptor antibodies), and chronic postoperative calcineurin inhibitors (eg, tacrolimus, cyclosporine), mycophenolate mofetil, sirolimus, and others.<sup>239</sup>

Cardiac allograft rejection is defined and classified on the basis of histologic findings obtained through surveillance endomyocardial biopsy following transplantation, and may not present as symptoms of allograft dysfunction.<sup>240</sup> Because of the association between rejection, graft failure, and death, biopsy-detected evidence of rejection should result in adjustment in the immunosuppressive regimen in order to successfully resolve the episode of rejection.<sup>222,225,239,240</sup> Thus CMS has only approved reimbursement for severe, drug-refractory rejection.<sup>219</sup> The histologic criteria for acute cellular rejection are summarized in Table 43-9.

Extracorporeal Photochemotherapy in the Treatment of Cardiac Allograft Rejection

Studies in support of ECP for treatment of cardiac allograft rejection focus on the effects of ECP on endomyocardial biopsy findings, rather than on survival or graft function.<sup>211,219</sup> Two pilot studies have shown evidence that the risk of acute cellular

rejection episodes can be decreased by incorporating ECP into the prophylactic immunosuppressive regimen of cardiac allograft recipients without increasing the risk of infection caused by immunosuppression.<sup>220,221</sup> Another prospective pilot trial has reported that development of panel-reactive antibodies (responsible for chronic rejection) and coronary artery intimal hyperplasia (a pathogenetic mechanism of graft failure in chronic rejection) are mitigated by the addition of ECP to the post-transplant immunosuppressive regimen for the first 2 years after transplant surgery.<sup>226</sup>

Dall'Amico and colleagues in Padua, Italy reported a prospective pilot trial in eight patients, with recurrent acute rejection episodes despite immunosuppression, who were treated with 2 consecutive days of ECP every 4 weeks for 6 months.<sup>243</sup> Seven benefited with a reduction in the number and severity of rejection episodes; reduction in daily prednisone, cyclosporine, or azathioprine doses; and improvement on endomyocardial biopsy specimens. The investigators conducted two follow-up studies—one a prospective uncontrolled study in 22 patients with two or more acute rejection episodes<sup>224</sup> and the other a prospective uncontrolled study of 11 patients with recurrent severe acute rejection episodes.<sup>244</sup> They reported that an intensive regimen of ECP (see Table 43-9) is highly effective in resolving and preventing recurrent acute rejection refractory to conventional immunosuppression, but cautioned that most acute rejection episodes, particularly nonsevere episodes, could be effectively managed using medical regimens without ECP.<sup>219</sup> Other small case series and case reports have presented corroborating data.<sup>222,223,225,245,246</sup> Evidence to support ECP in the management of renal or lung transplant rejection are insufficient to recommend its use in these settings.<sup>1,211</sup>

### Graft-vs-Host Disease

The ASFA 2007 evidence-based review of apheresis therapies lists skin manifestations of GVHD as a Category II indication for ECP.<sup>1,6</sup> CMS considers ECP reasonable and necessary for the treatment of chronic GVHD that is refractory to standard immunosuppressive drug therapy.<sup>219</sup>

### Background

GVHD in hematopoietic progenitor cell transplant recipients occurs when T cells of donor origin (either transplanted with, or that develop from, the graft) interact with tissue in the HLA-matched but genetically nonidentical host.<sup>247</sup> Classical acute GVHD develops within 100 days of transplantation with skin manifestations that vary from an erythematous morbilliform rash to epidermal necrolysis, mucosal inflammation causing diarrhea and abdominal cramping, and abnormalities of liver function tests.<sup>247,248</sup> GVHD that develops beyond 100 days of transplantation, or persists more than 3 months, is traditionally referred to as chronic GVHD, and is characterized by an oral, ocular, and mucous membrane sicca syndrome; skin involvement; scleroderma; bronchiolitis obliterans; joint contractures; myofasciitis; esophageal stricture; or other fibrotic

complications in various organ systems.<sup>247,249</sup> The cumulative incidence of acute GVHD is approximately 12% to 75%, and the cumulative incidence of chronic GVHD is approximately 15% to 70% after hematopoietic cell transplantation, depending on whether the donor-recipient pair are related or unrelated and on whether a myeloablative or nonmyeloablative conditioning regimen was used.<sup>249-251</sup>

The onset of acute GVHD may be delayed beyond 100 days in some patients such as those who receive nonmyeloablative conditioning regimens, and chronic GVHD may present within the first 2 months after transplantation in certain circumstances.<sup>250,251</sup> A consensus conference of the National Institutes of Health has proposed a categorization of GVHD based on these observations, taking into account the clinical overlap syndromes between the two (see Table 43-10).<sup>252</sup> Accurate diagnosis and staging is important in that recurrent or late onset acute GVHD may not require prolonged therapy as is required with chronic GVHD, while overlap syndromes may require shorter courses of typical treatments for chronic GVHD.<sup>253</sup>

### Extracorporeal Photochemotherapy in the Treatment of GVHD

The application of ECP to the treatment of GVHD has been extensively reviewed.<sup>211,219,254-256</sup> There are no controlled, blinded, randomized trials, and most reports have been case reports, case series, or retrospective analyses, although some prospective analyses are available.<sup>219,254</sup> Among the larger prospective reports is one from a London group that treated 28 patients who had developed steroid-refractory chronic GVHD following HLA-matched allogeneic marrow or peripheral blood progenitor cell transplant.<sup>227</sup> Among the patients, 27 were classified as having extensive chronic GVHD<sup>257</sup> and 20 had involvement of more than 50% of their skin surface. Patients were given ECP on 2 consecutive days every 2 weeks for the first 4 months, and monthly thereafter. ECP was initiated a median of 34 months (range 10-167) after transplantation and 23 months (range 2-164) from the onset of chronic GVHD. Of the 21 patients with cutaneous involvement who were evaluable, a 25% reduction in skin involvement was noted in eight (38%) after 3 months and in 10 (48%) after 6 months, and a statistically nonsignificant improvement in liver function tests was noted.<sup>227</sup> The authors contrasted their results to those of a retrospective report of 15 patients with extensive chronic GVHD who received ECP on a similar schedule, beginning a median of 12 months (range 3-44) after transplantation. Among those 15 patients, 12 (80%) achieved complete resolution of cutaneous manifestations of GVHD, seven of 10 (70%) patients with liver involvement had complete responses, and all 11 patients with oral mucosal disease had complete responses.<sup>258</sup>

A group from Boston enrolled 25 patients with extensive, steroid-refractory chronic GVHD in a prospective uncontrolled trial to evaluate ECP for skin and visceral involvement.<sup>259</sup> ECP was performed in the outpatient setting for 2 consecutive days every 2 weeks on 17 patients and weekly on eight patients who

lived a long distance from the treatment site. The median time from transplantation to initiation of ECP was 790 days (range 242-2928), and ECP continued, until best response or disease progression, for a median of 9 months (range 3-24). Sixteen patients (64%) responded ( $\geq 50\%$  improvement in skin rash;  $\geq 50\%$  improvement in bilirubin) in at least one site of disease. Twenty improved with respect to cutaneous involvement, including softening of sclerodermatous changes in six. Six of 13 with oral mucosal ulcers experienced healing of their ulcers during

ECP. Three of six patients with joint involvement had increased range of motion.<sup>259</sup>

An Italian group evaluated ECP in a prospective, uncontrolled study of 32 patients with chronic GVHD who began treatment a median of 5 months (range 1-56) after hematopoietic cell transplantation.<sup>260</sup> All but five had cutaneous involvement. The treatment schedule was the same as that used by the London group.<sup>227</sup> The investigators reported that 16 patients (50%) achieved a complete response and were able to have their

**Table 43-10.** Syndromes of Acute and Chronic Graft-vs-Host Disease (GVHD)<sup>252</sup>

\*Any of these features are considered sufficient to establish a diagnosis of chronic GVHD

GI = gastrointestinal; BOOP = bronchitis obliterans with organizing pneumonia.

immunosuppressive drug doses decreased by at least half (the “determinant” group). In seven patients (22%) ECP was declared ineffective in that either progression was observed in at least one involved organ system, it was necessary to increase the dose of immunosuppressants, or immunosuppressants were not reduced by >50% but no clinical complete responses were obtained. The remaining nine patients (28%) were considered responders if their outcomes were better than the “ineffective” group but not as good as the “determinant” group. Thus, with an overall response rate of 78%, the authors concluded that ECP is beneficial for steroid-refractory chronic GVHD.<sup>260</sup>

A pilot study from Vienna is the principal source of data regarding the use of ECP to treat steroid-refractory acute GVHD.<sup>261</sup> In this prospective, unblinded, nonrandomized study, 21 patients who underwent marrow (n = 19) or peripheral blood progenitor cell (n = 2) transplantation and who experienced acute GVHD unresponsive to corticosteroids and cyclosporin A, were treated with ECP on 2 consecutive days (one cycle) at 1- to 2-week intervals until improvement and then every 2 to 4 weeks until maximal response was reached. ECP was tapered thereafter on an individual basis. The onset of acute GVHD occurred a median of 19 days (range 13-33) after transplantation and drug therapy was given for a median of 21 days (range 9-49) before the start of ECP. The maximal response to ECP was achieved after a median of four cycles (range 1-13) or 2 months (range 0.5-6) of treatment. Complete resolution of acute GVHD was achieved in 60% of patients after 3 months of ECP. Three months after initiation of ECP, complete responses were obtained in 60% of patients with cutaneous manifestations, 67% of patients with liver manifestations, and no patients with gut manifestations of acute GVHD.<sup>261</sup> Overall transplant-related mortality was similar to that achieved using conventional second-line immunosuppressive therapy for steroid-resistant acute GVHD.<sup>253</sup>

Corroborating data in support of the benefit of ECP in mucocutaneous chronic GVHD are provided by smaller prospective and several retrospective studies.<sup>262-267</sup> At present, the report of the combined workshop of the British Photodermatology Group and the UK Skin Lymphoma Group on evidence-based practice of photopheresis considers the available evidence sufficient to recommend ECP for the treatment of steroid-refractory chronic GVHD but not for acute GVHD.<sup>211</sup> CMS also supports the use of ECP as reasonable and necessary for patients with chronic GVHD whose disease is refractory to standard immunosuppressive drug treatment but does not consider acute GVHD in its analysis.<sup>219</sup> ASFA considers skin manifestations to be a Category II indication for ECP but does not distinguish chronic from acute in its recommendation.<sup>1,6</sup>

## Specialized Therapeutic Plasma Processing

In its 2007 evidence-based review of apheresis therapies, ASFA lists 30 Category I, II, or P indications for therapeutic plasma processing, 24 of which are indications for therapeutic plasma exchange (TPE).<sup>1</sup> The physiology of TPE and its indications are

addressed in Chapter 42. The discussion herein focuses on therapeutic procedures that, rather than removing whole plasma, are designed to remove a specified fraction of the plasma and return the processed plasma to the patient. A pathogenic plasma substance (for example, a specific autoantibody) is usually present at relatively low levels in the circulation: a typical plasma exchange may remove 150 g of healthy plasma protein in order to eliminate 1 to 2 g of offending substance.<sup>268</sup> To minimize the sacrifice of healthy plasma proteins, selective extraction of pathologic plasma constituents has been proposed for the treatment of patients with disorders that might otherwise be treated using TPE.<sup>269</sup>

### Immunoadsorption Apheresis

Immunoadsorption systems employ the principle of affinity chromatography and make use of immobilized sorbents or ligands that have enhanced or specific binding affinity for a specific antigen, antibody, immune complex, or other substance in the patient's circulation.<sup>269,270</sup> Examples include 1) staphylococcal protein A or sheep antihuman immunoglobulin (IgG) antibody for extraction of IgG and immune complexes from the circulation, 2) sheep antihuman low-density lipoprotein (LDL) or apolipoprotein B antibody for extraction of LDL, 3) synthetic blood group substances for removal of ABO isoagglutinins, and 4) DNA for removal of DNA antibody. Two immunoadsorption systems that have received approval from the US FDA are the staphylococcal protein A-agarose column (Immunosorba, Fresenius HemoCare, Redmond, WA),<sup>271</sup> and the staphylococcal protein A-silica column (Prosorba, Fresenius HemoCare).<sup>272</sup>

Protein A is a cell-wall constituent of the Cowan I strain of *Staphylococcus aureus*. Mammalian IgG binds to five homologous regions at its amino terminus, but interaction of protein A with other plasma proteins is insignificant. Protein A interacts strongly with IgG1, IgG2, and IgG4, but only to a variable extent with IgG3, IgM, and IgA. The affinity of protein A is higher for complexed IgG than for free IgG. Processing of 2.5 plasma volumes using a protein A-agarose column resulted in a 97% reduction in IgG1, a 98% reduction in IgG2, a 40% reduction in IgG3, a 77% reduction in IgG4, a 56% reduction in IgM, and a 55% reduction in IgA, while plasma levels of albumin, fibrinogen, and antithrombin were reduced by less than 20%.<sup>270</sup> Thus, in principle, plasma adsorption with protein A affinity columns permits the processing of more plasma than does TPE without unacceptable loss of other essential plasma constituents.<sup>268</sup>

The commercial distribution of both protein A immunoadsorption systems in the United States was discontinued in 2006.<sup>6</sup> The use of these devices in a variety of clinical conditions has been extensively reviewed.<sup>268</sup> A brief discussion of current Category II or P indications<sup>1,6</sup> for therapeutic immunoadsorption follows.

### Immune Thrombocytopenic Purpura

Immune thrombocytopenic purpura (ITP, also known as idiopathic thrombocytopenic purpura) presents with thrombocytopenia and mucocutaneous bleeding and is caused by accelerated

clearance of IgG-coated platelets that interact with Fc $\gamma$  receptors on tissue macrophages, primarily in the spleen and liver.<sup>273</sup> Antibodies against platelet surface glycoproteins, typically glycoprotein IIb/IIIa or Ib/IX, may be naturally occurring, a result of ingestion of medication, or a manifestation of autoimmune or lymphoproliferative disorders.<sup>273</sup> Treatment focuses on immunosuppressants, with corticosteroids serving as traditional first-line therapy, and splenectomy often used in the case of steroid failure.<sup>273,274</sup> Other effective or promising treatments, including intravenous IgG, anti-D immunoglobulin, and rituximab have proven more popular among practitioners than immunoadsorption for the treatment of otherwise refractory cases,<sup>273-276</sup> and a new generation of therapies for ITP may yet supercede current treatment approaches.<sup>277</sup> Immunoadsorption with the Prosorba column was reported effective in a group of 72 patients with ITP who had failed to improve on at least two other therapies.<sup>276</sup> An increased platelet count was achieved in 33 (46%) of refractory ITP patients who had failed at least two other treatments (including steroids and splenectomy), but responses in seven of the 33 responders lasted less than a month.<sup>276</sup> The remaining (79%) responding patients did not experience a relapse of thrombocytopenia over a mean follow-up period of 8 months.<sup>276</sup> In another report, six of 10 platelet-refractory, alloimmunized patients achieved at least a doubling of their platelet count after Prosorba treatment.<sup>278</sup> In both reports, many of the patients continued to receive other therapies, and there was no control group. Furthermore, little or no corroborating data have been published. Nonetheless, ASFA considers refractory ITP a Category II indication for immunoadsorption.<sup>1,6</sup>

### Rheumatoid Arthritis

The Prosorba column was approved by the FDA "... for use in the therapeutic reduction of the signs and symptoms of moderate to severe rheumatoid arthritis (ra) in adult patients with long-standing disease who have failed or are intolerant to disease-modifying anti-rheumatic drugs (dmards)."<sup>279</sup> The serendipitous observation of apparent improvement in symptoms of patients with rheumatoid arthritis who were receiving Prosorba treatment for ITP resulted in a pilot study in which nine of 11 patients with refractory rheumatoid arthritis showed apparent benefit.<sup>280</sup> A properly conducted pivotal randomized trial assessed Prosorba vs placebo in 91 patients who had failed to respond to methotrexate or at least two other second-line drugs.<sup>281</sup> Efficacy was assessed 7 to 8 weeks after completion of 12 weekly true or sham treatments. An independent data safety monitoring board stopped the trial after a planned interim analysis because 31.9% of the 47 patients in the Prosorba arm reached the defined therapeutic endpoint while only 11.4% of the 44 sham-treated patients did ( $p = 0.019$ ). Subsequent reported experience was consistent with the study findings.<sup>282</sup> As it happened, Prosorba was introduced almost simultaneously with a new generation of anti-rheumatic drugs (including leflunomide, entercept, and infliximab) and these quickly overshadowed Prosorba in the management of severe rheumatoid arthritis.<sup>283,284</sup> Although it has been suggested

that Prosorba may be preferable for patients in whom chronic infection renders potent immunosuppressive agents less desirable,<sup>285</sup> its market withdrawal renders the issue moot, at least in the United States.

### Coagulation Factor Inhibitors

Alloantibody inhibitors to coagulation factors may arise in approximately 20% of patients with severe hemophilia A (Factor VIII deficiency) and 12% of patients with severe hemophilia B (Factor IX deficiency).<sup>286</sup> The risk may be higher in patients treated solely with recombinant, as opposed to plasma-derived, clotting factor replacement.<sup>287</sup> Autoantibody inhibitors, most typically directed against Factor VIII ("acquired hemophilia") occur at a rate of approximately one person per million per year, and 40% to 50% of cases are seen in association with other conditions including pregnancy, autoimmune disorders, hematologic or other malignancies, and use of drugs such as antibiotics or anticonvulsants.<sup>288</sup>

Nilsson<sup>289</sup> first reported the use of protein A-Sepharose (Sigma-Aldrich Co., St. Louis, MO) adsorption, in combination with immunosuppression, in the management of a patient with hemophilia B and a high-titer Factor IX inhibitor. A number of case reports and small case series have since reported successful lowering of inhibitor titer using the Prosorba, Immunosorba, or TheraSorb-Ig [sheep antihuman immunoglobulin coupled to Sepharose (Miltenyi Biotech GmbH, Bergisch Gladbach, Germany)] columns in patients with congenital and acquired hemophilia.<sup>290-294</sup> In these procedures, approximately 2.5 to 3.0 plasma volumes are processed at up to 50 mL/minute (plasma flow rate), and a series of one to six procedures is performed at 1- to 2-day intervals, thus lowering inhibitor titers by as much as 90% to 100%.<sup>290,294</sup> Patients with high-titer inhibitors must receive concurrent immunosuppressive treatment in order to prevent rebound of the inhibitor after several days or in order to induce tolerance to Factor VIII or IX.<sup>288,290</sup>

Because of the use of concurrent medication (eg, Factor VIIa, activated prothrombin complex concentrates, large doses of human Factor VIII concentrates, porcine Factor VIII) it is difficult to assess the specific contribution of the apheresis procedure to the achievement of hemostatic control in reported cases.<sup>288</sup> Because of this, and in the absence of clinical trial data, ASFA has designated management of coagulation factor inhibitors a Category III indication for immunoadsorption apheresis (paucity of data).<sup>1,6</sup> Immunoadsorption may be useful as an adjunct to early management of patients with inhibitors who are hemorrhaging or who need surgery too emergently to await the outcome of immunosuppressive therapy and who do not respond adequately to factor replacement therapy.<sup>290,292-294</sup> And as stated earlier, the removal of the relevant devices from the US market renders the issue moot in the United States.

### Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) describes a cardiac disorder in which the left ventricle is dilated and exhibits impaired contraction.

It may be idiopathic, familial, post-viral, alcohol- or drug-induced, or related to other cardiac disease. Both ventricles may be affected. It presents with heart failure, often progressive, and may be complicated by arrhythmias, thromboembolic events and sudden death.<sup>295</sup> It is the most frequent antecedent cause of heart transplantation throughout the world.<sup>239</sup> Approximately 60% to 80% of patients with DCM harbor autoantibodies directed against cardiac myosin heavy chain, myocardial  $\beta_1$ -adrenergic receptors, or other cardiac tissue with a predominance of antibodies of the IgG 3 subclass.<sup>296-301</sup> Antibodies directed against cardiac tissue targets, similar to those involved in DCM, induce structural and functional changes consistent with DCM in animal models.<sup>302,303</sup>

The potential relevance of heart antibodies to clinical DCM was explored in a pilot study of eight patients with DCM and advanced congestive heart failure who were subjected to a series of four or five immunoadsorption procedures per week over 2 weeks using the Therasorb-Ig system.<sup>304</sup>  $\beta_1$ -adrenoreceptor autoantibody levels decreased and heart failure symptoms improved in seven of the subjects, but the effect was transient: autoantibodies and symptoms were restored to baseline 75 days after completion of immunoadsorption.<sup>304</sup> In a companion pilot trial, nine patients were subjected to daily immunoadsorption treatments for 5 days using Therasorb-Ig.<sup>305</sup> Patients received 35 g of intravenous polyclonal immunoglobulin after the final procedure. Once again, plasma levels of  $\beta_1$ -adrenoreceptor autoantibody were substantially reduced and significant improvement in hemodynamic parameters (including cardiac output, mean arterial pressure, mean pulmonary arterial pressure, left ventricular filling pressure, and systemic vascular resistance) was demonstrated, thus providing objective preliminary evidence of the clinical benefit of antibody removal by immunoadsorption.<sup>305</sup> Immunoadsorption was also shown to diminish histologic evidence of myocardial inflammation in another cohort of 25 patients with DCM.<sup>306</sup>

In a randomized, prospective but nonblinded trial, 18 patients with DCM and advanced heart failure were randomly assigned to either best medical therapy (control group) or best medical therapy with the addition of immunoadsorption.<sup>307</sup> During the first course of immunoadsorption, procedures were performed on 3 consecutive days and patients received 0.5 g/kg of polyclonal IgG by intravenous infusion. Three subsequent courses of immunoadsorption, performed on 2 consecutive days at 4-week intervals were also followed by infusions of intravenous IgG at the same dose. Immunoadsorption was performed using the Therasorb-Ig column. After the first course of immunoadsorption/IgG, left ventricular ejection fraction, cardiac index, stroke volume index, and systemic vascular resistance improved significantly in the treatment group and these changes remained evident after the final series. Improvement in symptoms and functional status paralleled the hemodynamic changes. The control group demonstrated no hemodynamic improvement at the end of the 3-month study.  $\beta$ -adrenergic receptor antibodies decreased by >80% after the first course of immunoadsorption but tended to rise between monthly courses of treatment.

Although the studies described above demonstrated a response to immunoadsorption in patients with DCM and severe heart failure, subjects in those studies received a cumulative dose of intravenous IgG equal to that used in another study in which patients with DCM and advanced heart failure received a single course of 2 g/kg of intravenous IgG and showed persistent hemodynamic and functional improvement for a year of follow-up.<sup>308</sup> Two randomized, blinded, placebo-controlled trials yielded conflicting results regarding IgG infusion in DCM. One trial, in which patients initially received a total of 2 g/kg followed by 0.4 g/kg monthly for 5 months, demonstrated significant improvement in left ventricular ejection fraction in the treatment group but not the placebo group.<sup>309</sup> A second trial, in which patients received a single course totaling 2 g/kg demonstrated no effect of intravenous IgG on left ventricular ejection fraction after 6 or 12 months (although both the treatment and the placebo group showed improvement).<sup>310</sup> In a pilot study of four patients with DCM who received immunoadsorption with Immunosorba columns, procedures were performed daily for 5 consecutive days and no intravenous IgG was given.<sup>311</sup> Total IgG decreased by 95% and IgG3 decreased by 61%. Functional parameters including mean left ventricular ejection fraction, left ventricular end-systolic and diastolic volumes, and global end-systolic strain improved but not to a statistically significant degree. However, a quality of life assessment demonstrated significant improvement at 6 months.<sup>311</sup> ASFA has designated DCM a Category P (pending) indication for immunoadsorption apheresis.<sup>1,6</sup>

## Selective Extraction of Low-Density Lipoproteins

### Background

Familial hypercholesterolemia (FH), a dominantly inherited disorder, is a major cause of death or early disability resulting from premature atherosclerotic heart and peripheral vascular disease.<sup>312,313</sup> Autosomal dominant FH is caused by mutations in the gene for the LDL receptor, with frequencies of 1:500 for heterozygotes and 1:1,000,000 for homozygotes.<sup>313</sup> Clinical features including xanthomas, xanthelasmas, corneal arcus, and the occurrence of coronary heart disease, stroke, and death are common in the fourth or fifth decade of life.<sup>312,313</sup> A serum LDL-cholesterol level below 100 mg/dL (achieved through diet, lifestyle modification, and 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibiting drugs or statins) can lower cardiovascular morbidity and mortality in high-risk patients, but a sizable minority of high-risk patients fail to meet LDL-cholesterol-lowering goals by this approach.<sup>314,315</sup>

Manual, then automated, plasmapheresis was successfully employed as an adjunct to lipid-lowering therapy beginning over 40 years ago. However, the kinetics of restoration of plasma lipid levels and the unwanted lowering of essential plasma proteins (eg, fibrinogen, albumin) rendered this approach somewhat impractical for long-term therapy.<sup>312,316</sup> The development of devices that permit a more selective removal of plasma LDL-cholesterol and related substances has provided a practical apheresis-based approach to managing statin-resistant patients

in conjunction with statins and other medical therapies.<sup>316</sup> Two apheresis systems for selective removal of LDL-cholesterol are FDA-approved for use in the United States.<sup>317,318</sup>

ASFA has designated FH a Category I indication for LDL apheresis in homozygotes and a Category II indication for LDL

**Table 43-11.** FDA-Approved Indications for Use of LDL Apheresis to Acutely Lower Plasma LDL-Cholesterol Levels in Certain High-Risk Patient Populations<sup>317,318</sup>

| Patient Group | Description*                                                                                                                         |
|---------------|--------------------------------------------------------------------------------------------------------------------------------------|
| Group A       | Functional hypercholesterolemic homozygotes with plasma level of LDL-cholesterol >500 mg/dL                                          |
| Group B       | Functional hypercholesterolemic heterozygotes with plasma level of LDL-cholesterol ≥300 mg/dL                                        |
| Group C       | Functional hypercholesterolemic heterozygotes with plasma level of LDL-cholesterol ≥200 mg/dL and documented coronary heart disease† |

\*Stated LDL-cholesterol levels defined as the mean value of three serum samples obtained during a 2- to 4-week period after a 6-month trial of an American Heart Association Step II diet (or equivalent)<sup>314</sup> and maximum tolerated combination drug therapy defined as an adequate trial of drugs from at least two separate classes of hypolipidemic agents (eg, anionic exchange resins/bile acid sequestrants, HMG-CoA reductase inhibitors (statins), fibric acid derivatives, or niacin/nicotinic acid).

†Documented coronary heart disease defined as having one or more of the following:

- Prior documented myocardial infarction
- Prior coronary artery bypass graft surgery
- Prior percutaneous transluminal coronary angioplasty with or without atherectomy or coronary artery stent placement
- Significant angina pectoris documented by thallium or other heart stress test

LDL = low-density lipoprotein; HMG-CoA= 3-hydroxy-3 methylglutaryl co-enzyme A.

apheresis in heterozygotes.<sup>1,6</sup> The eligibility criteria for patients referred for LDL apheresis, according to the conditions of FDA approval of the devices, are presented in Table 43-11.<sup>317,318</sup> A regimen that combines medical therapy with LDL apheresis on a biweekly schedule can effectively lower LDL-cholesterol by 60% to 80% in otherwise treatment-resistant patients, improve the physical stigmata of hypercholesterolemia such as xanthomas and xanthelasma, improve myocardial perfusion and coronary artery patency, and favorably affect other markers of cardiovascular risk (eg, triglycerides, fibrinogen, homocysteine, C-reactive protein, adhesion molecules).<sup>312,319-324</sup> A summary of LDL apheresis systems is provided in Table 43-12.

**LDL Apheresis Devices Approved by the FDA**

The Liposorber LA-15 system<sup>317</sup> (Kaneka Pharma America, New York, NY) uses dextran sulfate bound to cellulose to selectively extract LDL-cholesterol from plasma. In this system, plasma is initially separated from the cellular components of blood by filtration through a disposable semipermeable polysulfone hollow fiber column, and the separated plasma is then perfused over a disposable adsorption column that contains 150 mL of dextran sulfate. The dextran sulfate has strong affinity for lipoproteins that contain apolipoprotein B [eg, LDL-cholesterol, VLDL-cholesterol, lipoprotein (a)] and adsorbs these from the plasma. The system has two adsorption columns connected in parallel to the tubing set, each capable of binding 7.1 g of LDL. One column is used to process 500 mL of plasma, and then the plasma is diverted to the second column, allowing for regeneration of the first column with a hypertonic saline solution that desorbs the bound lipoproteins from the dextran sulfate. The alternate use and regeneration of the two adsorption columns is controlled by a microprocessor.

The H.E.L.P. system<sup>318</sup> (B. Braun Medical, Bethlehem, PA) employs a 0.55-micron hollow fiber column to separate the plasma from the cellular elements of the blood. The plasma is

**Table 43-12.** LDL Apheresis Devices<sup>317,318,323-326</sup>

| Device                                               | Principle of Operation                                                                                                                                     | Anticoagulation      |
|------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------|
| *Liposorber LA-15 (Kaneka)                           | Electrostatic adsorption of apolipoprotein-B-containing lipoproteins to negatively charged immobilized dextran sulfate                                     | Heparin              |
| H.E.L.P. (B Braun)                                   | Precipitation of apolipoprotein-B-containing lipoproteins from acidified plasma by addition of heparin                                                     | Heparin              |
| *Direct Adsorption of Lipoproteins (DALI, Fresenius) | Adsorption of apolipoprotein-B-containing lipoproteins directly from whole blood perfused over negatively charged polyacrylate-coated polyacrylamide beads | Heparin and/or ACD-A |
| *Liposorber D (Kaneka)                               | Adsorption of apolipoprotein-B-containing lipoproteins directly from whole blood perfused over dextran sulfate covalently bound to cellulose               | ACD-A                |
| Therasorb-Ig (Miltenyi Biotech)                      | Adsorption of plasma lipoproteins using sheep antihuman-apolipoprotein B immobilized on Sepharose gel                                                      | Heparin              |
| Lipopak (Pocard)                                     | Adsorption of plasma lipoproteins using sheep antihuman-Lp(a) bound to Sepharose                                                                           | Heparin              |

\*Perfusion of plasma over negatively charged surfaces may result in excessive bradykinin generation and atypical or anaphylactoid-reactions in patients who are taking angiotensin-converting enzyme inhibitor drugs.<sup>327-329</sup>

acidified with 0.3M sodium acetate buffer and heparin is added to precipitate LDL-cholesterol. The LDL-cholesterol/heparin precipitate is filtered from the plasma using a 0.45-micron polycarbonate filter, excess heparin is adsorbed from the filtered plasma with a DEAE cellulose membrane filter, and the filtered plasma is then restored to physiologic pH by bicarbonate hemodialysis.

## Rheopheresis

Rheopheresis is a term that describes the therapeutic application of double filtration plasmapheresis to clinical disorders whose pathophysiology is believed to involve compromised microcirculatory blood flow.<sup>330</sup>

## Background

Rheopheresis is an apheresis technique in which whole blood is first pumped through a polyethylene hollow fiber membrane column [Plasmaflo OP-05W(L), Asahi Kasei Medical, Tokyo, Japan] which separates plasma from the formed elements of the blood. The plasma is then passed through a hollow fiber membrane column (SR-20 polysulfone, or AR-2000 cellulose diacetate, both from Asahi Kasei Medical) that filters large molecules, including LDL-cholesterol, fibrinogen,  $\alpha_2$ -macroglobulin, IgM, and von Willebrand factor from the plasma, resulting in a 50% to 60% decrease in their plasma levels after one plasma volume is processed.<sup>330,331</sup>

Clinical conditions in which rheopheresis therapy is under investigation include critical limb ischemia,<sup>332</sup> sudden sensorineural hearing loss,<sup>333</sup> and ischemic diabetic foot syndrome.<sup>334</sup> Rheopheresis has also been used to remove excess plasma phytanic acid in patients with Refsum's disease, an autosomal recessive disorder caused by mutations of phytanoyl/pristanoyl-CoA-hydroxylase.<sup>335</sup> But, arguably, the most important application of rheopheresis, at present, is in the treatment of dry age-related macular degeneration.<sup>331,336</sup>

## Rheopheresis in Dry Age-Related Macular Degeneration

In 2002 the World Health Organization considered 161 million people worldwide to be visually impaired, 37 million of whom were blind. Age-related macular degeneration (AMD) was identified as the primary cause of blindness in developed countries, accounting for at least 50% of blindness in North America, northern Europe, and Australia, and the third leading cause worldwide.<sup>337</sup> Based on demographic data from the 2000 US Census, over 50% of blindness among Americans of European heritage was a result of AMD, a proportion expected to increase as the American population ages.<sup>338</sup> The phrase "age-related" reflects the increasing risk of developing AMD after age 60. Over 13 million Americans above age 40 have signs or symptoms of macular degeneration, and 10% have the advanced "wet" stage of the disease.<sup>339,340</sup>

Current hypotheses regarding the pathophysiology of AMD consider diffusion of nutrients across Bruch's membrane, and the rheologic characteristics of blood flow through the choriocapillaris, to be deficient.<sup>341,342</sup> In part, these circumstances might result from a failure in the regulation of inflammation, as suggested by the strong association between macular degeneration

and inherited polymorphisms in the gene for complement factor H,<sup>342-347</sup> and the association of macular degeneration with elevations of C-reactive protein.<sup>348,349</sup> Therefore, rheopheresis would both improve microcirculatory flow in the choriocapillaris and across Bruch's membrane, and remove proinflammatory complexes from the blood, in the treatment of AMD.<sup>342</sup>

Based on promising early results from pilot studies in Germany<sup>350</sup> and the United States,<sup>341,342</sup> a properly powered prospective, randomized, multicenter, double-masked, placebo-controlled, Phase III trial of rheopheresis in dry AMD was conducted in 13 clinical centers in the United States.<sup>351,352</sup> The Multicenter Investigation of Rheopheresis for Age-Related Macular Degeneration (MIRA-1) trial randomly assigned patients to receive eight actual or sham rheopheresis treatments over a 10-week treatment period and tracked the change in best corrected visual acuity through 12 months after enrollment. At the conclusion of the study, 37% of study subjects in the treatment group, and 29% in the placebo group, were found to either not have met enrollment criteria or to have significantly violated the study protocol after enrollment, resulting in the absence of a statistically significant treatment effect in the final analysis of study outcome data.<sup>352</sup> Although a post hoc analysis that excluded the protocol violators indicated a significant treatment effect, the size of the study population evaluable for that analysis did not provide sufficient statistical power for conclusive interpretation of the results.<sup>352</sup> The study's sponsor, OccuLogix, Inc., a Toronto-based company, obtained permission from the FDA to conduct a follow-up study, RHEO-AMD, in order to definitively settle the issue of the efficacy of rheopheresis in AMD.<sup>353</sup> In 2007 OccuLogix suspended the RHEO-AMD trial because of financial considerations; thus, the future development of the technology for the treatment of dry AMD in the United States is uncertain.<sup>354</sup> Nonetheless, dry AMD is designated by ASFA as a Category P (pending) indication for double filtration plasmapheresis.<sup>1,6</sup>

---

## Conclusion

The continued growth of therapeutic apheresis as a treatment option in diverse clinical conditions depends on an understanding of the pathophysiology of the disorders in question and the acquisition of evidence, from properly conducted clinical studies, of the efficacy of apheresis therapies in their management.
